The chemicals legislation of the European Union is seen as one of the most advanced in the world regarding protection of human health and environment. REACH - Regulation concerning the Registration, Evaluation, Authorisation and Restriction of Chemicals enhances risk communication on the supply chain and makes a ground for generation of chemicals safety information, e.g., feeds the information needed for communicating chemicals' risks down the supply stream including classification, labeling and safety data sheets as required by the regulation on CLP (Classification - Labelling - Packaging) according to GHS (Globally Harmonized System of Chemicals). The main responsibility about chemicals' safety is placed on the industry; however, the most dangerous chemicals are restricted and banned in a transparent and systematic way. Are the risk assessment measures upstream sufficient for the ecodesign? Is it needed to judge upon chemical risks of the non-chemical products during design phase to achieve higher standards for the environmental and human health protection?
This study indicates the benefits from the REACH system for the ecodesign, as well as highlights the needs for an enhanced risk communication on the supply chain compared to the current legislative requirements, especially regarding the materials: intended content of chemicals and residues /impurities. For example, in order to demonstrate compliance with environmental labelling criteria, very detailed information about the chemicals contained in materials is required.

**MO 382**
**A scheme for the analysis of the results and dissemination and exploitation activities of in silico models**
E Benfenati, R Gonella Diaza
Istituto Mario Negri, MILANO, Italy
ORCHESTRA (Organising dissemination on results of projects on Chemical evaluation, spreading techniques for Risk Assessment) is a project funded by the European Commission,

aimed to disseminate and exploit the European research activities dealing with computer models for the environment. Nine EC funded projects have been chosen as case studies to develop and apply a dissemination/exploitation strategy for in silico models promotion. Each of these projects produced (or is producing) results and developed a dissemination and exploitation plan. In order to improve the dissemination and exploitation strategies, the selected projects have been analysed, from the point of view of the goodness and importance of the results produced and of how they have disseminate these results. Then, the outcome of this analysis has been used to try to evaluate and explain the impact obtained by the considered research activities.
Thus, the target of this is not to identify a winner project, regarding results or dissemination strategy. On the contrary, the target is to identify good results and, on the basis of these examples, learn from success stories, but also on not optimal experience done within these nine projects. The lesson we will get will be obtained on the basis of the comparison of what has been achieved. The overall, improved, strategy for dissemination is the final goal. On the basis of this analysis, the ways which are more suitable to achieve a broad dissemination and use of in silico models are identified. This involves suitable communication ways and strategies, but also evaluation of the user's need. We will describe the in silico tools which appeared more promising for this, and the reasons which produced the higher possibility of dissemination.

**Stakeholder perceptions of opportunities and challenges for the use of in silico methods in Europe**
C Mays[1], S Pardoe[2], E Benfenati[3], R Knauf[4]
[1]Institut Symlog de France, PARIS, France
[2]PublicSpace Ltd. Research Communication, ULVERSTON, United Kingdom
[3]Istituto di Ricerche Farmacologiche "Mario Negri", MILANO, Italy
[4]Federchimica, MILANO, Italy
Europe's 2007 REACH regulation (Registration, Evaluation, Authorisation and Restriction of Chemical substances) has created an urgent demand for testing large numbers of chemicals for toxicity. *In silico* methods may be of significant help in meeting that demand. *In silico* methods rely on computer modelling. Results from existing *in vivo* or *in vitro* tests are used to model the ways in which a chemical behaves in the body and in the environment. The toxicity of a particular chemical used in a particular setting can be predicted and assessed without further tests on animals or living cells.
Development of *in silico* models may generate a more sophisticated and more reliable understanding in the future of how a chemical may affect humans and the environment. *In silico* methods inevitably have limitations as well as potential. The limitations must be clarified in order to ensure that these methods are applied wisely and are adequately supervised and regulated.
The EU has funded the ORCHESTRA project (2009-12) to promote wider understanding, awareness and appropriate use of *in silico* methods. ORCHESTRA will support good practice and regulation by bringing together EU research on *in silico* methods and practical feedback from their use. The project web portal will become a central resource for sharing of knowledge and experience between professionals who are developing and using *in silico* models. For industry users and regulators, it will also provide downloadable software for *in silico* models reviewed by the project.
Experience of applying *in silico* methods to respond to regulatory requirements is built up on a case-by-case basis. Both industry and regulators are learning by doing. Dialogue is needed between researchers, stakeholders and regulators to identify zones of uncertainty and success. ORCHESTRA contributes to this clarification. In September 2010, ORCHESTRA invited 234 regulators and industry stakeholders to input using a specialist questionnaire (view and fill out online at www.in-silico-methods.eu).
Responses provide insight into current:
1. Awareness of and interest for *in silico* methods
2. Perceived benefits and attractions of *in silico* methods
3. Barriers to the use of *in silico* methods
4. Professional and policy needs
5. Stakeholders' sources of information on methods in toxicology.

The poster reports and analyzes responses received until April 2011, and highlights responsive actions taken in the context of ORCHESTRA.

**MO 384**
**IFRA environmental standards: risk and hazard assessment update for 2011**
AA Lapczynski
Research Institute for Fragrance Materials, WOODCLIFF LAKE, United States of America
The International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. The development of this program was reported previously at SETAC (Seville, 2010). To identify materials for risk assessment refinement, fragrance materials were screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in Environmental Toxicology and Chemistry (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screened with preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the developing IFRA Environmental Standards, reported here are the results of these additional tests (for both risk and hazard assessments). These studies include persistence testing (ready biodegradation tests and die-away studies), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materials will also be presented.

**MO 385**
**Complexity of regulatory enforcement under various legislations and effective communication of possible environmental impact and hindrances in addressing public awareness**
V Saini
M/s. Pesticide Regulatory Affairs - INDIA, FARIDABAD ( HARYANA ), India
INDIA, is considered as an advanced developing country, having great potential for maintaining a meaningful global presence. Legislations have been enacted in the plenty to practically satisfy all stakeholders in every situation. Unfortunately as and when a situation demands a new legislation is enacted or framed, with a little understanding of the already existing regulations in enforcement. A quos is created and a lack of clarity of the exact regulations required create a confusion in manners which are often devastating. The paper attempts to reflect the complexity of understanding all legislations involved and regulated through various ministries at a political level and relevance of scientific opinion. The complex network of such legislations being enforced in a bureaucratic and scientific conflict, leaving the stakeholders vulnerable to an outcome which is usually unpredictable and a matter of grave concern.

**MO 386**
**Risk mitigation measures for biocidal products - how to develop a harmonised approach for product authorisation?**
J Fischer[1], S Gartiser[2], M Kasper[1], E Petersohn[1], K Ziegler[1]
[1]Umweltbundesamt, DESSAU-ROβLAU, Germany
[2]Hydrotox GmbH, FREIBURG, Germany
In assessing the impact of biocides on the environment, specific measures to reduce a risk to the environmental compartments may be required. The evaluation of biocidal active substances up to now showed that the Rapporteur Member States have followed different approaches of risk mitigation measures (RMM). For the environmental risk assessment a harmonisation of possible RMM is missing.
This research project contributes to establish RMM required for a harmonised assessment of biocidal products in the EU and compiles appropriate solutions to prevent/reduce the identified risks for the environment. This is elaborated exemplarily on biocidal products used as wood preservatives and for the control of insecticides. Therefore RMM proposed by producers, industrial/professional users, and authorities are collected and critically evaluated in terms of practicability and efficiency. This project focuses on the mitigation of environmental risks.
The RMM proposed in Competent Authority Reports and considered in the Inclusion Directives are based on the intended uses and a representative biocidal product, which might not cover all applications. Product integrated RMM implemented during product development, design and distribution are immediately practicable while those referring to the user of biocidal products mainly depend on the communication of risks, risk awareness, education, specific training and on the information availability. However, apart from RMM being addressed in regulatory decisions, a broader strategy of sustainable use of biocides is required. Further, little information is available on the efficiency of RMM since e.g. only few monitoring data for active substances in the receiving environmental compartments exist. More specific RMM may be included in the authorisations of biocidal products when full information on the formulation and the conditions of use are available.

## RA14 - Waste fluxes around the world and the associated risks

**Socioeconomic aspects on emissions of chemicals from the flow of global e-waste**
V Rydberg
IVL Swedish Environmental Research Institute, GÖTHENBURG, Sweden
The purpose of this study is to start outlining aspects of the socio-economic negative impacts of the global WEEE flows in general and hazardous substances contained in this WEEE flow in particular. This may ultimately form a framework for the socio-economic assessment of the costs and benefits of chemicals in products. The present study will focus on literature data regarding the costs for damages, on human health and the environment, which can be assigned to hazardous chemicals present in WEEE flows.

**MO 391**
**Risk-based management of chemicals and products in a circular economy at a global scale**
V Grundmann, B Bilitewski
Technische Universität Dresden, PIRNA, Germany
Products undergo a recycling process and make their ways into a recovered material with unpredictable and not foreseen health and safety problems. The primary aim of RISKCYCLE is to identify future R&D needs required to establish a risk-based assessment methodology for chemicals and products that will help reduce animal testing while ensuring the development of new chemicals and product management pattern leading to minimized risks for health and the environment. The project is focussing on consequences due to the behaviour of chemicals and their release during recycling of the six fractions: paper, electronics, leather, lubricants, plastics, textiles. The critical points throughout the products life cycle for the release of chemical substances and the hazardousness of the material set free will be evaluated. Beyond this it is also important to know if the effects caused by the chemicals have a global or only local meaning and if the release of specific substances in the circular economy is an actual risk or a perceived risk.
The current results of the project will be presented within this poster.

**MO 392**
**A new tool to assess uncertainty in risk assessment**
V Kumar[1], M Mari[2], M Schuhmacher[2], JL Domingo[2]
[1]University of Sheffield, SHEFFIELD, United Kingdom
[2]Universitat Rovira i Virgili, TARRAGONA, Spain
The characterization and quantification of uncertainty and variability in health risk assessment are important to prevent erroneous inferences in multimedia modelling and exposure assessment, which may lead to major environmental policy implications. Health risk assessment calculations require a better understanding of exposure variables and uncertainty associated with them. Although there are many sources of uncertainty in system models, two basic kinds of parametric uncertainty are fundamentally different from each other: natural/stochastic and epistemic uncertainties. However, conventional methods such as standard Monte Carlo Sampling (MCS), which assumes vagueness as random property, may not be suitable for this type of uncertainty analysis. An improved systematic uncertainty and variability analysis can provide insight into the level of confidence in model estimates, and it can aid in assessing how various possible model estimates should be weighed. The main goal of the present study was to introduce Fuzzy Latin Hypercube Sampling (FLHS), a hybrid approach for incorporating epistemic and stochastic uncertainties separately. An important property of this technique is its ability to merge inexact generated data of the LHS approach to increase the quality of information. The FLHS technique ensures that the entire range of each variable is sampled with proper incorporation of uncertainty and variability. A fuzzified statistical summary of the model results produces a detailed sensitivity analysis, which relates the effects of variability and uncertainty of input variables to model predic-

tions. The feasibility of the method has been tested with a case study, analyzing total variance in the calculation of incremental lifetime risks due to polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) for the residents living in the surroundings of a municipal solid waste incinerator (MSWI) in Spain. The results showed that FLHS clearly separates controllable and uncontrollable uncertainty associated with models, which helps the models /and decision makers to identify the priority area in order to improve the results.

**MO 393**

**Local laboratory reactant exchange network**

F Martins, C Delerue, C Neves, P Duarte
Instituto Superior de Engenharia do Porto, PORTO, Portugal

The experimental work performed in laboratories use many chemicals with different characteristcs. Some of them presente several dangers that can affect people that work in the laboratory and also the environment if they are not carefully used/managed. The wastes produced can also be dangerous and demand careful attention.
In many laboratories there are reactants that are rarely used and that become out of date and create a problem of waste management since they must be correctly disposed. In order to prevent these problems we developed a computational application (website) for promoting the exchange of reactants between laboraties.
This Local Laboratory Reactant Exchange Network is useful to perform a sustainable management of a laboratory since it allows the adoption of suitable strategies to deal with reactants and wastes assuring the safety of the people that work in the laboratory but also some more general environment and social advantages. In spite of the quantities are relatively small the risk associated with some of the reactants/wastes raises the problem of its correct management. A good management will contribute to the ecosystems protection. In this way it will be possible to maintain or increase the quality of life since it decreases with the degradation of the ecosystems.
The development and implementation of this computational application is important to achieve a sustainable management of laboratories since it improves the laboratory operational, economical, social and safety performance. It will allow a better use of resources and will contribute to the prevention of chemical waste generation.

**Panorama of the lubricating oil sector and recycling in Brazil**

GA Lovón-Canchumani, A Magrini
Federal University of Rio de Janeiro, RIO DE JANEIRO, Brazil

The Brazilian market for basic Lubricants oils is the world's sixth largest. The present paper analyzes this sector and succinctly presents its current panorama, identifying the market structure, productive chain, actors and balance of production versus recycling. The feedstock oils in the sector come from three streams: the basic oil produced at three of the refineries operated by Petrobras, the state-controlled oil company; the basic oil imported by the 41 companies authorized for this by the National Petroleum Agency (ANP); and the oil re-refined from used oil collected in the Brazilian market, at 19 refineries. At present, about 15% of the lubricants Oils sold in Brazil is from re-refining ANP (2010). Over the period from 1991 to 2006, demand for lubricants grew by an average of 4.5% a year. In 2009, Brazil consumed some 1.2 billion liters of lubricant oil. Used lubricants are dangerous to the environment: they contain engine metal particles (lead, chrome, barium and cadmium) and various contaminants that harm the soil, water and air. Of these, water pollution is the most severe problem. According to the U.S. Environmental Protection Agency, a liter of lubricating oil has the potential to contaminate up to a million liters of potable water. Although good progress has been made in this respect in Brazil, there is still room for further improvement, particularly regarding quantitative and qualitative monitoring of the lubricant market. There is a need to provide consolidated official data representing the entire market. In this sense, it is necessary to invest in research to develop and consolidate a method for life cycle assessment of lubricants, to allow obtaining consistent and reproducible results.

**Methane-bearing rock waste**

V Palchik
Ben-Gurion University, BEER-SHEVA, Israel

Waste rock in coal mining is the overburden material that is excavated and disposed of in order to access valuable coal seam. In particular, such rock waste as natural stone (sandstone and limestone) is used as bulding material and, therefore, it can be exported to other countries. The sanstone and limestone are applied as aggregates, ornamental and dimension stones. Some sandstones and limestones are methane-bearing. After methane-bearing waste rock has been excavated from its original location, it is important to evaluate the methane emission from the waste to the atmosphere. Methane is greenhouse gas that remains in the atmosphere and is over 20 times more effective in trapping heat in the atmosphere than carbon dioxide. Methane poisoning, fire and explosion can occur when methane concentration on the ground surface reaches a potentially dangerous value. In this study, duration of methane emission from excavated gas-bearing waste (waste rock pile), gas volumetric flow rate from rock waste, iniatial gas content of rock before the rock was excavated, height and volume of waste rock pile, and number and dimensions of large and unconsolidated rock fragments in waste rock pile were observed. Observations show that the duration of gas emission from waste rock pile can achieve 60-84 months, and maximum gas volumetric flow rate is between 0.003 and 0.011 cubic meter /min from 1 cubic meter of waste rock pile. It is established that the duration of methane emission from waste rock pile increases exponentialy with increasing initial gas content of waste and volumes of waste rock pile and rock fragments in the pile. It is revealed that increase in number of unconsolidated rock fragments in waste rock pile leads to decrease in duration of methane emission from the waste pile. It is found that gas volumetric flow rate from 1 cubic meter of rock waste and duration of gas emission can be presented as double exponential functions of iniatial gas content of rock, ratio between volume and height of waste rock pile, and number of rock fragments in waste rock pile. These double exponential functions suggest that the time-zero is time when rock waste was extracted from coal mine to the ground surface.

## CS03 - New approaches in the simulation of realistic multistress and multispecies scenarios

**Emergence in stream mesocosms before and after repeated short-term insecticide pulses**

R Berghahn, S Mohr, R Schmiediche, V Huebner, M Feibicke, W Mailahn, S Loth, T Ottenstroeer, R Schmidt
Federal Environment Agency, BERLIN, Germany

In contrast to established biotests for assessing the ecotoxicological effects of chemicals, contamination of lotic surface waters by spray drift and run-off events generally occurs in multiple short pulses. Besides other endpoints like mortality and organismic drift, effects on the timing and the extent of insect emergence may be relevant endpoints. In 2009, a comprehensive experiment with the insecticide imidacloprid was carried out in the indoor stream mesocosms of the Federal Environment Agency in order to exemplary investigate if the endpoint insect emergence besides other parameters can be used for risk assessment. 8 artificial streams were filled with sand and groundwater and equally stocked with macrozoobenthos from a reference creek. Organic straw was introduced as substrate and served as both hiding place and food for the invertebrates. After a short period of establishment in spring, 4 of the 8 streams were contaminated three times with 12 µg/L Imidacloprid in the evening at weekly intervals. Both the contaminated streams and the 4 control streams were flushed with uncontaminated water 12 h later. This scenario was repeated 4 weeks later in summer. Emergence was determined in the weeks before and after the pulses by means of 4 emergence traps which covered about 10% of the entire water surface in each stream. Repeated macrozoobenthos sampling allowed for the determination of the emergence relative to the corresponding population size. Direct and indirect (drift mediated) effects on insect emergence were detected.

**TU 003**

**Evaluation of the joint effect of glyphosate and dimethoate using a small-scale terrestrial ecosystem**

MJG Santos, R Morgado, NGC Ferreira, AMVM Soares, S Loureiro
Dept. Biology of Univ. Aveiro and CESAM, AVEIRO, Portugal

In the present work a small-scale terrestrial ecosystem ("STEM") containing a Mediterranean agricultural soil was used to survey the effects of the combination of the herbicide glyphosate and the insecticide dimethoate, mimicking real scenarios of exposure. Earthworms (Eisenia andrei), isopods (Porcellionides pruinosus), turnip seeds (Brassica rapa) and bait-lamina strips were placed in the STEM. The results showed that the application of the recommended field dose (ecological relevant concentration) of both pesticides did not cause any effect in their growing ability of both earthworms and plants. The application of the herbicide (even at 5 and 10 times the field dose) increased feeding activity (bait-lamina test) in soil, although the application of dimethoate led to a decrease in feeding activity in all concentrations tested. The binary mixtures performed showed that according to the independent action model, an antagonistic deviation (smaller effect than expected from the single exposures) was observed in both the shoot length and fresh weight of B. rapa. There was a decrease in the earthworm's weight in all concentrations tested, although no statistical differences were observed in any of the treatments made. Regarding the depth distribution of E. andrei in the field dose and five times the field dose of the two pesticides, antagonism was observed whereas in the highest concentrations tested (10 times the field dose of both pesticides) synergism took place (worms escaped more than predicted from the single exposures made). In all the binary mixtures performed a decrease in the feeding activity (bait-lamina consumption) of the soil fauna was observed. Biomarkers (Catalase, AChE, GST) assessed in the isopod led to a decrease in the enzymatic activity in the animals exposed to the highest concentrations of dimethoate and to the binary mixtures performed.

**TU 004**

**Applying a novel experimental system for the independent control of chemical and drought stress**

SN Schmidt, M Holmstrup, KEC Smith, P Mayer
National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark

In their natural habitat, soil organisms are not only exposed to different contaminants but also to a wide range of physical, chemical and biological stressors. The physical and chemical conditions in soil can greatly affect the toxicity of the contaminants present, and new experimental systems are therefore required in order to be able to test effects caused by multiple stressors. The aims of this study were (i) to develop a novel experimental system for the independent control of both chemical and drought stress and (ii) to apply it in two-factor experiments with both stressors. The three polycyclic aromatic hydrocarbons (PAHs) naphthalene, phenanthrene and pyrene were selected as test contaminants. (i) The experimental system; Exposure to the contaminants was controlled by passive dosing in 5-mL glass vials with PAH loaded silicone in the bottom. Three open passive dosing vials were placed inside a closed 120-mL glass jar with aqueous saline solution in the bottom which controlled the humidity within the entire jar. In this way, the test organisms are exposed to controlled chemical stress from below, while the drought stress is controlled from above. (ii) Application in a two-factor experiment; The terrestrial springtail Folsomia candida was selected as a test organism. The PAH exposure parameter was chemical activity (unitless, [0-1]), and the humidity was expressed in terms of water activity (unitless, [0-1]). The springtails were exposed to several combinations of chemical and drought stress in order to determine their combined effects on springtail survival (7 days).

**TU 005**

**Results of a 21-day fathead minnow fecundity study using a mixture of an EDC , ehtynylestradiol and ammonia.**

M Lazorchak[1], B Armstrong[2], M Crane[1], H Haring[2], D Bencic[1], A Biales[1], R Flick[1], C Murphy[3], M Smith[2]
[1]USEPA, CINCINNATI, United States of America
[2]The McConnell Group c/o USEPA, CINCINNATI, United States of America
[3]Michigan State University, EAST LANSING, United States of America

Aquatic organisms are exposed to a multitude of contaminants and stressors and to fully understand impacts of multiple stressors on fish populations, we must understand the mechanism of action of each different toxicant on an individual and how the combined effects manifest at the level of the individual. The synthetic estrogen, 17α-ethinylestradiol, is a common ingredient in oral contraceptives and is extremely difficult to completely remove from wastewater. This toxicant has been known to cause adverse reproductive effects in fish, including reduced fecundity and fertility, intersex and sex change by mimicking naturally produced estrogen at low concentrations. Ammonia is another common pollutant in aquatic systems and has also been shown to cause adverse reproductive effects and mortality in fish populations through attacks on the central nervous system. This study used a 21 day flow through diluter system to test the individual effects of these two contaminants, as well as their mixtures, on fathead minnow reproduction. We also wanted to determine if the mixture of these two contaminants at their respective environmentally relevant concentrations would result in adverse reproductive effects. Significant findings from this study indicate that the current U.S. EPA water quality criterion for unionized ammonia in waters where non-salmonids, such as fathead minnows, are present (8.4mg/L) is above the lowest observable effect concentration for fathead minnow reproduction. The lowest unionized ammonia concentration (5mg/L) tested during this study resulted in decreased fecundity. The mixture of both 17α-ethinylestradiol and ammonia at their respective environmentally relevant concentration resulted in increased mortality, however, did not to show adverse effects on reproduction. This study demonstrated the need for toxicity testing with multiple stressor scenarios and the importance of re-evaluating current U.S. EPA water quality criteria.

**TU 006**

**Effects of ultraviolet radiation on terrestrial isopod Porcellionides pruinosus (Crustacea, Isopoda) in three simulated environments**

RGC Morgado, NGC Ferreira, FA Ribeiro, AMVM Soares, S Loureiro
University of Aveiro, AVEIRO, Portugal

Nowadays climate changes are introducing extra stress to the environment. UV radiation reaching ecosystems is increasing due to ozone depletion and deleterious effects are expected to happen to living organisms. In this work, the effects of high doses of ultraviolet (UV) radiation to the terrestrial isopod Porcellionides pruinosus were investigated in three simulated environments. Organisms were exposed to two hours of visible light followed by eight hours of UV radiation and another four hours of visible light. After that, they were kept for recovery in a climatic chamber at natural light and temperature conditions. To evaluate isopod stress levels, the activity of the biomarkers acetylcholinesterase (AChE), glutathione S-transferases (GST), catalase (CAT), glutathione peroxidase (GPx), lactate dehydrogenase (LDH), lipid peroxidation (LPO), oxidized glutathione and reduced glutathione (GSH/GSSG) ratio was analyzed at the end of exposure, and after 24h, 96h and 7 days. Despite the behavioral responses observed during the exposure, no significant mortality was registered. Significant differences in biomarkers results were obtained, mainly on those related with oxidative stress (e.g. LPO increased during the recovery time). The results obtained highlight the value of biomarkers to assess the levels of stress on sub-lethal exposures to natural stressors, including UV radiation.

**TU 007**

**Potential of the European bullhead (Cottus sp.) to assess the effects of pollution using a set of biochemical biomarkers**

S Jolly[1], A Bado-Nilles[2], O Palluel[1], B Piccini[1], J Prygiel[3], C Blanchard[4], C Le Rohic[4], A Geffard[2], S Betoulle[2], JM Porcher[1], W Sanchez[1]
[1]Institut National de l'environnement industriel et des risques (INERIS), VERNEUIL EN HALATTE, France
[2]Université de Reims, REIMS, France
[3]Agence de l'eau Artois-Picardie, DOUAI, France
[4]Office national de l'eau et des milieux aquatiques (ONEMA), COMPIÈGNE, France

Multi-biomarker approach is extensively used to characterize the effects of ecosystem contamination on fish health. In order to measure multi-biomarker responses in freshwater ecosystems, numerous wild fish species have been used. However, the geographical distribution of these extensively characterized fish species did not allow a large sampling for ecotoxicological application and justifies the research of novel sentinel species for biomonitoring. The aim of this study is to characterize the potential of the European bullhead (Cottus sp.) as sentinel fish species to assess the effects of pollution using a set of biochemical biomarkers. This fish is widespread throughout Europe, and it's sedentary fish that allows assessing local disturbances conversely to migratory or mobile fish species. The selected biomarkers included biotransformation enzyme (i.e 7-ethoxyresorufin-O-deethylase, EROD), oxidative stress (i.e glutathione peroxidase, GPx and lipoperoxidation, TBARS) and neurotoxic parameters (i.e acetylcholinesterase, AChE). To evaluate the potential of European bullhead for biomonitoring, laboratory and field experiments were conducted. Laboratory investigations were performed to characterize chemical-induced variations of biomarkers using reference chemical compounds. For this purpose, bullheads were exposed to β-naphtoflavone (BNF), fenitrothion and copper in order to evaluate respectively EROD, AChE and GPx activities as well as TBARS data. BNF generated a rapid induction of liver EROD activity in bullhead. Fenitrothion had no effect on the AChE activities. In field, wild bullheads were sampled, in the North of France, between September and October 2008 at seven sites considered as benchmark by the Water Framework Directive, and five contaminated sites. The selected set of biomarkers was measured in fish from sites exhibiting various contamination levels to evaluate discriminant power of this tool and to characterize response profiles in a multi-contamination context. The response profile of AChE allowed a good discrimination between reference area exhibiting low AChE levels and contaminated sites with high AChE levels.

## EC04 - Environmental fate and bioaccumulation of organic pollutants in aquatic systems

**TU 010**

**Impact of organotin compounds at Brazilian Estuarine Systems: studies before and after banning**

DM Santos[1], MRR Marchi[2], A Turra[1], RC Montone[1]
[1]University of São Paulo, SÃO PAULO, Brazil
[2]Univ Estadual Paulista, ARARAQUARA, Brazil

Because of their wide use in many human activities, organotin compounds (OTs) were considered as the most deliberately introduced contaminant into the environment and, despite their ban in 2008, they can be found in all aquatic compartments. In Brazil, since 2001, many studies are developed involving abiotic and biotic matrices and the results still worrisome. Because of their hydrophobic behavior in aquatic systems, OTs are mainly found in sediment and are particularly available for organisms in direct contact with the bottom. However, due ressuspension and transport process in environment, the study of suspended particulate matter (SPM) can be considered important to estimate the risk of all system, even in areas without punctual sources. Studies with organisms demonstrate a bioaccumulation thought sediment feeding or even by thropic chain bring a serious ecological risk for these communities. Paranaguá Estuarine Complex is located on south coast and has the greatest harbour for grains export in Latin America. This area was previously OTs monitored, in 2006, and the contamination was founded in all sediment samples (250 to 3019 ng Sn.g-1 d.w) and SPM from maximum turbidity zone (14 to 700 ng Sn.L-1) located next to Paranaguá Harbor. Three years after, a new sampling was made in three regions of the estuary. The OTs analysis was carried using the same analytical procedure, involving GC-PFPD analysis. In sediments, butyltin concentrations range from <LD (LD=3.3, 8 and 12.5 ng Sn.g-1 for TBT, DBT and MBT respectively) to 1053 ng Sn.g-1. For SPM we have found these compounds in all samples ranging from 0.01 to 0.84 ng Sn.L-1, below the results detected on 2006. However, this difference can be caused by the different sampling points and beside this concentration, the impact cannot be unconsidered. The results has shown that even after ban, these compounds can be detect mainly in sediments of estuarine complex and the distribution pattern of BTs by ressuspension can also contribute for the impact acting on local biota and communities.

**TU 011**

**Occurrence of antifouling biocides in two Italian marine systems and comparison with previous monitoring surveys**

G di Landa, G Ansanelli, S Cannarsa, S Chiavarini, C Cremisini, M Fantini, P Massanisso, M Pezza, C Ubaldi
ENEA, PORTICI, Italy

Antifouling (AF) paints are used to prevent the attachment of living organisms to submerged surfaces of ships, boats and aquatic structures, usually by release of biocides. The serious environmental problems caused in aquatic ecosystems by extensive use of organotin compounds (e.g. tributyltin, TBT) drove to a global ban of TBT-based paints for all vessels. Alternative products were developed by paint manufacturers and usually contained Cu(I) compounds as main biocide, but this component was ineffective against some algae and diatoms; hence AF properties were enhanced by the addition of "booster"biocides.

Recently in some European countries (UK, Denmark, Sweden and the Netherlands) legislative restrictions have been introduced concerning use of two popular biocides irgarol 1051 and diuron in vessel paints, due to the adverse environmental persistence and toxicity. This measure did show a positive effect in decreasing levels of these antifoulants found in sensitive UK coastal areas. In Italy no regulations about their presence in AF paints have been enforced, but an indirect effect of these control measures on Italian market of AF paints cannot be ruled out because of the production at multinational level.

This study was designed to sample locations previously investigated inside the Gulf of Napoli to determine whether environmental concentrations of four common booster biocides (irgarol 1051, diuron, dichlofluanid and chlorothalonil) had significantly altered over a five year period. Analytical results showed that actual concentrations of diuron declined substantially on average to 10% compared with those recorded during 2005 monitoring survey, on the other hand concentrations of irgarol 1051 were found similar to those detected in the previous survey. Monitoring data were interpreted on the basis of active ingredients contained in the paints on sale in Italy. Spatial and temporal patterns of these compounds in seawater were investigated. Other booster biocides we screened for (dichlofluanid and chlorothalonil) were below limit of detection in all samples and this concurs with their environmental fate.

The presence of organotin compounds in the aquatic environment of Gulf of Napoli were also investigated, and the low concentrations we found suggested that these banned compounds were not being used for vessel's hull protection.

Moreover a parallel survey on alternative biocides and TBT was carried out in a different marine system that is Gulf of La Spezia.

**PCBs in the Mondego Estuary (Portugal): a preliminary survey**

M Nunes[1], P Marchand[2], B Le Bizec[2], F Ramos[3], MA Pardal[1]
[1]CFE - Centre for Functional Ecology, COIMBRA, Portugal
[2]LABERCA - ONIRIS, NANTES, France
[3]CEF - Center for Pharmaceutical Studies, COIMBRA, Portugal

The Mondego River flows along 227 km, draining the largest hydrological basin entirely comprised in the Portuguese territory. During its course, it runs through rural as well as highly urbanized and industrialized areas before reaching its 1,600 ha estuary. The Mondego River basin supports over half a million inhabitants and as a result the estuary has consequently been subjected to a strong anthropogenic pressure. Over the last 15 years, applied research has been conducted in the Mondego Estuary, providing a comprehensive dataset on several areas and an insight into the pollution levels of the ecosystem. However, in spite of the environmental persistence and toxicity of PCBs, the information available on their levels in the estuary is scarce and limited to sediment samples. Therefore, the present study aimed to report the occurrence of the twelve PCB congeners designated as toxic by the World Health Organization (non-*ortho* PCBs 77, 81, 126, 169; mono-*ortho* PCBs 105, 114, 118, 123, 156, 157, 167, 189) and the six indicator congeners (PCBs 28, 52, 101, 138, 153, 180) in sediment and biota from the Mondego Estuary.

PCB levels were measured by a high resolution gas chromatograph - high resolution mass spectrometer (HRGC/HRMS) in samples collected in November 2009 from the Mondego Estuary. Concentration in sediment on a dry weight basis was 199.23 pg.g$^{-1}$ dw for the sum of dioxin-like PCBs (∑dl-PCBs) and 1127.25 pg.g$^{-1}$ dw for the sum of indicator PCBs (∑iPCBs). Regarding biota, ∑dl-PCBs concentration on a wet weight basis ranged from 6.15 to 2807.97 pg.g$^{-1}$ ww in brown algae *Fucus* sp. and eel *Anguilla anguilla*, respectively. ∑iPCBs values ranged from 0.04 ng.g$^{-1}$ ww in *Ulva* sp. to 19.05 ng.g$^{-1}$ ww in *A. anguilla*. Lipid-normalised concentrations showed a different outcome: ∑dl-PCBs ranged from 3.62 to 29.25 ng.g$^{-1}$ lipid in macrophyte *Spartina maritima* and red algae *Gracilaria* sp., respectively, and ∑iPCBs ranged from 14.62 ng.g$^{-1}$ lipid in *S. maritima* to 132.86 ng.g$^{-1}$ lipid in sea bass *Dicentrarchus labrax*. Fish samples (*A. anguilla*, *D. labrax* and common sole *Solea solea*) presented higher lipid-normalised PCBs levels than those of benthic invertebrates (cockle C*erastoderma edule*, clam *Scrobicularia plana* and ragworm *Nereis diversicolor*). In general, the dl-PCBs profiles of the different matrices showed a predominance of the mono-*ortho* PCB 118 and PCB 105. Concerning iPCBs, PCB153 and PCB 138 accounted for the highest percentage of total iPCBs concentration.

**TU 013**

**Trend of surface water concentrations of nonylphenol and its ethoxylates in an impacted basin: the Lambro river (Northern Italy)**

M Rusconi, S Polesello, S Valsecchi, L Patrolecco
Water Research Institute - CNR, BRUGHERIO (MB), Italy

According to the Water Framework Directive (2000/60/EC) and its Daughter Directive on Priority Substances (2008/105/EC), nonylphenol has been inserted in the list of the priority hazardous substances (PHS) which should be phased out within 20 years, by applying the appropriate measures.

Chemical quality of the main Italian river, river Po, is strongly influenced by its tributary, Lambro river, which flows through the most urbanised and industrialised area of Italy, collecting discharge water also from the area of Milano. In the last 5 years new wastewater treatment plants, which treats the whole of Milano wastewater, became operative in order to improve the quality of the river.

The aim of this work was to compare the concentrations of nonylphenol and its ethoxylates in the river Lambro basin (Northern Italy) measured in two monitoring campaigns in 2004/05 and 2009/10, respectively before and after the WWTP building.

Trend of concentrations has been followed in different stations of the basin on Lambro river and on its main affluents (Seveso, Olona and Lambro Meridionale). Along the course of the river Lambro two stations, sited up- and downstream Milano, were monthly monitoring in order to understand the effectiveness of the treatment plants.

Comparison between the annual averages of 2004/05 and 2009/10 shows that the concentra-

tions of nonylphenol and its ethoxylates were reduced of more than 70% in all the measured stations, included stations upstream Milano. Therefore this reduction is attributed to the substitution of alkylphenols in detergents and formulates and not only to the new WWTPs. As an example, at the basin closure (Oriolitta station) we measured average concentrations of nonylphenol of 0.61 and 0.15 μg/l, respectively in the two annual campaigns. Average concentrations in 2002 and 2003 measured in the same station were even higher (1.82 and 1.02 μg/l respectively). The only peak of concentration (> 2 μg/l) in the last year was measured after an intentional oil spill event in Lambro on February 2010.
Nevertheless the effect of the new WWTPs in Milano is highlighted by the reduction of the nonylphenol fraction adsorbed on particulate which decreased from 35 % to 1%. This reduction is not observed in the station upstream Milano, which is located downstream an already operating WWTP. The mechanism of partitioning and transport of nonylphenol compounds in an impacted river is also discussed.

**TU 014**

**Polybrominated diphenyl ethers (PBDEs) and polychlorinated biphenyls (PCBs) in swordfish (Xiphias gladius) and bluefin tuna (Thunnus thynnus) from the Mediterranean Sea**

N Borghesi, C Burroni, MC Fossi, S Focardi, S Corsolini
University of Siena, SIENA, Italy

The swordfish (Xiphias gladius) and the bluefin tuna (Thunnus thynnus) are top predators of the Mediterranean Sea. They are important species from both ecological and economic point of view. These species bioaccumulate contaminants in their tissues and being largely consumed by humans, they may be responsible of transferring pollutants to humans. Polybrominated diphenyl ethers (PBDEs) are a class of chemicals extensively used in the last decades as flame retardants. Recently, increasing concentrations of PBDEs are reported in the environment and in animal and human tissues. Polychlorinated biphenyls (PCBs) are compounds that have been widely produced and used in the past. PBDEs and PCBs are persistent and they tend to bioaccumulate trough the food web. The aim of this study was to evaluate PBDE and PCB levels in the muscle of X. gladius and T. thynnus from the Mediterranean Sea. PBDE concentrations were higher in tuna than in swordfish (980 and 70 pg/g w.w., respectively), and also PCB levels were higher in tuna (46 ng/g w.w.) than in swordfish (27 ng/g w.w.). The BDE accumulation pattern varied between species and it was BDE47 > BDE154 > BDE100 in swordfish and BDE47 > BDE100 > BDE154 in tuna fish. In both species, the tetra-brominated isomers prevailed (48% in swordfish and 49% in tuna fish). Regarding PCBs, congener no.153 was always the most abundant (11% in swordfish and 14% in tuna fish) followed by congeners no. 138 and 105 in both species. Hexa-CBs, penta-CBs and tetra-CBs were the most abundant classes of PCB isomers and together they made up more than 88% of the total PCB residue in both species. Moreover, swordfish and tuna fish were analyzed according to the sex of specimen and PBDE concentrations were higher in female than in male: PBDE were 75 pg/g w.w. in female swordfish and 49 pg/g w.w. in male swordfish, while they were 1443 pg/g w.w. in female tuna and 714 pg/g w.w. in male tuna. In contrast, PCB levels were higher in male than in female and in swordfish PCB concentrations were 52 ng/g w.w. in male and 13 ng/g w.w. in female, while in tuna they were 47 ng/g w.w. in male and 34 ng/g w.w. in female. Although PBDE and PCB levels found in these specimen were lower than those evaluated in other fish from the Mediterranean Sea and from other European seas, these data are important from an ecological perspective and from the point of view of human health as swordfish and tuna fish are important in the diet of the Mediterranean populations.

**TU 015**

**Chlorinated chemicals in Boreogadus saida from the Greenland Sea**

C Burroni, S Corsolini, S Focardi
University of Siena, SIENA, Italy

Boreogadus saida (Polar cod) is one of a key-species in the Arctic ecosystems being a trophic link between producers and upper trophic levels. It is fished in the North Atlantic Ocean due to its commercial value for human consumption of its fillets and liver oil. Therefore it is important to evaluate the presence of toxic contaminants in their tissues. Samples of muscle tissues were excised from specimens collected in the Greenland Sea in order to evaluate the presence of some chlorinated persistent contaminants: polychlorobiphenyls (PCBs), dichloro diphenyl trichloroethane (DDT) and its isomers, hexachlorocyclohexannes (HCHs) and its isomers, hexachlorobenzene (HCB), polychorodibenzodioxins (PCDDs) and polychorodibenzofurans (PCDFs). Gas-chromatographic analyses revealed low concentrations of the pollutants. ∑PCBs (7.67±0.06 ng/g wet wt) made up most of the residue, followed by ∑HCHs (2.63±0.02), ∑DDTs (1.21±0.01 ng/g wet wt), and HCB (2.77±0.01 ng/g wet wt). The p,p'-DDE was he most abundant isomer of DDTs; it was 41% of ∑DDT. The PCDDs/Fs were found in some sample and were often below the limits of detection (LOD = 0,1 pg/g wet wt).
The levels of PCB and organochlorine pesticides measured in NE Greenland are of the same order of magnitude of those reported in other fish from remote areas like Antarctica. Despite low levels of chlorinated persistent contaminants have been detected, their potential transfer to higher trophic levels might be expected, due to the key position of the species in the food webs.

**TU 016**

**Assessment of representative and priority pesticides, in surface water of the Alqueva reservoir (South of Portugal)**

AD Palma[1], M Kuster[2], P Alvarenga[3], MJ López de Alda[2], D Barceló[2], IR Barbosa[4]
[1]Instituto Politecnico de Beja, BEJA, Portugal
[2]Institute of Chemical and Environmental Research of Barcelona (IIQAB), Spanish C, BARCELONA, Spain
[3]; Escola Superior Agrária, Instituto Politécnico de Beja, BEJA, Portugal
[4]Centro de Estudos Farmacêuticos, Faculdade de Farmácia, Universidade de Coimbra, COIMBRA, Portugal

Surface waters located in intensive agricultural areas are more vulnerable to the pesticides contamination, which is a major concern if the water is intended to be used for human consumption. The aim of this study was to evaluate the presence and the distribution of pesticides in the Alqueva reservoir, an important source of water supply (South of Portugal), considering their representativeness in the agricultural practice of the area. For the analysis of pesticides risk impact we used the environmental quality standards (EQS) in the field of water policy proposed by the European Commission. The pesticides belonging to the classes of phenylureas, triazines, chloroacetanilides, organophosphorous and were analysed by on-line solid phase extraction-liquid chromatography-tandem mass spectrometry. The pesticides more frequently detected were atrazine, simazine, diuron and terbuthylazine. The highest levels of these pesticides were registered in spring, after pesticides treatment, namely in olive-tree and vine crops. The priority pesticides atrazine and diuron reached values above the AA proposed in the EU legislation. The herbicide atrazine reached values that surpassed the proposed MAC (2 000 ng L-1). The sampling stations most affected by these pesticides were Sra. Ajuda, Lucefecit and Alcarrache, located in the northern part of the reservoir, closer to Spain where the agricultural activity is more intensive.

**TU 017**

**DDT bioaccumulation in fish tissues of the Lake Maggiore**

L Guzzella[1], G Poma[1], C Roscioli[1], P Volta[2]
[1]CNR-IRSA, BRUGHERIO, Italy
[2]CNR-ISE, VERBANIA, Italy

The research is focused on actual DDT contamination of the Lake Maggiore basin and its effects on aquatic living organisms. The level of DDT contamination has been measured in three fish species representative of different trophic levels. Fish sampling of twait shad (Alosa fallax lacustris), lake whitefish (Coregonus lavaretus) and common roach (Rutilus rutilus) has been carried out seasonally from March 2008 to December 2010 in the Lake Maggiore. Fish were age-selected in order to obtain a homogeneous age-class (2-3 years old) representative of relative young individuals. The muscle of the selected fish has been analysed from 2008 to 2010, whereas the DDT gonad concentration was calculated only in 2008 samples. The matrices were freeze-dried, extracted in a hot Soxhlet apparatus, concentrated and finally purified for the GC-MS analysis of DDT and its isomers and metabolites.
The results showed that the highest concentrations of contaminants were mostly observed in the period before spawning. Generally, the highest concentrations of DDT were detected in twait shad muscles, with values near or greater than the threshold levels for fish consumption, and in the lake whitefish gonads. In 2010, the lake whitefish muscles were reaching the limit concentrations and also the levels of contamination of common roach tissues were increasing. A significant correlation between DDT concentrations and the muscle lipid content was observed only for the twait shad, whereas no correlation was evident for other species.
Analyses of fish tissues on the DDT concentration levels from 2008 to 2010 showed an inverse trend of contamination than in the past, requiring further investigation on the contamination source in the lake basin.

**TU 018**

**Monitoring the effect of tides in the distribution of polar organic contaminants in the East River (NY)**

PA Lara-Martin[1], EGM Gonzalez-Mazo[1], MP Petrovic[2], DB Barcelo[2], BJB Brownawell[3]
[1]University of Cadiz, PUERTO REAL, Spain
[2]Institute of Environmental Assessment and Water Research, BARCELONA, Spain
[3]Stony Brook University, STONY BROOK, United States of America

The aim of this work was to determine the concentrations of a wide group of polar organic contaminants in surface waters from the East River (NY), their partitioning between dissolved and particulate phases, and the tidal effect on their distribution. Two different classes of contaminants were selected: synthetic surfactants (LAS, linear alkylbenzene sulfonates, NPEO, nonylphenol ethoxylates, and AEO, alcohol ethoxylates) and pharmaceutically active compounds (PhACs, a selection of 70 substances including different types of analgesics, antibiotics, beta-blockers, lipid regulators, psychiatric drugs[3DOTS]). Analysis of surfactant degradation metabolites such as SPC (sulfophenyl carboxylic acids), NPEC (nonylphenol ethoxycarboxylates), NP (nonylphenol) and PEG (polyethylene glycols) was also carried out. A multi-residue analytical methodology was employed for the analysis of this wide range of compounds, using a combination of time-of-flight and triple-quadrupole detectors for their identification and quantification. Surfactant concentrations in filtered water ranged from 0.01 to 1.20 ppb, while their degradation metabolites showed values higher than 10 ppb. Concentrations in suspended solids were significantly higher, from 3320 to 25327 ppb depending on the surfactant considered. Partitioning coefficients (log K) were calculated from this data, being in the range between 3.9 and 5.4, and lower for degradation products (log K < 3) due to their higher polarity. On the other hand, and in spite of the low detection limit values (typically <1 ppb), 90% of target pharmaceuticals were hardly detected in suspended solids and/or they were below quantification limits. This is mainly due to their lower volume of use compared to surfactants, their relatively poor sorption capacity and/or fast degradation in the water column. Only those compounds having the highest hydrophobicity values and/or production volumes (e.g., ibuprofen) could be detected. Overall, the occurrence and distribution of these contaminants in the sampling area were directly related to the existence of wastewater discharges coming from NY City, as the highest concentrations were measure during the flooding, when the water flow comes from urban areas, and the lowest values during the ebbing, when the tidal wave enters the East River from the open ocean.

**TU 019**

**Monitoring sewage derived contamination in Guadalete River (SW, Spain) by analysis of synthetic surfactants**

C Corada-Fernández[1], PA Lara-Martín[1], L Candela Lledó[2], E González-Mazo[1]
[1]University of Cádiz, PUERTO REAL, Spain
[2]Universidad Politécnica de Catalunya, BARCELONA, Spain

The presence and longitudinal distributions of some of the most world wide used synthetic surfactants, alkyl ethoxysulfates (AES), alcohol polyethoxylates (AEOs), nonylphenol polyethoxylates (NPEOs), linear alkylbenzene sulfonates (LAS) and their carboxylated metabolites (SPCs) have been studied in water and sediment grabs from Guadalete river (SW, Spain). In general, concentrations values in water ranged from 14.62 to 2765.93 ppb for LAS, from 3.53 to 72.19 ppb for AES, from 5.27 to 49.26 and from 0.23 to 1.89 ppb for AEOs and NPEOs respectively. Concentrations values in sediment grabs ranged from 0.11 to 242.55 ppm for LAS, from 0.20 to 0.59 ppm for AES, from 0.97 to 3.04 and from 0.12 to 0.47 ppm for AEOs and NPEOs respectively. Urban wastewaters discharges were identified as the main contamination sources for these compounds and their metabolites. The highest concentrations of synthetic surfactants were found in water and sediments grabs associated to untreated wastewaters discharges from small urban areas of Jerez de la Frontera, farms and individual households. The relative distribution of LAS, AEOs and AES homologues in sediments showed higher percentages for those having longer alkyl chain due to differential sorption and degradation processes. SPCs concentrations values in water ranged from 163.49 to 486.63 ppb, being measured the highest concentrations near a WWTP effluent discharge outlet. The general trend shows a progressive shortening in the alkyl chain of SPCs homologues, predominance of short-homologues (C6SPC and C7SPC) compared with long homologues (C11SPC, C12SPC and C13SPC) in each sampling point.

**TU 020**

**Contaminant distribution in harbour porpoises, Phocoena phocoena, stranded along the Dutch coast.**

J Van den Heuvel-Greve[1], T Glorius[1], M Bierman[1], JJ Kotterman[1], C Klok[2]

[1]IMARES Wageningen UR, YERSEKE, The Netherlands
[2]IMARES, DEN HELDER, The Netherlands
In the past decennium an increasing number of harbour porpoises, Phocoena phocoena, beached on the Dutch coast. In winter time, beached animals contained a thick blubber layer and seemed to be victims of accidents or bycatch of fishery. In summer time, beached porpoises were mainly found emaciated, predominantly without visible physical injuries. To assess redistribution processes of organic contaminants due to starvation, the liver and blubber of 36 beached harbour porpoises were analysed for PCBs, PBDEs, HBCD, PFCs and organotin compounds. No differences were found for concentrations of non-lipophilic compounds (PFCs) between summer and winter. Concentrations of PCBs and PBDEs in both liver and blubber on lipid weight were on average higher in emaciated porpoises (beached in summer) when compared to porpoises with a good nutritional status (beached in winter), and showed slightly deviating profiles in liver. This may point at remobilisation of lipophilic contaminants during emaciation. Our data indicate that concentrations and profiles of organic contaminants in marine top predators, such as harbour porpoises, will not only be influenced by common bioaccumulation processes such as e.g. uptake from food and metabolism, but also by starvation.

**TU 021**

**Occurrence and fate of organic pollutants in aquifer systems of Jerez de la Frontera region (Cádiz, Spain)**

E Pérez-Carrera[1], CC Corada[1], VL León León[2], EGM González Mazo[3]
[1]Cadiz University/ York University, YORK, United Kingdom
[2]Instituo Español Oceanográfico, MURCIA, Spain
[3]Cadiz University, PUERTO REAL CADIZ, Spain
Because organic compounds are now used so extensively, it is necessary to evaluate their presence and distribution in various different environmental compartments. In this work, polycyclic aromatic hydrocarbons (PAHs), polychlorinated byphenyls (PCBs) and pesticides (carbamates, pyrethroids, organochlorinates, organophosphorus and organonitrogenates) have been monitored in two aquifers, those of Jerez de la Frontera and the Alluvial Guadalete, also including samples from the Guadalete River. PAHs and some pesticides were detected at significant concentrations at specific points. In fact three pollutants (chlorfenvinphos, chlorpyrifos and prometryn) were detected at more than 100 ng L-1 in groundwater samples, and endosulfan sulfate, terbutryn, terbuthylazine, alachlor, prometon, pyrene and fluoranthene were found at low concentrations (1 to 50 ng L-1). The chemicals found in the soil matrix were the most hydrophobic pollutants, including apolar pesticides and high molecular weight PAHs, and at higher levels (μg L-1) than those present in groundwater samples.

**TU 022**

**Air-sea exchange of current-use pesticides in the North Sea**

GC Guangcai[1], ZY Zhiyong[1], M Axel[2], S Renate[2], E Ralf[1]
[1]Helmholtz-Zentrum Geesthacht, Centre for Materials and Coastal Research, Insti, GEESTHACHT, Germany
[2]HZG, Institute of Coastal Research, GEESTHACHT, Germany
Increased public and regulatory attention during the 1970s and 1980s resulted in bans for many legacy pesticides and led to the development and licensing of new pesticides with less persistence. This group of newer compounds is called current-use pesticides (CUPs). High usages and new concerns regarding the prevalence and effects of these compounds in the environment resulted in CUPs becoming a significant issue for environmental and toxicological studies. Recently, increasing levels of some current-use pesticides(CUPs) have been found in remote areas, e.g. in the Arctic and in some elevated mountains, however, compared with the legacy organochlorine pesticides, data of CUPs in the marine environment are relatively sparse.
Sampling in the German Bight of the North Sea took place during three sampling cruises with the German Research Vessel RV Heincke in March, Mai and September 2009. Air samples were collected with a high-volume air sampler equipped with a glass fibre filter (GFF) connected with a glass column packed with PUF/XAD-2 resin. Water samples were pumped through a GFF followed by a glass column packed with PAD-2.
Atmospheric and aquatic concentrations of CUPs in the North Sea have been determined by GC/MS-system. The seasonal distribution and partitioning between different phases of CUPs in air and seawater have been investigated. Air-sea exchange fluxes of CUPs were estimated using a two-film model. Varying fluxes indicated that air-sea exchange is an important process which intervenes in the mass balance of CUPs in the North Sea.

**TU 023**

**Benthic Degradation and sorption to soot carbon are key processes controlling the occurrence and fate of Polycyclic Aromatic Hydrocarbons in Lakes**

J Dachs[1], SN Meijer[2], P Fernandez[1], JO Grimalt[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]Lancaster University, LANCASTER, United Kingdom
Semivolatile organic pollutants have potential for long range atmospheric transport and thus can reach pristine lakes by atmospheric deposition. While the environmental fate and occurrence of persistent organic pollutants (POPs), such as polychlorinated biphenyls, in lakes has been assessed and modeled previously, there is still a poor knowledge of the main factors controlling the fate of non-persistent organic pollutants, such as polycyclic aromatic hydrocarbons (PAH), in the environment. Here we show a soot-inclusive environmental fate model for PAHs in lakes and its validation/application to Lake Redó in the Pyrenees Mountains. A model for the refractory soot carbon has been coupled to the general organic carbon based POP model. In addition, degradation in benthic waters and sediments has also been included in the model. This model allows to predict water and sediment concentrations of pollutants from knowledge of atmospheric concentrations and Lake characteristics. It is shown that only when soot carbon and degradation processes are included in the model, it is possible to predict similar PAH concentrations in the sediment to those measured in Lake Redo. The extend of the degradation sink due to benthic degradation is quantified and compared to the reservoir of PAHs accumulated in the sediment and other cycling fluxes in the lake.

**TU 024**

**Occurrence and trends of POPs in the Southern Ocean and Antarctic region**

CJ Galbán-Malagón, N Berrojalbiz, G Caballero, MJ Ojeda, J Dachs
IDAEA-CSIC, BARCELONA, Spain
POPs transport and occurrence in Polar Areas have been focused in the North Hemisphere (Ockenden et al., 2001). Few Studies have reported seawater, atmospheric and biota POPs cocentrations in the southern Ocean and Antarctic area (Dickhutt et al., 2005; Cincinelli et al., 2009). Gas phase concentration data were the most studied in the area (Oeckenden et al., 2001; Cincinelli et al., 2009).Seawater concentration of POPs have been reported for surface microlayer in 2001 by Fuoco et al. and for surface seawater in 2009 by Cincinelli et al. In the case of biota a lot of studies have reported concentrations of POPs for mammals, fish, and Krill (Chiuchiolo et al., 2004). But none of them mentioned Phytoplankton concentrations and possible implications of the role drived in the cycling of POPs and the keyrole of the Biological Pump in Polar Areas. None of the published studies have mentioned concentration for the particulate and aerosol concentratios. In the present work we show concentration and trends of Chlorinated and Polyciclic Aromatic Hydrocarbons in the Gas, Aerosol, Particulate, Seawater, Phytoplankton and Krill for the first time.

**Urban tributaries as a pathway of PCBs, PBDEs, PAHs, and polycyclic musks to adjacent Lake Ontario, Canada**

PA Helm[1], M Robson[2], G Kaltenecker[1], B Gilbert[1], ML Diamond[2], L Melymuk[2], C Brimacombe[1], T Chen[1], T Kolic[1], EJ Reiner[1]
[1]Ontario Ministry of the Environment, TORONTO, Canada
[2]University of Toronto, TORONTO, Canada
Urban rivers continue to deliver contaminants such as the legacy polychlorinated biphenyls (PCBs) and current/recent-use chemicals to receiving waters like the Great Lakes where they may persist, bioaccumulate, and impact biota. To investigate the relative roles of urban contaminant fate pathways (atmospheric deposition, tributary, municipal wastewater) to adjacent waterbodies, using Toronto, Canada and Lake Ontario as examples, we measured concentrations for a suite of organic compounds of varying uses and sources and estimated stream loadings. This presentation highlights results for the urban tributary pathway and its contributions relative to atmospheric deposition and municipal wastewater discharges.
Bulk water concentrations of PCBs, polycyclic aromatic hydrocarbons (PAHs), polybrominated diphenylethers (PBDEs), and polycyclic musks (PCMs) were determined in dry and wet weather samples collected from 10 sites in 6 watersheds across the Toronto area in 2007 through 2009. Wet weather events were intensively sampled on 3 occasions to provide an indication of the variability with hydrological change. For all analytes, concentrations were greatest at the downstream sites located in intensively developed urban areas. Median (maximum) concentrations across the downstream sites ranged from 2.2-6.7 (19-144) ng/L for ΣPCBs, 100-950 (1700-19300) ng/L for ΣPAHs, 5.1-6.6 (25-46) ng/L for ΣPBDEs, and 29-1800 (53-5800) ng/L for ΣPCMs. BDE-209 was the dominant PBDE, while PCMs consisted mainly or HHCB and AHTN. Concentrations of PCBs, PAHs, and PBDEs were higher during wet weather when streams were much more turbid. However, PCM concentrations tended to decline during wet weather, suggesting sewer cross-connections may be a source of PCMs. PCM concentrations were considerably higher in the Don River which receives municipal wastewater discharges.
Stream contaminant loads to Lake Ontario were calculated using USGS's LOADest for the 6 downstream sites. Estimated average annual loads were 2200 kg/yr for ΣPAHs, 42 kg/yr for ΣPCMs, and 8 kg/yr each for ΣPCBs and ΣPBDEs. On a mass basis, the tributaries were the most important pathway for ΣPAHs, contributing 60% of loads compared to atmospheric and wastewater pathways from urban Toronto. In comparison the tributaries were estimated to contribute 40% for ΣPBDEs, 20% for ΣPCBs, and 4% for ΣPCMs. Urban tributaries are important contributors of compounds with urban sources to adjacent aquatic environments.

**Bioaccumulation and biomagnification of chlorinated and perfluorinated persistent organic pollutants in a pelagic food web from the Mediterranean Sea**

S Corsolini, N Borghesi, CB Burroni, CG Guerranti, SF Focardi, MC Fossi
University of Siena, SIENA, Italy
Mediterranean swordfish (Xiphias gladius), bluefin tuna (Thunnus thynnus) and longfin tuna (Thunnus alalunga) are large pelagic species heavily caught for commercial purposes, being an important resources for fish markets. The anthropic impact is heavy on these species due to their top position in the trophic webs, thus it is very important to know their health status and evaluate the toxicity for humans. To these purposes, the presence and amount of persistent organic pollutants were determined in their tissues and their preys: polychlorobiphenyls (PCBs), perfluorinated compounds (PFCs), chlorinated pesticides (HCB, HCHs, DDTs, dieldrin, eldrin), polychlorodibenzodioxins (PCDD), and polychlorodibenzofurans (PCDFs) were determined. Moreover, the 2,3,7,8-tetrachlorodibenzo-p-dioxin toxic equivalents (TEQs) were also calculated to assess risk for humans due to fish consumption.
The contaminant trend was PCBs>DDTs>HCHs>HCB in all samples; concentrations were in the ranges 15-27 ng/g wet wt of PCBs, <0.001-0.3 ng/g wet wt of HCB, 0.004-0.3 ng/g wet wt of HCHs, and 0.2-62 ng/g wet wt of DDTs in predators and lower in preys. Concentrations in males were higher than in females of tuna and swordfish, and were lower than those reported earlier, likely due to the young age of specimens. Penta- to hepta-PCBs made up most of the PCB residue.
Coplanar PCBs were below detection levels in most samples, except in a few specimens of tuna and swordfish (PCB77>PCB81>PCB126>PCB169). Concentrations of PCDDs and PCDFs
were mostly <2 pg/g wet wt and <1.2 pg/g wet wt and very few congeners were found in the samples analyzed. TEQs were between 2.6 and 17.1 pg/g wet wt ; bluefin tuna muscle samples showed the highest values.
p,p'-DDE was the most abundant DDT isomer in predator and prey samples.
PFCs were below detection limits in most of the samples of predator and preys. PFOS and PFOA were above the detection limit (0.5 ng/g wet wt) in 9 of 61 and 2 of 61 samples, respectively.

[8]IDAEA/ CSIC, Catalan Institute for Water Research (ICRA), BARCELONA, Spain

Organohalogenated compounds are one of the main pollutant groups that affect the ecosystems due to their persistence and toxicity. There are many studies concerning these compounds in marine mammals around the world, nevertheless the South Atlantic Ocean remains poorly known. Franciscana dolphin, Pontoporia blainvillei, is the most impacted cetacean off the eastern coast of South America by human activities. The Santos Estuary (23º55'S, 46º20'W) in São Paulo State, southeastern Brazil, South Atlantic Ocean, represents the most important Brazilian example of environmental degradation by hydric and atmospheric pollution from industrial origin in coastal areas. The aim of this work was evaluate the occurrence of organochlorine and organobrominated compounds in samples from 87 livers, 3 milks, 2 placentas and 1umbilical cord of franciscana dolphins, collected in 4 States along the southwestern and southern off Brazilian coast (Espírito Santo, n = 12; São Paulo, n = 42; Santa Catarina, n = 07; Rio Grande do Sul, n = 26). Among organochlorines, PCBs were the predominant compounds on lipid weight basis (0.3 - 42.2 ug g-1), followed by DDTs (0.1 - 7.2 ug g-1), HCB (< 0.002 - 0.15 ug g-1) and HCHs (n.d. - 0.05 ug g-1). PCBs concentrations in São Paulo coast presented the major values to franciscana in all of its distribution (Brazil, Uruguay and Argentina), showing the high industrial influence on this part of Brazilian coast. PCBs and HCB values found in this study were comparable to the values found in coastal cetaceans from developed countries in north hemisphere. Among the organobrominated, the higher concentrations observed came from the natural compounds, mainly 2'-MeO-BDE 47 (n.d. - 792 ng.g-1) and 6-MeO-BDE 68 (n.d. - 268 ng.g-1). PBDEs concentrations were also higher in the samples from São Paulo coast (n.d. - 450 ng.g-1). Higher contributions of naturally-produced organobrominated compounds are an indication of the presence of sponges, algae or associated organisms. The concentrations obtained for cetaceans from Brazilian waters are among the highest detected to date in marine mammals.

**24 POPS - Comprehensive analysis of all Stockholm convention and candidate POPS in marine biota**

F Neugebauer, C Temme, O Paepke, M Petersen, M Opel, P Ebsen
Eurofins GfA GmbH, HAMBURG, Germany

In the last few decades, there has been a tremendous increase of knowledge about the adverse effects of persistent organic pollutants (POPs). Their persistency, accumulation and transport within the ecosphere together with risks for humans as well as for animals became obvious and lead after first agreements on a European scale to the internationally recognised Stockholm Convention in 2001. With its ratification in 2004, a ban and/or restriction of a first group of purposefully produced or unintentionally synthesised substances came into force on a global scale. Since then, additional compounds have been added to the first list and further chemicals are under review or discussed. All together, there are 12 substances from the original list (2001), 9 others which have been added in 2009 and actually 3 candidates, in total up to now 24 substances which we understand here as "Stockholm POPs / candidates".

The present paper tries for the first time a comprehensive analytical approach in order to get complete data sets for the whole range of POPs and to set up an analytical strategy for this approach. The presented study demonstrates the methodological feasibility for the whole range of the Stockholm Convention-/candidate POPs as well as giving for a first time complete data sets for certain marine biota. We see it as a starting point for an overall view on the most common contaminations in the field of POPs. The present data reflect a first step into this effort, focussed onto high resolution mass spectrometry as one of the most capable and sensitive techniques for production of unambiguous results for scientific purposes. Also, for some of the analysed compounds only very limited data has been available up to now, e.g. for SCCP or for fluorinated compounds in cod liver.

**A yearlong survey for diverse classes of estrogenic disrupting compounds suggests significant pollution in the estuary of the Ave River and nearby seacoast, Portugal**

MJ Rocha[1], C Cruzeiro[2], C Peixoto[2], C Caldas[2], E Rocha[3]
[1]CIIMAR - CIMAR LA and ISCS-Norte/CICS, Porto, Portugal, PORTO, Portugal
[2]CIIMAR-CIMAR LA, PORTO, Portugal
[3]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal

The Ave River rises in North-Portugal at the Cabreira Mountain and reaches the Atlantic Ocean at Vila do Conde. During its course of ca. 85 km it crosses agricultural fields and intense industrial areas. In spite of the visible local pollution, this study is the first that investigates the presence of endocrine disruptor compounds (EDCs) from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins in this area. For this purpose, water samples were collected during one year, every two months, at 8 sampling stations located at the river, at the estuary and at the sea. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. Preliminary data showed the presence of FORM (ca. 2,000 ng/L), DAID (ca. 200 ng/L), GEN (ca. 200 ng/L), BIO-A (ca. 350 ng/L), SITO (ca. 7,000 ng/L), E1 (ca. 100 ng/L), EE2 (ca. 150 ng/L), OPs (∑= ca. 200 ng/L), NPs (∑= ca. 1,000 ng/L), APEOs (∑= ca. 7,000 ng/L) and BPA (ca. 150 ng/L) in both river and seacoast. Facing reference literature values, the current data strongly suggests that this area in under significant impact by estrogenic EDCs and needs urgent depollution measures; nonetheless further chemical and biological monitoring analyses are being undertaken.

**Climate-induced fate of biocides in sediments**

K Broeder, MP Schluesener, TA Ternes
Federal Institute of Hydrology, KOBLENZ, Germany

Climate-induced fate of biocides in sediments
K. Bröder, M. Schlüsener, T. Ternes

In recent years, biocides and UV-filters have gained increasing interest as so called emerging contaminants since they are ingredients of various products used in every day life such as personal care products (PCPs), cleaning agents and paints and coatings. Biocides are biological active compounds applied to destroy or to inhibit the growth or action of organisms, even low environmental concentrations might have negative impacts on the aquatic environment. For example, triclosan has been shown to induce changes in the thyroid hormone-mediated process of metamorphosis of the North American bullfrog Rana catesbeiana and to cause a significant shift in the community structure of a natural river algae community at environmental relevant concentrations as low as 30 and 15 ng Lð'1, respectively.

The fate of biocides in the aquatic environment, particularly in river and stream sediments, remains poorly understood. This is at least in part due to the lack of analytical methods for quantification of these drugs in sediment and water samples. Concentration data in sediments needs to compliment data on aqueous phase concentrations, particularly in light of the high susceptibility of biocides to microbial (and abiotic) degradation.

The aim of the study is to examine the influence of climate change on the sorption and degradation behaviour of biocides in sediment. Therefore, an extensive data set on the sorption and degradation kinetics of selected biocides to sediments and the concentration dependence of sorption are collected. Batch experiments according to OECD 106 and 308 are performed to determine the sorption and degradation kinetics of selected biocides, e.g. triclosan. Sorption isotherms are also constructed. Isotherms spanned 2 orders of magnitude in initial analyte concentrations (i.e., 1, 3.2, 10, 32 and 100 ng/mL). The systems are equilibrated for 24 h, which was long enough to attain apparent uptake equilibrium based on the results of the kinetic experiment. At 24 h, biocides concentrations are quantified in the sediment and the water phases in duplicate batch reactors. To determine the influence of a possible climate chance, all experiments are performed at different temperatures ranging from 4 to 36°C.

**Chemical monitoring of sixteen polycyclic aromatic hydrocarbons reveals a high sediment pollution load in the Douro River estuary, Porto, Portugal**

MJ Rocha[1], P Ferreira[2], P Reis[2], C Cruzeiro[3], E Rocha[4]
[1]CIIMAR - CIMAR LA and ISCS-Norte/CICS, Porto, Portugal, PORTO, Portugal
[2]CIIMAR-CIMAR LA, PORTO, Portugal, PORTO, Portugal
[3]CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal

Recent findings in fish caught in Douro River estuary and nearby Porto sea coast point to the presence of polycyclic aromatic hydrocarbons (PAHs) in Porto region. Because these compounds are extremely toxic, from aquatic animals to humans, and are highly lipophilic, their evaluation in coastal sediments are of the most interest. Their eventual appearance is always of great concern for both environmental and public health. Thus, we developed an analytical method based on microwave-assisted extraction (MAE) of sediments, followed by solid phase micro-extraction (SPME) and gas chromatography mass spectrometry (GC-MS) to simultaneously quantify sixteen PAHs in marine and estuarine sediment samples. The analysed compounds were those included in the US Environmental Protection Agency (US EPA) priority list which includes naphthalene, acenaphthylene, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo[k]fluoranthene, dibenz[a,h]anthracene, indeno[1,2,3-cd]pyrene and some potentially carcinogenic for humans; in particular benzo[a]anthracene, chrysene, benzo[b]fluoranthene, benzo[a]pyrene and benzo[ghi]perylene. Method detection limits were between 0.07 and 0.76 μg/kg. Sediment samples from the Douro River estuary and Porto marine sea coast showed an average load of all above mentioned PAHs of ca. 100 μg/kg and ca. 55 μg/kg, respectively, demonstrating that both studied areas are strongly impacted by this type of pollutants. The data agrees with former findings reporting bioaccumulation in local fish, with unknown impacts for them and consumers.

**Annual monitoring of seventeen endocrine estrogenic disrupters reveals a high load of anthropogenic pollution in the Douro River estuary and nearby seacoast, Porto, Portugal**

MJ Rocha[1], C Cruzeiro[2], C Peixoto[2], C Caldas[2], E Rocha[3]
[1]CIIMAR - CIMAR LA and ISCS-Norte/CICS, Porto, Portugal, PORTO, Portugal
[2]CIIMAR-CIMAR LA, PORTO, Portugal
[3]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal

The Douro River flows along ca. 900 km, from its source near Duruelo de la Sierra (Spain) to its estuary at Porto (Portugal). Due to its dimensions and huge watershed (98, 000 km2), this river passes throughout many different regions that include densely inhabited areas, industrial poles, and large agricultural fields, which, as a whole, contribute to its pollution. At the present, beyond the construction of one dam, the Crestuma-Lever, inside the innate estuary of the Douro River, the drainage rates of the river to the Atlantic Ocean are also affected by the recent construction of jetties at the mouth of the estuary. In a previous survey with HPLC based methods we detected several estrogenic chemicals. The data called for further and wider monitoring, eventually using more sensitive methods. Thus, this study reports the simultaneous evaluation of seventeen potential endocrine disruptors from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins in this area. For this propose, water samples were collected during one year, every two months, at 8 sampling stations located at low and upper estuary and at the seacoast located nearby. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. Briefly, the results showed the presence of FORM (ca. 220 ng/L), DAID (ca. 20 ng/L), GEN (ca. 90 ng/L), BIO-A (ca. 800 ng/L), SITO (ca. 2,500 ng/L), E1 (ca. 25 ng/L), E2 (ca. 2.5 ng/L), EE2 (ca. 6 ng/L), OPs (∑= ca. 60 ng/L), NPs (∑= ca. 500 ng/L), APEOs (∑= ca. 2,000 ng/L) and BPA (ca. 100 ng/L) in this area. The data confirmed the estrogenic prone scenario we previously reported. Thus, we conclude that conditions for endocrine disruption risk by estrogenic exposure, mainly from industrial origin, exist in this area. Biomonitoring is needed to evaluate effects.

**TU 033**

**A one year survey for seventeen estrogenic pollutants reveals endocrine disruption risks in the estuary of the Lima River and nearby sea coast (Portugal)**

MJ Rocha[1], C Cruzeiro[2], C Peixoto[2], C Caldas[2], E Rocha[3]
[1]CIIMAR-CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal
[2]CIIMAR-CIMAR LA, PORTO, Portugal
[3]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal
The Lima River rises in Galicia (Spain) and reaches the Atlantic Ocean near Viana do Castelo (North of Portugal). During its course of ca. 100 km it crosses agricultural fields, but the estuary receives effluents from both urban and industrial discharges suggesting the possible presence of endocrine disruptors compounds (EDCs) in this area. Despite that, the river is still the natural habitat of important commercial fish species (e.g., trout). So, we evaluated the levels of seventeen EDCs from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins at upper and lower estuary and seacoast. For this propose, water samples were collected during one year, every two months, at 8 sampling stations. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. The results showed the presence of FORM (ca. 500 ng/L), DAID (ca. 80 ng/L), GEN (ca. 200 ng/L), BIO-A (ca. 350 ng/L), SITO (ca. 600 ng/L), E1 (ca. 30 ng/L), EE2 (ca. 20 ng/L), OPs (∑= ca. 150 ng/L), NPs (∑= ca. 500 ng/L), APEOs (∑= ca. 2,000 ng/L) and BPA (ca. 1,000 ng/L) in both estuary and seacoast. Facing the values and literature data on the effects of those chemicals, we conclude that endocrine disruption risks by estrogenic effects likely exist in this area but under a vaster context, and comparatively with other habitats we studied in Portugal, the Lima area is nevertheless one of the less polluted.

**Quantification of estrogenic endocrine-disrupting chemicals in a supposedly reference ecosystem - the Mira River, Alentejo, in Southwestern Portugal**

MJ Rocha[1], M Pardal[2], C Cruzeiro[3], M Reis[2], E Rocha[4]
[1]CIIMAR-CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal
[2]CFE - Centre for Functional Ecology, Dep. Life Sciences, U. Coimbra, COIMBRA, Portugal
[3]CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal
The Mira River rises in the northern slopes of the Serra do Caldeirão and pursues a southeast-northwest course of 145 km with a generally mild inclination to the Atlantic Ocean, where it discharges through a small calm delta, near the town of Vila Nova de Milfontes, 115 km south to Lisbon. It is one of the two only rivers in Portugal with a chiefly south-north orientation (the other being its neighbour Sado) and one of the few rivers in Europe with this orientation. Mira basin borders Sado River basin, at north, and Guadiana River basin eastwards. Until the moment it is considered a reference river in ecotoxicology due to its low levels of pollution. However, no local surveys for estrogenic endocrine-disrupting compounds (EDCs) were undertaken to this date. To evaluate whether this river is as a valid reference also for several classes of EDCs, this study reports the evaluation of EDCs from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins. For this propose, water samples were collected during one year, every two months, at 6 sampling stations located at the river estuary and at the sea. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations of the above referred pollutants were evaluated by GC-MS. Briefly, the results showed the presence of FORM (ca. 600 ng/L), DAID (ca. 18,000 ng/L), GEN (ca. 2,000 ng/L), BIO-A (ca. 1,000 ng/L), SITO (ca. 20,000 ng/L), OPs (∑= ca. 7,500 ng/L), NPs (∑= ca. 350 ng/L), APEOs (∑= ca. 2,600 ng/L) and BPA (ca. 300 ng/L) in this area. Facing the diversity and the amounts of the chemicals, we conclude that the Mira River must be faced with caution as to be considered a reference when comparing estrogenic effects in biomonitoring. Actually, facing the literature the amounts we found may even pose a local toxicological risk.

[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal
The Mondego River rises in the centre of Portugal, at the Mountain Range of Serra da Estrela and reaches the Atlantic Ocean at Figueira da Foz. During its course of 227 km it runs through rural as well as highly urbanized and industrialized areas before reaching its 1,600 ha estuary, where it becomes visibly polluted. Its main pollution sources are waste waters, different types of industries, and the agricultural run-off; end result of 15,000 ha of cultivated land (mostly rice and corn fields) located upstream. In a previous survey with HPLC based methods we detected a few estrogenic chemicals. The data called for further and wider monitoring, eventually using more sensitive methods. Thus, this study reports the simultaneous evaluation of seventeen potential endocrine disruptors from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins in this area. For this propose, water samples were collected during one year, every two months, at 8 sampling stations located at the river, at the estuary and at the sea. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. Briefly, the results showed the presence of FORM (ca. 2,000 ng/L), DAID (ca. 1,500 ng/L), GEN (ca. 1,700 ng/L), BIO-A (ca. 14,000 ng/L), SITO (ca. 1,500 ng/L), E1 (ca. 150 ng/L), EE2 (ca. 50 ng/L), OPs (∑= ca. 800 ng/L), NPs (∑= ca. 800 ng/L), APEOs (∑= ca. 5,000 ng/L) and BPA (ca. 50 ng/L) in this area. The data confirmed the estrogenic prone scenario we previously reported. Thus, we conclude that conditions for endocrine disruption risk by estrogenic exposure, mainly from vegetal origin, exist in this area. Biomonitoring is needed to evaluate effects.

**Occurrence of estrogenic pollutants in the Ria de Aveiro Lagoon (Portugal)**

MJ Rocha[1], M Pardal[2], C Cruzeiro[3], M Reis[2], E Rocha[4]
[1]CIIMAR-CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal
[2]CFE - Centre for Functional Ecology, Dep. Life Sciences, U. Coimbra, COIMBRA, Portugal
[3]CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal
The Aveiro Lagoon is located on the Atlantic coast in North Portugal. Its average area covers approximately 75 $km^2$ and is the local where four small rivers (Vouga, Antuã, Boco and Fontão) launch their final flow. Due to the strategic location of this area several cities are located here, being the Aveiro city the most important urban centre. Beyond fisheries, this zone also holds an important industrial sector and some protected areas where saltmarshes and seagrass meadows are present. To help evaluating local toxicology risks for the biota, this study aims to investigate, as exhaustively as possible, the presence of estrogenic endocrine disruptors, from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins. For this propose, water samples were collected during one year, every two months, at 8 sampling stations covering all area of the lagoon. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. The obtained results showed the presence of FORM (ca. 150 ng/L), DAID (ca. 120 ng/L), GEN (ca. 50 ng/L), BIO-A (ca. 1,000 ng/L), SITO (ca. 4,000 ng/L), EE2 (ca. 40 ng/L), OPs (∑= ca. 100 ng/L), NPs (∑= ca. 1,000 ng/L), APEOs (∑= ca. 9,800 ng/L) and BPA (ca. 5,300 ng/L) inside the lagoon and in the seacoast. Considering the toxicological effects reported in the literature for natural and experimental exposures, within those concentration magnitudes, we conclude that endocrine disruption risk by estrogenic exposure may exist in this area; anyway, further analysis are being done.

**Off-site environmental impacts of wildfires: evaluation of the toxicity of runoff from a burnt area on freshwater aquatic species**

IN Campos[1], N Abrantes[2], T Vidal[3], F Gonçalves[3], JJ Keizer[2]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Universidade de Aveiro, CESAM & Departamento de Ambiente, AVEIRO, Portugal
[3]Universidade de Aveiro, CESAM & Departamento de Biologia, AVEIRO, Portugal
Wildfires have been found to increase the levels of polycyclic aromatic hydrocarbons (PAHs) in surface water bodies within and downstream of recently burnt areas. Whilst PAHs are well-known for their potential toxicity, environmental persistence and tendency to bioaccumulation, the potential toxicity of the runoff from burnt areas on aquatic species has received little research attention. The present work addresses this knowledge gap by laboratory assays with species from different taxonomic groups representing distinct trophic levels.

In the framework of EROSFIRE-II project, post-fire runoff generation and erosion has been monitored in a forest area in Góis municipality, central Portugal. Following a moderate-severity wildfire in August 2008, runoff samples were collect from a slope-scale erosion plot in a eucalypt stand on two occasions, namely in October 2008 after the first rains and about one year later, in September 2009. The concentration of the sixteen PAHs identified by US EPA as priority contaminants were determined for the particulate and dissolved phases of both runoff samples. The ecotoxicological assays were carried out with the following aquatic species: the bacteria (Vibrio fischeri), the green alga (Pseudokirchneriella subcapitata), the macrophyte (Lemma minor), and the invertebrate (Daphnia magna).

The PAH contents in the particulate as well as the dissolved phase of both runoff samples were dominated by compounds of the low (2-3 rings) and medium (4 rings) molecular weight. In general, the different PAHs revealed higher contents in the particulate phase than in the dissolved phase. The PAH contents differed for the two sampling occasions but not in straightforward manner. Namely, some PAHs revealed higher contents immediately after the fire, whereas others did in September 2009. These temporal patterns agree with the known persistence of the various PAHs.

The four species revealed different responses to the two runoff samples. Both samples were highly toxic to V. fischeri, P. subcapitata and L. minor, whereas they did not affect D. magna in a statistically significant manner. Furthermore, the non-filtered samples tended to produce greater effects than the filtered samples. The observed toxic effects can be explained well by the samples' PAHs contents.

This study underlines the importance of furthering knowledge of the potential deleterious impacts of wildfires on the aquatic species as a result of the PAHs production.

**Natural and man-made estrogenic endocrine-disrupting chemicals exist in superficial waters of the Ria Formosa Lagoon, a natural park in Algarve, South of Portugal**

MJ Rocha[1], M Pardal[2], C Cruzeiro[3], M Reis[2], E Rocha[4]
[1]CIIMAR-CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal
[2]CFE - Centre for Functional Ecology, Dep. Life Sciences, U. Coimbra, COIMBRA, Portugal
[3]CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal
Ria Formosa is a shallow mesotidal lagoon in the south coast of Portugal, with natural biogeochemical cycles essentially regulated by tidal exchanges at the seawater boundaries and at the sediment interface. By law, this area is a protected zone but, in reality, many focuses of pollution exist and several reports in local media have been made, denouncing the presence of direct discharges from urban, industrial and even naval sources. Thus, we anticipated that despite the law enforcements the area may be subject to pollution by estrogenic compounds. This study reports the evaluation of endocrine disruptors from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins. For this propose, water samples were collected during one year, every two months, at 9 sampling stations located in the lagoon and close to the sea. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations and identities of the above referred pollutants were evaluated by GC-MS. Seventeen compounds were screened. Briefly, the results showed the presence of FORM (ca. 2,300 ng/L), DAID (ca. 7,000 ng/L), GEN (ca. 10,000 ng/L), BIO-A (ca. 300 ng/L), SITO (ca. 12,800 ng/L), EE2 (ca. 50 ng/L), OPs (∑= ca. 6,000 ng/L), NPs (∑= ca. 2,000 ng/L), APEOs (∑= ca. 13,800 ng/L) and BPA (ca. 40 ng/L) in this area. Considering the literature data on effects on the range of concentrations found, we conclude that endocrine disruption risk by estrogenic exposure may exist in this area. Facing the particular law status of the area, the data calls for a continuous local monitoring, both with analytical and biological

approaches.

**Chemical monitoring of seventeen estrogenic endocrine-disrupting compounds expose risk for the biota in the Portuguese 'dolphin estuary' (Sado River)**

MJ Rocha[1], M Pardal[2], C Cruzeiro[3], M Reis[2], E Rocha[4]
[1]CIIMAR-CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal
[2]CFE - Centre for Functional Ecology, Dep. Life Sciences, U. Coimbra, COIMBRA, Portugal
[3]CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR-CIMAR LA, ICBAS-U.Porto, PORTO, Portugal

The Sado River, which is located in the West of the Iberian Peninsula, in Portugal, flows from the Serra do Caldeirão to the Atlantic Ocean. It is one of the few European rivers flowing South to North. During its course of 175 km, it runs mainly through rural areas before reaching its estuary that is highly industrialized. It is most famous for harboring a permanent (and slowly declining) community of about 30 bottlenose dolphins to this date. For these species and other local biota endocrine disruption phenomena is a potential risk. Suspecting that there is ongoing exposure to waterborne disruptors, this study aimed the evaluation of estrogenic endocrine disruptor compounds (EDCs) from vegetal (formonometin, FORM; daidzein, DAI; genistein, GEN; biochanin A, BIO-A; and sitosterol, SITO), biological (estrone, E1 and estradiol, E2), pharmaceutical (ethynylestradiol, EE2) and industrial (octylphenols, OPs; nonylphenols, NPs; alkylphenols ethoxylates, APEOs; and bisphenol A, BPA) origins. For this propose, water samples were collected during one year, every two months, at 10 sampling stations covering all the area of the estuarine system. The samples were filtrated, preconcentrated in Oasis HLB cartridges, cleaned in silica cartridges, and the concentrations of the above referred pollutants were evaluated by GC-MS. Briefly, results showed the presence of FORM (ca. 2,500 ng/L), DAID (ca. 250 ng/L), GEN (ca. 7,500 ng/L), BIO-A (ca. 150 ng/L), SITO (ca. 4,800 ng/L), EE2 (ca. 14 ng/L), OPs (∑= ca. 80 ng/L), NPs (∑= ca. 350 ng/L), APEOs (∑= ca. 7,000 ng/L) and BPA (ca. 25 ng/L) in this area. Despite the efforts to protect the Sado the fact is we found all these EDCs, showing that anthropogenic estrogens are the most prevalent ones in the area, and in concentrations that do not exclude at all a toxicant potential for evoking endocrine disruption. Chemical monitoring in parallel to a biomarker approach seem particularly advisable to implement in this unique ecosystem.

**Monitorization of pesticides reveals a high contamination load in the Douro River estuary and nearby seacoast, Porto, Portugal**

MFT Ribeiro[1], C Cruzeiro[2], F Figueiredo[2], E Rocha[3], MJ Rocha[4]
[1]REQUIMTE, ISCS-Norte/CICS and CIIMAR - CIMAR LA, GANDRA, PAREDES, Portugal
[2]CIIMAR-CIMAR LA, PORTO, Portugal
[3]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal
[4]CIIMAR - CIMAR LA and ISCS-Norte/CICS, PORTO, Portugal

The Douro River flows along ca. 900 km, from its source in Spain to its estuary at Porto (Portugal). Due to its dimensions and huge watershed (98,000 km2), this river passes throughout many different regions that include large agricultural fields, where pesticides are widely used and its water is commonly used for local irrigation. In spite of this, the evaluation of local contamination by these compounds has been neglected. Moreover, because we believe that upper stream contamination may arrive at the estuary where they may remain for long periods of time due both to the presence of a dam inside the estuary, the Crestuma-Lever, and also the recent construction of jetties that protect houses and stores at the estuary margins from the aggressiveness of the North Atlantic Ocean, but diminishes the flow of the river into the sea. In this sense the main objective of this study was to check for the presence of 39 priority pesticides, both in surface water and sediments, collected in the Douro River estuary and in the Porto sea coast. Target compounds included several groups: organochlorines, organophosphorous, triazines, pyrethroids and others miscellaneous. Analyzes were performed using previously validated methods involving solid-phase extraction and ultrasonic extraction of pesticides from surface water and sediment samples, respectively, followed by GC-MS. Our data revealed the present of several pesticides in water (ng/L) and sediments (μg/kg dw). Those compounds found simultaneously in water and sediments were the DDTs (ca. ∑DDTs= 150 ng/L and 15 μg/kg dw), endosulfan sulfate (ca. 100 ng/L and 15 μg/kg dw), chlorfenvinphos Z (ca. 160 ng/L and 10 μg/kg dw), hexachlorocyclopentadiene (ca. 360 ng/L and 17 μg/kg dw) and atrazine-desethyl (ca. 6.5 ng/L and 14 μg/kg dw). So the obtained results not only prove that there is an ongoing significant pollution by these compounds but also agree with former findings reporting bioaccumulation of these type of compounds (mainly DDTs) in local fish, with unknown impacts for them and for the consumers health.

**Occurrence of Irgarol, terbutryne, and a degradation product in German surface waters**

W Mailahn, M Feibicke, B Katona, D Schnee, S Rust, J Laurisch, R Schmidt
Federal Environment Agency, BERLIN, Germany

The structural closely related herbicides Irgarol (cybutryne) and terbutryne came up worldwide in the 1950s and are still in use outside the EU for weed control. From the 1980s Irgarol was also used as an antifoulant, mostly combined as a co-biocide. According to the EU Biocidal Products Directive Irgarol and terbutryne are also used as preservatives and in masonry.The occurrence of both s-triazines and the degradation product M1 (2-methylthio-4-tert-butylamino-6-amino-s-triazine, GS 26575) were measured in 208 water samples at 94 sites of German surface waters from 2005-2008 in cooperation with regional authorities.Sampling sites cover large streams like Elbe and Rhine as well as tributaries like Havel and Spree, backwaters, various channels, large lakes like 'lake Constance' and 'Müritz' as well as smaller lakes or lake-like enlargement of smaller rivers also addressed as lakes, and some creeks and ditches. Sampling stations were situated at hot spots like local pleasure boat marinas and landing stations, close to effluents of factories and sewage treatment plants, and at greater distance of these in the middle or at the outlet of lakes. Samples preparation and analyses were done by use of solid phase extraction (RP-ENV+) and GC-MS detection.Seasonal patterns were detected and local pollution sources identified. The origin of the metabolite M1 from Irgarol and terbutryne is discussed.

**Spatial and seasonal trends of organic pollutants in a small temporary Mediterranean river impacted by sewage effluents**

A David[1], C Bancon-Montigny[2], C Salles[2], C Rodier[2], MG Tournoud[2]
[1]Laboratoire HydroSciences Montpellier, MONTPELLIER, France
[2]HydroSciences, MONTPELLIER, France

Contaminants such as alkylphenols, organotins or polycyclic aromatic hydrocarbons (PAHs) present in sewage effluent have to be monitored in surface waters and european union members are required to respect environmental quality standards (EQS). The temporary rivers, where many processes concerning contaminant behaviours remain poorly studied, provide thus a significant challenge in developing appropriate sampling strategy for their monitoring. Our study took place in the Vène River, a small intermittent coastal river located on the French Mediterranean coast. The objective of this work was to assess organic contamination of the Vène river for different hydrological conditions. Four spatial one-day sampling campaigns using key locations (i.e., sites located downstream and upstream point-pollution sources) were realized at different hydrological periods (the beginning and the end of the dry period and a period of high flow). At each station, grab water and sediment samples were collected. Alkylphenols, PAHs and polychlorobiphenyls were determined with chemical analyses in sediment and organotin in water and sediments. In addition to the organotin concentrations in water, nutrient and major ion concentrations and physico-chemical data were used for multivariate analysis such as principal component analysis (PCA) to study the spatial variations of water quality. Results of the PCA showed that sites downstream direct sewage effluents were strongly correlated with the first factor which was positively correlated with anthropic variables (nutrients and organotins) during low flow period but not for high flow period. For the temporal variations, the analyse of variance revealed significant differences for monobutyltin concentrations among the different hydrological periods ($p<0.05$) but not for dibutyltin and tributyltin (TBT) concentrations. However, large variations of TBT concentrations were observed among the different hydrological periods (from 0.11 to 0.72 ng/l during the high flow period and from 0.05 to 2.47 ng/l during the low flow period). For sediments, preliminary results showed that organic contaminant concentrations seemed more stable in time (i.e., from 0.05 to 0.23 μg/kg for TBT concentrations). The use of EQS as an annual average could be difficult in temporary rivers because of the large variations of contaminant concentrations observed among the different hydrological periods.

**Dicyclohexylamine: discovery of an environmental contaminant using in-silico screening tools**

A Malmvärn[1], A Kierkegaard[1], M Radke[2], T Alsberg[1], MS Mclachlan[1], J Arnot[3], K Breivik[4], T Brown[3], F Wania[3]
[1]ITM, Stockholm University, STOCKHOLM, Sweden
[2]University of Bayreuth, Hydrology, BAYREUTH, Germany
[3]University of Toronto, SCARBOROUGH, Canada
[4]Norwegian Institute for Air Research, NILU, KJELLER, Norway

Dicyclohexylamine has been discovered in water and sediments in the Stockholm region. Concentrations in water from the Stockholm Harbour region were in the range of 1-5 ng/L, while water from Lake Mälaren, a large lake to the west of the city, contained about 0.5 ng/L. The concentrations in a small lake with no discernable anthropogenic influence was <0.1 ng/L, which excludes long range atmospheric transport and deposition as the major source of contamination to the other water bodies. Dicyclohexylamine was also found in Stockholm drinking water at concentrations similar to those found in Lake Mälaren, which is Stockholm's major source of drinking water. Dicyclohexylamine is a high production volume chemical with a wide range of uses including in paints, as an antiseptic agent, and as a fuel additive. Which sources are mainly responsible for its emissions to the environment remains to be explored.

Dicyclohexylamine was discovered as a result of a chemical screening exercise. A model of chemical fate and bioaccumulation in the environment was used to screen a total of 12600 high- and low-production volume chemicals for their concentration in the environment and in top predators. An initial estimate of the total emissions of each chemical was made using production volume information and emission factors. Key physical chemical properties of each chemical were estimated using QSARs. For the chemicals with the highest predicted concentrations, a literature search was conducted and the models' predictions were closely scrutinized. From the chemicals which passed this test and which were not known environmental contaminants, several were selected. One of these was dicyclohexylamine.

**Persistent organic pollutants in farmed sea bass (Dicentrarchus labrax L.) in two different rearing systems in the Mediterranean Sea**

V Paiano[1], C Generoso[1], A Mandich[2], I Traversi[2], M Palmiotto[1], R Bagnati[1], A Colombo[1], E Davoli[1], R Fanelli[1], E Fattore[1]
[1]"Mario Negri" Institute for Pharmacological Research, MILAN, Italy
[2]University of Genoa, Department of Biology, GENOA, Italy

Persistent organic pollutants (POPs) are ubiquitous toxic compounds, highly persistent and bioaccumulative. Due to their chemical properties, POPs pose a risk of causing adverse effects to human health and environment. In this study we measured the concentration levels of polychlorobiphenyls (PCBs), perfluorooctanesulfonate (PFOS) and perfluorooctanoate (PFOA) in the edible part of farmed sea bass reared in two different farms (site 1 and site 2) in Liguria, a region situated in northern Italy. The analytical method was based on isotope dilution with 13C labeled internal standards, followed by instrumental analysis using high-resolution gas chromatography coupled with high-resolution mass spectrometry (HRGC-HRMS) for the determination of PCBs, and liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the determination of PFOS and PFOA. We analyzed 47 samples with the aim of establishing the contamination level and human exposure to these pollutants through fish consumption.

Concentration levels (mean ± standard deviation) of DL-PCBs were $0.39 \pm 0.41$ and $0.45 \pm 0.40$ pg ΣTEQ-PCB /g (f.w.) in site 1 and 2, respectively, whereas concentrations of the six indicators of NDL-PCBs were $8.66 \pm 21.4$ and $10.7 \pm 8.27$ ng Σ6 PCB /g (f.w.) in site 1 and 2, respectively. The concentration levels found in the farm located in site 1 were generally lower than those detected in the samples from site 2. Moreover, principal component analysis (PCA) showed differences also in the congeners profile between the two sites, since higher-chlorinated PCBs were more abundant in site 1 whereas lower-chlorinated PCBs were more abundant in site 2. Concerning PFOS and PFOA, most of the measured concentrations, especially of PFOA, were below the limit of detection (LOD = 0.05 ng/g f.w.). In particular, only about 10% of the samples analyzed showed levels slightly higher than the LOD value. A possible reason of these low levels, could be that these pollutants do not accumulate in lipids but mainly in liver and blood. Exposure assessment using these data showed that farmed fish consumption may contribute significantly to PCBs through diet, whereas for PFOS and PFOA such contribution seems to be low.

**TU 045**
**Evaluation of the potential risk of contamination of the guarani aquifer in Santa Catarina, Brazil**
HL Soares, E Baptista
Universidade Federal de Santa Catarina, FLORIANOPOLIS, Brazil
Of the total area of the Guarani Aquifer (1,195,500 km2), approximately 12.8% is represented by the zones of outcrop, i.e. 153,000 km2 (ANA, 2001), with 67.8% (104,000 km2) located in Brazil, 30.1% in Paraguay and 2.1% in Uruguay. The Guarani Aquifer, which consists of sandstones, is more vulnerable to contamination in its area of outcrop because this is an important site of direct recharge of the aquifer. In Ponte Alta , SC, Brazil, the Canoas riverbed overlaps areas of outcrop of the Guarani Aquifer. The aim of this study was to investigate the possible contamination of the aquifer Guarani and which sources. Possible changes in the degree of surface and groundwater pollution of the Guarani Aquifer and Canoas river were regularly monitored (four months) by analysis of the physicochemical and biological parameters. The results showed that the Canoas river in this area exhibited altered physicochemical characteristics, particularly regarding to total phenols concentration (0.3 ppm), sulfides (1.4 ppm) and nitrate (0.5 ppm) caused by the release of waste from a pulp and paper mill. Toxic effects were found for algae, daphnia and fish. Some samples of water from the aquifer exhibited altered concentrations of phenols and metals. It was noticed that extensive outcrop and recharge areas of the aquifer are busy with the planting of pine. The thickness of the sandstone in this area was quite variable, being the 100m thicknesses the most common.

**TU 046**
**Status of environmental contamination indicated by multi-proxies around an important commercial port of South America (Paranaguá Harbor, Brazil)**
CC Martins[1], Z Camargo[1], C Bicego[2], CL Figueira[2]
[1]Universidade Federal do Paraná, PONTAL DO PARANÁ, Brazil
[2]Universidade de Sao Paulo, SAO PAULO, Brazil
Paranaguá Harbor is the main South American grain shipping port, being the third most important of Brazil in loading and unloading operations with 8,540,000 ton (2010). It is located in Paranaguá Bay (25°30'S; 48°25'W) considered one of the most important estuarine complex at Brazilian coast. Its economical importance is related to fishing activities, urban and touristic exploration, besides industries that produce fertilizer compounds. Anthropogenic inputs include domestic discharges and sewage from the port, industries and population (around 126,076 people). In order to assess the contamination level of sediments in the area under human activities, the organic compounds (PAHs, aliphatic hydrocarbons and coprostanol) and metals were analyzed. Results of PAHs and metals were compared to two Sediments Quality Guidelines (SQGs), the ERL/ERM and the TEL/PEL values. The concentration of total PAHs (16 EPA) varied since 1.0 to 1630 $ng.g^{-1}$ and it did close the TEL level in one of eleven sites analyzed. Only 2 (18 %) of stations studied presented individual PAHs higher than TEL and ERL. According to the individual PAH isomer pair ratios, the main sources of these compounds are petroleum, biomass and coal combustion. Metals (As*, Cd, Cr, Cu, Ni, Pb and Zn) presented concentrations below TEL levels in all sites analyzed. Total aliphatic (including UCM) and corpostanol varied, respectively, since 0.2 to 2221 $\mu g.g^{-1}$ and < LD to 16 $\mu g.g^{-1}$, showing contamination by oil hydrocarbons and sewage in three sites analyzed (27 %). The contamination level of sediments around Paranaguá Harbor and city could be considered high in sites very close the main human activities. Levels decreased in 10-100 times 1km far from the main sources of pollution. Given that this environment may be relatively unpolluted, the monitoring and bioaccumulation of contaminants in this ecosystem should be avoided.

**TU 047**
**Historical accumulation of polycyclic aromatic hydrocarbons (PAHs) in important economic area of a large South American tropical estuary (Paranaguá Estuarine System, Brazil)**
CC Martins[1], V Mansur[1], C Bicego[2]
[1]Universidade Federal do Paraná, PONTAL DO PARANÁ, Brazil
[2]Universidade de Sao Paulo, SAO PAULO, Brazil
Polycyclic aromatic hydrocarbons are organic pollutants prevalent in the sediments of marine and freshwater environments. They are mainly derived from anthropogenic sources including the combustion of fossil fuels (oil and coal) and biomass, sewage, vehicular emissions and spillages of petroleum. The aims of this study were to describe the temporal distribution and sources of PAHs in sediment cores collected in three different sectors of Paranaguá Bay, where human activities have intensified over the last 100 years, and to assess the historical record of local anthropogenic material input as result of the influence of human occupation in this area. The Paranaguá Estuarine System is one of the most important estuarine environments of the South American coast where fishing, urban and tourist activities, industries and the main Brazilian grain shipping port are potential sources of PAHs in this area. Sediment cores (50 cm depth) were taken by scuba diver from sites P1, P2 and P3 during September, 2008. The cores were sectioned at 2 cm intervals and PAHs were determined by gas chromatograph with a mass spectrometer after Soxhlet extraction and purification by column chromatography. In general, the sources of PAHs were fossil fuels combustion, industrial and domestic residues, introduction of petroleum by boats and ships, charcoal and biomass combustion. The parameters involving different PAHs isomers indicated that the majority sources of PAHs as related to pyrolitic processes. In the site P3, the PAHs were associated to multiples sources, and the high concentration of PAHs in intermediate layers, related with the dredging activities realized in adjacent areas of this site. Natural sources of perylene for the environment were verified, associated to input by terrigenous precursors. The concentration of PAHs varied between 1.72 and 168.5 $ng.g^{-1}$, however the individual concentration did not exceed the limits TEL and PEL, established by EPA, with an exception of acenaphthylene, found with values slightly higher compared to TEL. The comparison of total PAHs values with another studies in different locations around the world, suggest that the Paranaguá Estuary Complex, even though the urban and industrial development have been increased, it is still a local area that has not yet suffered a relative significant impact related to input of organic contaminants analyzed in this study.

**TU 048**
**Biomonitoring of polycyclic aromatic hydrocarbons (PAHs) in eastern Baltic Sea: effects on flounder (Platichthys flesus) and eelpout (Zoarces viviparus)**
R Kreitsberg[1], A Tuvikene[2], K Rumvoldt[1]
[1]University of Tartu, TARTU, Estonia
[2]Estonian University of Life Sciences, TARTU, Estonia
Eastern Baltic Sea near Estonian coast is heavily navigated sea by numerous cargo ships and oil tankers. Hundreds of accidents and oil spills happen in this area every year. Still there is a lack of data about distribution of polycyclic aromatic hydrocarbons in ennironment. In case of major accident there is no supplementary data about area's background level. Starting from 2006 we have measured PAH metabolites, enzyme activities (EROD), parasites and other biomarkers from European flounder (Platichthys flesus) and eelpout (Zoarces viviparus). A wide range of monitoring stations in coastal areas in Gulf of Finland and Gulf of Riga were chosen. The aim of our research was to specify the distribution of PAHs in a different sea areas, as well as evaluate the physiologycal effect of pollutants in two species of fish. The results showed that fish from the Gulf of Riga had lower levels of PAH metabolites, suffered less by parasites and had better liver somatic index (LSI) and body mass index (CF) than fish close to the Baltic proper and in the Gulf of Findland. This might be due to major shipping routes close to coastal areas of North-West of Estonia. The relationships between biomarker values and study areas are discussed.

**TU 049**
**Pesticides and polychlorinated biphenyls in bowhead whale blubber layers**
EM Robinson
Baylor University, WACO, United States of America
Bowhead whale blubber samples (n = 36) were collected during the 1996ð'2001 native Inuit subsistence harvests in the arctic marine environment of Barrow and Kaktovik, Alaska. Full depth blubber samples were available for 18 of the bowhead whales. Five depth layers each ~8-13 cm thick were available for most of the bowheads. Blubber layers (~ 1.5 g) were examined for historic and current-use pesticides, polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs). Contaminants were simultaneously extracted and isolated using pressurized liquid extraction combined with silica gel utilizing an accelerated solvent extractor. Silica gel was used to remove the more polar interferences and was present in the ASE cell during the extraction. Larger-molecular weight interferences, such as lipids, were removed using gel permeation chromatography. Contaminants were analyzed for using gas chromatography-mass spectrometry with electron capture negative ionization. The method was validated by a triplicate spike and recovery experiment. Using isotopically-labeled surrogates, the average percent recovery was 103% with a relative standard deviation of 9.4%. The precision and accuracy of the analytical method was validated in triplicate using NIST standard reference material 1945 for organics in whale blubber. The average absolute percent difference and standard deviation were 21% and 12%, respectively. Generally, pesticides and PCBs were detected in all blubber layers, and PBDEs were only detected in a single layer. Pesticide, PCBs, and PBDEs in blubber layers were analyzed to determine their trends in individual Bowhead whale blubber.

**TU 050**
**Analysis of glyphosate and AMPA in several matrixes using SPE-LC-MS/MS and their environmental fate in two calcareous vineyard parcels of western Switzerland**
S Daouk[1], D Grandjean[2], LF de Alencastro[2], N Chèvre[1], HR Pfeifer[1]
[1]IMG-CAM, LAUSANNE, Switzerland
[2]EPFL-LCE, LAUSANNE, Switzerland
Glyphosate [N-(phosphonomethyl)glycine] is a broad spectrum herbicide largely used in Switzerland for weed and vegetation control representing 30% of all herbicides sales in 2005. As it shows strong sorption ability and a relatively low persistence in soils, it is often assumed to not reach water bodies. Two vineyard parcels of a small catchment were investigated in order to study glyphosate transfer within soils and surface waters. Based on liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS), the analysis of glyphosate and its main degradation product aminomethylphosphonique acid (AMPA) has been set up. The method is based on derivatization with 9-fluorenymethylchloroformate (FMOC-Cl) and their concentration by solid phase extraction (SPE). Spiking tests in several matrixes revealed satisfying LOQ and recovery rates for Evian© bottled water, river water and soil solutions, as well as for calcareous soil samples. The parcels were equipped with lysimeters and runoff collectors in order to get soil solution at 4 different depths, as well as runoff water. River water was sampled together with drainage water of several vineyards. Despite its assumed low mobility, glyphosate was found to be leached and run off from the soil surface layer. The role of preferential subsurface pathways was studied, revealing the importance of textural boundaries between the more clayey deep and the silty surface layers in the transport of these compounds. Moreover, runoff water was highly loaded after rain events and glyphosate and AMPA turned out to be transported mainly by small colloids: the median of 'dissolved' fractions (<0.45µm) is located between 70 and 80% of the total concentration. The adjacent river showed concentration peaks over the 0.1µg/l threshold limit during main rain events, revealing the transfer of these compounds from the field to surface water. The highest peak had a concentration of 0.8 µg/l of glyphosate in August. Moreover, drainage systems showed much higher concentrations of up to 4 µg/l, revealing the importance of artificial channels within the urbanised landscape in the transfer of these compounds. These results give a better understanding of the environmental behaviour of glyphosate, which is largely used in viticulture and agriculture in Switzerland, due partly to the increase of simplified tillage practices.

**TU 051**
**PAHs, PCBs and chlorinated pesticides in sediments and fish species from Milazzo (South Italy) marine area**
G Perra[1], CG Guerranti[1], MM Mariottini[1], MG Graziosi[1], SF Focardi[1], FA Andaloro[2], TR Romeo[2]
[1]University of Siena, SIENA, Italy
[2]Institute for Environmental Protection and Research, PALERMO, Italy
Marine sediments are usually regarded as the ultimate sink for persistent pollutants discharged into the environment. The aim of the present study is to determine the levels of several organic pollutants (PCBs, PAHs, DDTs, HCHs and HCB) in order to assess the contamination in Milazzo (South Italy) marine area. The distribution of pollutants of environmental interest was investigated also in fish (*Serranus scriba, Serranus cabrill*a and *Serranus hepatus*) collected from Milazzo marine area. Sediment and fish samples were lyophilized and extracted for organic contaminants with accelerated extractor (ASE) system and quantified by GC-MS and HPLC. Muddy sediments with high organic matter content dominate the study area. Total PAH concentrations ranged LOD-211.17 ng/g dry weight indicating low to moderate PAH pollution. The comparative evaluation of PAHs with low/high molecular weight and isomeric ratios suggest that the pollution source is pyrolytic and that terrigenous flows do not affect the PAH balance of the marine area. Organochlorine compounds levels indicate that sediments are not significantly polluted by HCH (max mean value of total HCHs = 8.52±8.17 ng/g d.w.), HCB (max mean value of HCB = 1.85±1.55ng/g d.w..), DDT and its metabolites (max mean value of total DDTs = 30.57±3 ng/g d.w.) and PCBs (max mean value of total PCBs = 93.60±92.78 n/g d.w.). The identification of organic contaminants sources in the Milazzo marine area ecosystem could be useful to plan the polluted sediments management activities and the restoration strategies. The organic pollutants concentrations indicate a low to moderate pollution level with an heterogeneous distribution in

the marine area. The maximum mean level of total PAH was measured in liver of *Serranus hepatus* (6.04±1.54 ng/g w.w.), while organochlorines were never detected in this species.

**Distribution and partitioning of polybrominated diphenyl ethers in East River, South China**

H Deng[1], Y Chen[1], KC Jones[2], J Gong[1], X Luo[3]
[1]Guangzhou University, GUANGZHOU, China
[2]Lancaster University, LANCASTER ENVIRONMENT CENTRE, LANCASTER,, United Kingdom
[3]Guangzhou geochemical institute, GUANGZHOU, China

Distribution and Partitioning of Polybrominated Diphenyl Ethers in East River, South China
The distributions and partitionings of polybrominated diphenyl ethers (PBDEs) in water columns from the Dongjiang River were investigated in the present study. Water samples were taken in Shilong Section of Dongjiang River, South of China, during four intensive sampling campaigns in 2008 and 2009. ∑14PBDEs (BDE28, 47, 66, 100, 99, 85, 154, 153, 138, 183, 206, 207, 208, and BDE209) were analyzed . The levels of ∑14PBDEs were 0.04-2.69 ng/L, whereas those of BDE47, 99, 153 and 209 were 0.01-0.09 ng/L, 0.01-0.10ng/L, 0.001-0.11ng/L and 0.009-2.05 ng/L, respectively. BDE47, 99 153 and BDE209 were detectable in all dissolved and particle samples, which contributed higher than 80.5% of total ∑14PBDEs. The PBDEs concentrations in water samples were lower in dry season than in flood season. SPM could play certain roles in determining the distribution and partition of PBDEs between particle and dissolved phases, but their effects varied with the water properties. Calculated values of the organic carbon-water partition coefficient (KOC) were strongly correlated with literature values of the octanol-water partition coefficient (KOW). The data suggest that sorption of BDEs to colloids is important in this system, although quantifying the extent of colloid sorption is difficult.

**Evaluating daily PCB exposures to children from dietary supplements containing fish oils**

TF Ashley[1], JS Ward[2], MW Schafer[3], L Zaoudeh[3], DJ Velinsky[3]
[1]Philadelphia University, PHILADELPHIA, United States of America
[2]ICQ Global, HORSHAM, United States of America
[3]Academy of Natural Sciences, PHILADELPHIA, United States of America

Children's dietary supplements containing fish oils have become a popular means of increasing children's intake of polyunsaturated fatty acids (PUFAs). However, there is growing concern that the levels and potential health effects of lipophilic organic contaminants such as polychlorinated biphenyls (PCBs) may diminish some of the health benefits associated with daily consumption of fish oil supplements. In this study, thirteen over-the-counter fish oil supplements available in the United States were analyzed for PCBs and daily exposures were calculated. Concentrations of t-PCBs ranged from 0.4 to 20.0 ng/g wet wgt and were low compared to our recent study of adult fish oil supplements (3.1 to 264 ng/g wet wgt). Based on manufacturers' recommended dosages, a child's daily intake of PCBs would range from 2.8 to 50.3 ng/day. Daily consumption of fish oil supplements expose children to PCBs, albeit at low levels. However, in comparison to ingestion of fresh fish to gain equivalent amounts of PUFAs contained in supplements, children's fish oil dietary products may decrease daily PCB exposure.

### TU 054

**Use of innovative technology for analysis of 54 VOCs in water: ITEX solution**

A Togola, B Girardeau, L Amalric
BRGM, ORLEANS, France

Contamination of aquifers by one or more volatile organic compounds (VOCs) is a national issue of potential concern because of the widespread and long-term use of many of these compounds. Many (VOCs) are toxic and some are considered to be carcinogenic, mutagenic, and teratogenic. Contamination also depends on the locations and types of VOC sources, the relative locations of wells, and the transport and fate of VOCs. The occurrence of low-level contamination of one or more VOCs in an aquifer also can provide managers with an early indication of the presence of VOCs that eventually might adversely affect the quality of water
Considering the high variability of VOCs concentration in groundwater especially in the case of industrial impacted groundwater, VOCs analysis is an important and sensitive point for understanding behaviour, attenuation or determining sources of the pollution.
Rapid sensitive and robust analysis of 54 VOCs including, BTEX and chlorinated solvents was developed using In Tube Extraction (ITEX) combined with GCMS for analysis in groundwater, effluent and surface waters. The study presents optimization of the method, validation on several matrices (occurrence of suspended, matter, organic matter content). Validations, considering potential trap needle saturation process and matrix effects were undertaken, highlighting robustness of the ITEX technology.
Detection limits ranged from 0.25 µg/L to 2 µg/L were validated with recoveries ranged from 85% to 103% depending on the studied compounds. Applications for the monitoring of VOCs in polluted areas will be presented showing the efficiency and accuracy of ITEX use and the obtaining of robust data concerning degradation of VOCs and natural attenuation for some of them.

### TU 055

**Chemo- and bioanalyses of the partitioning of radiolabelled organic chemicals in sediment-water-organism-systems**

A Simon[1], H Zielke[1], B Schmidt[1], TB Seiler[1], A Schäffer[1], JVK Kukkonen[2], H Hollert[1]
[1]Institute of Environmental Research, RWTH Aachen University, AACHEN, Germany
[2]University of Eastern Finland, Department of Biology, JOENSUU, Finland

Sediments can act as a sink as well as a source for environmental pollutants. A multitude of factors can influence this dual quality and the related partitioning between organisms as potentially affected targets, water and sediment. Those factors include sediment properties, water quality, the type of organism and substance characteristics. Direct sediment-contact tests are excellent tools to assess these complex systems. In these whole-sediment toxicity tests, the test species are introduced directly onto or into the sediment. Aim of the present project was to investigate the influence of short-term ageing on the partitioning of organic pollutants in a system comprising sediment, water and organisms.
Zebrafish (Danio rerio) embryos and the sediment dwelling worm Lumbriculus variegatus were used as model organisms. Two natural sediments (Altrip, back water of the Rhine and Höytiäinen, lake in eastern Finland) as well as an artificial sediment (OECD 218) were used, each spiked with pentachlorophenol (PCP) and/or fluoranthene (FA). Concentrations of labeled chemicals were below lethal effect levels for the bioaccumulation study (10000 dpm/g dw sediment), whereas in the ageing study with non-labeled PCP, 15 mg/kg dry weight sediment were applied.
In the L. variegatus test, scintillation counting was carried out in order to quantify the radioactivity in the different test compartments after 14 days of exposure after ageing the sediment for 5 and 18-21 days, respectively. In addition to accumulated concentrations, bioaccumulation factors were determined after 14 days of exposure. The steady state of bioaccumulation was not reached within 14 days, however, one short-term ageing effect became apparent. For PCP, bioaccumulation could be shown in both sediments. A twofold ageing-related decrease in accumulation was found in the natural sediment. On the contrary, no bioaccumulation of FA was observed independent on the aging period of 5 or 18-21 days.
Furthermore, zebrafish samples were analysed at different time-points after the initial spiking to obtain data on ageing-dependent changes in observable effect. As expected, ageing natural sediments for 6 weeks and artificial sediments for 9 weeks resulted in a complete loss of effects for both chemicals.
In conclusion short-term ageing effects within only 3 to 6 weeks of ageing were uncovered in the two experiments. This clearly shows the need to account for ageing when assessing results of direct sediment contact tests.

### TU 056

**Trophic magnification of poly- and per-fluorinated compounds and determination of known and unknown organic fluorine content in biological samples from Mai Po Marshes Nature Reserve, Hong Kong**

IH Loi[1], WY Yeung[2], E Yamazaki[3], S Taniyasu[2], KS Lam[1], K Kannan[4], N Yamashita[2]
[1]City University of Hong Kong, HONG KONG, Hongkong
[2]National Institute of Advanced Industrial Science and Technology (AIST), IBARAKI, Japan
[3]Hosei University, TOKYO, Japan
[4]State University of New York at Albany, ALBANY, United States of America

Perfluorinated compounds (PFCs) have been manufactured and widely used for various applications for over 60 years. Concern about PFCs has been growing since the 1990s because of their toxicities, environmental persistence, and ubiquitous occurrence in wildlife and human populations. Several field studies from the Canadian and European Arctic and tropical regions have indicated that PFCs biomagnify in aquatic food webs, especially PFOS and some long-chain perfluorocarboxylates (PFCAs). However, no PFC bioaccumulation studies in the sub-tropical region have been reported thus far. In the present study, bioaccumulation of PFCs was investigated in a food web composed of phytoplankton ($p$=3), zooplankton ($p$=2), gastropods ($p$=3), worms ($p$=10), shrimps ($p$=4), fishes ($n$=21), and waterbirds (PFCs analyzed in the livers of grey herons (*Ardea cinerea*) and Chinese pond herons (*Ardeola bacchus*); $n$=6) sampled from a tidal shrimp pond in the Mai Po Marshes Nature Reserve in Hong Kong. Biota samples were generally extracted by the ion-pair method, followed by ENVI-Carb and SPE OASIS-WAX cleanup. Individual PFCs were quantified using HPLC-MS/MS. Trophic magnification was observed for PFOS, PFDA, PFUnDA, and PFDoDA and the trophic magnification factor (TMF) values ranged from 1.30-1.75. PFUnDA (TMF=1.75) was found to have the greatest TMF. In addition to known PFCs, recent studies demonstrated the presence of large amounts of unidentified organofluorines in wildlife. In the present study, extractable organic fluorine (EOF) (based on the ion-pair method) and total fluorine (TF) in the samples were analyzed using refined combustion ion chromatography for fluorine (CIC-F). A large proportion of inorganic fluorine and non-extractable organic fluorine (around 99%) were found in lower trophic organisms (i.e., gastropod, worm and shrimp) when compared to fish liver (57-71%). Relatively similar EOF contents were found in all samples. The contribution of known PFCs to EOF increased significantly with increasing trophic levels (i.e., fish liver (41-76%) > shrimp (10-12%) > worm (0.5-3.7%) > soft tissue of gastropod (0.4%)). The small PFC-to-EOF ratios found in lower trophic organisms might be due to differences in the exposure level, rate of uptake and elimination of PFCs in different species.

### TU 057

**Transport of particle-bound pollutants by urban runoff to the bottom of boreal Lake Vesijärvi**

O Bausheva, AL Rantalainen
University of Helsinki, LAHTI, Finland

Urban runoff is known to be contaminated with a range of hydrophobic organic compounds (HOCs), which are usually bound to particulate matter and therefore settle to the sediments. Polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) are among the best known compounds. They are recognized as priority pollutants, often toxic to aquatic life and known to have urban origin. The city of Lahti has approximately 100 000 inhabitants and is a growing Finnish urban area. It abuts on Lake Vesijärvi, which is an important provider of recreational and fishing activities in the region. Most of urban runoff in Lahti discharged directly to Lake Vesijärvi. However, knowledge on the amount and fate of HOCs in urban runoff is insufficient. In previous studies PAH and PCB compounds were found in Lake Vesijärvi sediments and their concentrations tended to decrease with the distance from urban shore and stormwater outlets which could be possibly caused by the impact of urban surface runoff.
Present study aims to evaluate concentrations of HOCs in sediments from stormwater traps and possibly link them to concentrations in the Lake Vesijärvi. Grab sediment samples were taken from stormwater traps at 15 locations in areas with various degrees of urbanization (urban, mid-urban and suburban). Samples were analyzed for 16 PAHs (EPA) and 28 PCBs using isotope dilution technique and gas chromatography-mass spectrometry (GC-MS) method. Concentrations of both PAHs and PCBs varied greatly with different sampling locations but were of similar level with concentrations found in Lake Vesijärvi. Local factors (bigger road or parking lot; smaller road or parking lot; side walk or green area) tended to have more significant effect on PAH than PCB concentrations, while general urbanization level seemed to impact distribution of PCBs stronger than PAHs. Pollutant profiles in different study areas were also compared.

### TU 058

**Distribution and seasonal variation of organic pollutants in surface marine sediments in the Mar Menor Lagoon (SE SPAIN): Flood impact**

R Moreno-González, JA Campillo, V García, E González, VM León
Instituto Español de Oceanografía, SAN PEDRO DEL PINATAR, Spain

Mar Menor is a hypersaline (42-47 psu) coastal lagoon with a mean depth between 3-4 m and the maximum depth is over 6 m. It is one of the largest lagoons of the Mediterranean Sea located in the Cartagena Field area at the South East of Spain. This semi-arid area is subject to intensive agriculture, phreatic level rise, recreational activities and sporadic torrential rainfall regime. In this study we have characterized the distribution of PAH´s, PCB´s, and pesticides, before (Spring 2009) and after (Autumn 2009) two flood events. The aims of this study were: a) to characterize the distribution of organic pollutants in sediments from Mar Menor Lagoon, b) to evaluate the seasonal variation of organic pollutants levels in sediments and c) to estimate the input and the impact of floods events on the distribution of organic pollutants in sediment.

PAHs and organochlorinated pollutants were extracted using a Soxhlet apparatus and were analyzed by HPLC for PAHs and GC-MS for PCBs and organochlorinated pesticides.The rest of pollutants (triazines and organophosphorus pesticides) were extracted using sonication extraction and were analyzed by GC-MS. Organic pollutant concentrations were also determined in water and suspended particulate matter during the flood event. These water extractions were performed using Stir Bar Sorption Extraction (SBSE) and thermal desorption coupled to GC-MS. The distribution of PAHs, PCBs and pesticides in the Mar Menor lagoon on Spring 2009 was heterogeneous. The three target groups of pollutants did not show the same pattern. The highest PAHs concentrations were detected in the northern and southern areas, particularly in the south(≈ 230 ng/g). The distribution of PCBs showed the highest concentrations in the central, and particularly in the south area. In general, the organophosphorus and organonitrogenated pesticides concentrations were lower than PAHs ones. During flood events several water and suspended solid matter samples were taken in the Albujón Watercourse mouth to estimate the organic pollutant input in these rare events. These water samples were analyzed by SBSE/GC/MS using full scan mode. As a result of the massive influx of water and suspended materials during the flood events especially through Albujón Wadi, the distribution in the sediment of all the contaminants groups studied was heterogeneous, and significant seasonally differences were observed in the organic pollutants concentrations associated to flood impact.

**TU 059**

**Bioaccumulation of mercury in birds: a comparative study in Ciconiiformes, Charadriiformes and Pelecaniformes**

SA Santos, MS Monteiro, AMVM Soares, S Loureiro
CESAM (Centre for Environmental and Marine Studies), AVEIRO, Portugal

One of the most widespread pollutants threatening both wildlife and human heath, mercury (Hg) occurs in a wide range of forms, both organic and inorganic, being methylmercury (organic) the most stable and toxic form. Aquatic birds, as top predators, show high mercury levels due to biomagnification of methylmercury through the food webs and are therefore good indicators of mercury contamination in aquatic ecosystems.
The main aim of this study was to monitor mercury exposure in different species of birds from the orders Ciconiiformes, Charadriiformes and Pelecaniformes, which show different feeding preferences. To achieve that, liver samples from necropsied animals were lyophilized and then Hg was measured in triplicate by atomic absorption spectrometry (ASS) with thermal decomposition. Data obtained reported high levels of mercury burdens accumulated in almost all species. Significant differences in the burdens of mercury accumulated were also reported, being mercury levels higher in species with a fish-selective diet than in species with a generalist diet. This corroborates the hypothesis that the main source of mercury contamination in top predators such as birds (and in parallel men) is through uptake of contaminated fish. Even though some mercury levels reported seemed to be high enough to induce sub-lethal or lethal effects on the individuals, it was not possible to establish any correlations as these values are difficult to interpret without data associating tissue and exposure levels.

Abstract
Aquatic sediments are well known sinks for numerous persitent pollutants such as POPs and heavy metals. Pollutants accumulated in sediments can be partially bioavailable and may represent a threat for aquatic ecosystems.
In order to study time-course of pollution in the Seine estuary and also toxicity of accumulated pollutants in bottom sediments, a 110 cm-depth sediment core was sampled in the Seine estuary in a disused dock in Rouen harbor in april 2008 (Rhapsodis project). The core was splited in twenty 5 cm-thick slices which were analyzed for size grain, organic carbon, sulfurs, metals (13 elements), PAHs and persitent organic pollutants (PBDEs, OCPs, PCBs). Toxicity of sediment organic extracts was measured by using a large panel of in vitro toxicity assay : Microtox®, ER and DR-Calux®, SOS Chromotest and AChE inhibtion assay.
For all analyzed chemicals except Be, Mo and Cd a clear increase of pollutant concentrations was observed with depth. Strinkingly, peak of concentration for various polluants (PCBs, PAHs, sulfured PAHs, OCPs, Hg and Pb) was observed at 92.5cm depth. All sediment extracts exhibited high toxic potency. Acute toxicity (Microtox®) was shown to increase with depth. DR-Calux® activity (dioxine-like activity) was also increasing with depth while ER-Calux® activity related to estrogen-like compounds was globally low. AChE inhibition activity and genotoxicity (SOS-Chromotest) were mainly measured in surface and sub-surface sediments.
This study brings first evidences of global pollution decline in the Seine estuary during the last three or four decades notably for heavy metals, PCBs, OCPs and PAHs. It also highlighted the high toxic potency of accumulated pollutants and putative risk they could represent for aquatic organisms living in the Seine estuary.
This study was supported by the Seine-Aval program.

**Bioaccumulation of organochlorine pesticides and biomarker responses in Dreissena polymorpha and Dreissena bugensis after exposure to native suspended particulate matter**

S Schaefer[1], B Hamer[2], B Treursic[3], C Möhlenkamp[4], D Spira[1], G Reifferscheid[1], E Claus[1]
[1]Federal Institute of Hydrology, KOBLENZ, Germany
[2]Ruder Boskovic Institute, ROVINJ, Croatia
[3]University of Pula, PULA, Croatia
[4]Federal Instiute of Hydrology, KOBLENZ, Germany

The zebra mussel, Dreissena polymorpha, is widely used as sentinel organism for the assessment of environmental contamination in freshwater environments. In Germany, it is collected e.g. for regular chemical monitoring and for long-term storage of samples for retrospective research in the frame of the German environmental specimen bank (ESB). However, in the river Rhine the D. polymorpha population is declining while the closely related quagga mussel Dreissena bugensis is found in high numbers at some sampling locations. In the present laboratory study, D. polymorpha and D. bugensis were exposed to natural sediments for up to two weeks. Wet sediment (< 63 µm, 100 mg L-1 dry weight) was simulated as suspended particulate matter to mimic the mussels' main uptake route for chemicals. The sediments were sampled in a) the river Elbe in Dessau, a site known to be highly polluted with e.g. organochlorine pesticides, and b) in Havelberg in the river Havel, one of the Elbe's tributaries and a relatively unpolluted site.
Chemical analysis of organochlorine pesticides (7 PCBs, DDT and metabolites, HCHs, HCB) in soft tissue of mussels showed significantly higher values of PCB 101, PCB 118, PCB 153, PCB 138, PCB 180, the sum of seven PCBs as well as p,p'-DDD in D. bugensis compared to D. polymorpha. 14 days of exposure increased the concentration of p,p'-DDE and p,p'-DDD in both species. Furthermore, exposure to the Dessau sediment resulted in elevated levels of p,p'-DDD in mussel tissue compared to Havelberg sediment. Interspecific differences were less pronounced when regarding chemical concentrations to lipid content instead of dry weight of tissue since D. bugensis had higher levels of total lipid than D. polymorpha.
DNA damage in gills, measured with the COMET assay, was higher in D. bugensis compared to D. polymorpha. Simultaneously, the content of heat shock protein (Hsp70) in gills was higher in D. polymorpha than in D. bugensis. DNA damage and Hsp70 were not induced by neither exposure time nor sediment type. Protein carbonylation in gills and soft tissue, however, showed no difference between species and exposure time, but in soft tissue it was slightly elevated in mussels exposed to the Havelberg sediment.

**TU 062**

**Dioxin-like activity of sediments of the Elbe River and associated flood areas**

K Eichbaum[1], TBS Seiler[1], SK Keiter[1], G Umlauf[2], B Stachel[3], H Hollert[1]
[1]RTWH Aachen University, AACHEN, Germany
[2]Institute for Environment and Sustainability European Commission - Joint Researc, ISPRA, Italy
[3]Ministry of Urban Development and Environment, HAMBURG, Germany

The aim of the present study was the determination of cytotoxic hazard potential and dioxin-like activity of sediments from the riverbed of the Elbe River and of associated flood areas. Of peculiar interest were industrial locations with high contamination. Soil samples from the flood areas of the Elbe River were taken in the year 2003, one year after the flood disaster. The riverbed samples originate from the river head down to the estuary and were sampled in the year 2008, after the flood. Freeze-dried sediments were extracted with n-hexane:acetone (1:1, v/v) by means of pressurized liquid extraction (PLE). The Neutral red assay on cytotoxicity and the EROD (7-ethoxy-resorufin-o-deethylase) assay on dioxin-like activity were then applied with the resulting extracts using the RTL-W1 permanent cell line. Within this study the main focus was set on polychlorinated biphenyles (PCBs), polycyclic aromatic hydrocarbons (PAHs) and polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (PCDDs/Fs), which interact with the aryl hydrocarbon receptor (AhR) and cause EROD induction. Moreover, in order to identify whether PAHs, PCDDs/Fs or PCBs cause the strongest effects in the EROD assay, a multilayer fractionation was performed. Finally, results of the bioassays were compared with available analytical data to evaluate the significance of the used in-vitro bioassays.

**Accessibility and chemical activities of PAHs and PCBs in anthropogenic impacted sediment cores of the main sedimentation basins of the Baltic Sea**

KM Schmidt, SC Lang, L Rehberg, G Witt
Hamburg University of Applied Sciences, HAMBURG, Germany

Many polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) have been classified as "Priority Pollutants"by the Stockholm Convention on Persistant Organic Pollutants (POPs), due to their ubiquity, persistence, bioaccumulation carcinogenic or mutagenetic potentials. The distribution of POPs between pore water and sediment affect their fate, transport and ecotoxicological risks in the marine environment. To date, there are only a few limited studies that have used field data to give information about the direction of the diffusive mass transfer, which always takes place from areas of high to low chemical activity. A very important question remains. Does the sediment act as a diffusive source or as a diffusive sink for the POPs in the water column? This question calls for the determination of the chemical activity of POPs in the pore water, which can be measured by equilibrium sampling techniques. To calculate chemical activity, freely dissolved concentrations of PAHs and PCBs were measured in the pore water of sediment samples using solid-phase microextraction, a cost- and time-efficient method with detection limits in the lower nanogram per liter range. Additionally, total sediment concentrations were measured in sediments to calculate the distribution of contaminants between the two compartments. Sediment-pore water partitioning of POPs was studied in sediment cores of the main sedimentation basins of the Baltic Sea. Chemical activities of the POPs in the sediment cores were used to predict the regional baseline toxic potential of the contaminant mixture. Finally, gradients in Cfree and chemical activity were used to determine the direction of diffusion within the sediment and to obtain a spatial characterization of pollutant exposure. Cfree and chemical activity are important exposure parameters for the prediction of bioconcentration and toxicity in sediment organisms, and their measurement should be included in risk-assessment and pollution-management strategies.

**TU 065**

**Photo-transformation of AhR-active hydrophobic organic compounds in presence of humic substances**

M Bittner[1], P Macikova[1], J Ospalik[1], JP Giesy[2], L Bláha[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Dpt. of Biomedical Veterinary Science and Toxicology Centre, U. of Saskatchewan, SASKATOON, Canada

Hydrophobic organic compounds (HOCs), frequent anthropogenic environmental pollutants, can cause many adverse effects in organisms. Activation of arylhydrocarbon receptor (AhR) can be very important mechanism of toxicity for so-called AhR-active HOCs, such as benzo[a] pyrene (B[a]P), dibenz[a,h]anthracene (DB[a,h]A), and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Humic substances (HS), being naturally occurring compounds (up to 50 mg/L in waters), can occur together with HOCs in contaminated water. Beside other important ecological properties, HS serves as a natural source of reactive oxygen species that are formed after HS irradiation. Direct photolysis of HOCs is a very important way of their degradation in the aquatic environment. Nevertheless, oxygen species, formed after HS irradiation, can enhance the photochemical degradation of HOCs. In present study, we have assessed the ability of various HS to enhance photo-degradation of upper mentioned HOCs, and its mixture. Aqueous HOCs+HS solutions were irradiated by low/pressure mercury lamp in Pyrex tubes (retaining UV radiation <300 nm). Photo-degradation of HOCs, studied by chemical analysis using GC/MS(MS), was observed, where HOCs in mixtures with HS were photo-degraded more rapidly. To evaluate whether any new AhR-active compounds has been formed as a products of HOCs phototransformation, AhR-mediated toxicity of complex samples was assessed using *in vitro* assay based on the H4IIE-*luc* transgenic cell line. Obtained results have been in good accordance with results from chemical analysis. Supported by projects GACR 525/08/P464 and CETOCOEN (European Regional Development Fund no. CZ.1.05/2.1.00/01.0001).

### TU 066

**Equilibrium sampling of environmental pollutants in fish - Comparison with lipid-normalized concentrations and homogenization effects on chemical activity**

A Jahnke[1], P Mayer[2], M Adolfsson-Erici[1], MS Mclachlan[1]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Aarhus University, AARHUS, Denmark

Equilibrium sampling of hydrophobic organic pollutants into the silicone polydimethylsiloxane (PDMS) has been used in numerous environmental matrices and has recently been applied in lipid-rich biological tissues [1, 2] including fish. The concentrations of chemicals in the polymer ($C_{PDMS}$) can then be multiplied with lipid/PDMS distribution ratios ($D_{Lipid,PDMS}$ [3]) according to eq. 1 to obtain concentrations in fish lipids ($C_{Fish,lipid,equilibrium}$):

$C_{Fish,lipid,equilibrium} = C_{PDMS} * D_{Lipid,PDMS}$ (1)

In this study, PDMS thin-films [4] were placed in intact tissue of two eels and one salmon for equilibrium sampling of polychlorinated biphenyls (PCBs). A 'classical' exhaustive extraction technique to determine lipid-normalized PCB concentrations, which assigns the body burden of the chemical to the lipid fraction of the fish, was additionally applied. Lipid-based PCB concentrations obtained by equilibrium sampling were in good agreement with those determined using total extraction. These results support the validity of the equilibrium sampling technique, while at the same time confirming that the fugacity capacity of these lipid-rich tissues for PCBs was dominated by the lipid fraction.

Further, we provide equilibrium sampling data obtained in homogenates of the same fish tissues. The PCB concentrations were 1.2-2.0 times higher in the PDMS immersed in homogenized tissues as compared to PDMS immersed in intact tissues, indicating that homogenization increased the chemical activity of the PCBs and decreased the fugacity capacity of the tissue.

On the basis of the presented data, we describe a novel approach to confirm that (a) the equilibrium sampling technique and (b) the widely used environmental monitoring approach of assigning the body burden of pollutants to the organism's lipid fraction are valid in lipid-rich biota. Further, we provide experimental evidence of reduced fugacity capacity of homogenized tissue as compared to intact tissue. This observation may have consequences for (1) equilibrium sampling, (2) physiologically based pharmacokinetic models since these are often based on tissue/air and tissue/water partition coefficients determined using tissue homogenates and (3) the mechanisms of dietary absorption of organic contaminants.

**Bioaccumulation of micropollutants in an estuarine food chain**

E van Ael, A Covaci, R Blust, L Bervoets
University of Antwerp, ANTWERP, Belgium

Due to anthropogenic activities trace metals and organic micropollutants have been introduced in the aquatic ecosystem where they can accumulate and persist for many years. Those pollutants can become available for uptake by organisms and cause toxic effects. Persistent pollutants have the ability to be transferred through food chains and even become a threat for human health. Bioaccumulation of chemical substances depends on two main factors. First, pollutants must be available for uptake by organisms. This bioavailability is strongly influenced by the chemical properties of the pollutant, by several physical and chemical processes and by environmental characteristics of the surrounding water and sediment, which can be highly variable in certain environmental systems like estuaries. These characteristics determine the chemical speciation and distribution of pollutants over the environmental compartments.

Secondly, bioaccumulation is influenced by the exposure route. Which exposure route is important for an aquatic organism is highly dependent on its physiology, habitat preference and feeding strategy.

This project aims to determine the exposure route most responsible for bioaccumulation in organisms with different feeding strategies and trophic level, and this for various pollutants. Therefore we conducted passive as well as active biomonitoring studies in the Scheldt estuary. We related accumulated levels of micropollutants (trace metals, organic pollutants) in caged and free living animals to levels in environmental compartments (water, SPM, pore water, sediment).

**Bioaccumulation and trophodynamics of emerging contaminants in tropical mangrove food webs**

C Kelly, S Bayen, Z Zhang
National University of Singapore, SINGAPORE, Singapore

Tropical mangroves are important ecosystems in Southeast Asia, as well as other tropical and subtropical regions of the world. These unique ecosystems provide essential habitat for numerous species of aquatic and terrestrial organisms. In 2004, field measurements in Singapore have demonstrated legacy persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs), dichloro-diphenyl-trichloroethanes (DDTs) and chlordanes (CHL) exhibit a high degree of biomagnification in local mangrove food webs. The objectives of the present study were conduct a field study to assess the occurrence, levels and bioaccumulation behavior of various emerging contaminants of concern in Singapore mangrove food webs. Target analytes included a comprehensive list of pharmaceuticals and personal care products (PPCPs), current-use pesticides (CUPs) and brominated flame retardants (BFRs). A comprehensive field survey of surface waters, sediments and mangrove organisms, including various species of algae, plankton, mollusks, crabs and fish, was conducted at several mangrove sites around Singapore. Water samples were filtered/extracted using a filtration apparatus containing glass fibre filters and solid-phase extraction (SPE) disks in order to determine freely dissolved and particulate bound chemical concentrations. Sediments and tissue samples were extracted using accelerated solvent extraction (ASE) and further cleaned-up using gel permeation chromatography (GPC), SPE and/or Florisil chromatography. Identification and quantification of target compounds was performed using liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) or gas chromatography mass spectrometry (GC-MS). 13C or deuterated mass-labeled standards were used as internal standards to correct for matrix effects. Measured concentrations and observed trophic magnification factors (TMFs) of the various emerging contaminants of concern are compared to observations of legacy POPs. The bioaccumulation behavior and overall biomagnification potential of these contaminants in the mangrove food webs are evaluated and discussed.

### TU 069

**Accumulation of butyltin compounds in minke whales and long-beaked common dolphins from the Korean coast**

M Choi[1], HB Moon[2], YR An[1], SG Choi[1], ZG Kim[1], DY Moon[1], HG Choi[1]
[1]National Fisheries Research and Development Institute, BUSAN, South-Korea
[2]Hanyang University, ANSAN, South-Korea

Butyltins (BTs) including mono- to tri-butyltins (MBT, DBT and TBT) were determined in the liver of minke whales (Balaenoptera acutorostrata) and long-baeked common dolphins (Delphinus capensis) caught off the Korean coast. Total concentrations of BTs ranged from 15.7 to 297 ng/g on a wet weight basis (wet wt) in minke whales and from 59.0 to 412 ng/g wet wt in long-baeked common dolphins. DBT was the predominant BT in the liver, contributing to 63% of total BTs. Significant species-specific difference in concentrations and composition of BTs was found between minke whales and common dolphins. A gender difference in BT residues between male and female common dolphins was not observed. However, concentrations of BTs in minke whales increased with body length. The overall BT levels in cetaceans from Korean coastal waters were lower than those reported worldwide, and the levels were consistent with BT contamination in the Korean coast.

## EC07 - Integrated chemical and biological approaches for toxicant identification

### TU 074

**Estimating metal bioavailability in sediment by DGT for avoiding overdosing of chelatants in TIE protocols**

A Caillat[1], M Grote[1], JM Garnier[2], Y Nia[1], P Ciffroy[1]
[1]EDF, R&D Division, CHATOU, France
[2]CEREGE, Université Paul Cézanne, UMR 6635 CNRS, AIX EN PROVENCE, France

The protocol for Sediment Toxicity Identification Evaluation ("sediment TIE") recommended by the US-EPA proposes generic quantities of resin to be added to sediments for adsorption of different compound classes and then toxicity reduction. However, the overdosing of a given chelating resin aiming at specifically binding divalent metals may lead to misinterpretation of observable toxicity reduction as its organic polymer matrix is also able to interact with organic toxicants. The aim of the current work is to better understand the effect of chelatants on the reduction of the metal bioavailable fraction and thus to optimize the quantity of chelating resin to be added according to sediment physico-chemical properties.

For this purpose, artificial sediments were prepared as a mixture of silica sand, clay minerals (kaolinite), calcite and additional components (iron oxide like goethite or ferrihydrite, Humic acids) and spiked with copper (Nia et al, 2011). Bioavailable fractions of Cu (before and after chelatant addition) and kinetic effects of the chelatant were estimated by the technique of diffusive gradients in thin-film (DGT): DGT devices were inserted into each sediment and removed at different contact times. A multi-compartmental model simulating transport in diffusion layer (DGT gel) and sediment porewater, as well as sorption/desorption kinetics (Ciffroy et al, 2011) and allowing to estimate Cu-adsorbent capacity of the sediment (total Kd and labile Kd) and adsorption/desorption kinetics rates (kads;kdes) was used for estimating the effect of chelatant concentration on copper lability.

In parallel, toxicity of this set of spiked sediments (with or without resin addition) was assessed by the Danio rerio embryo-larval biotest. Comparative analysis aimed at showing whether the reduction of lability (estimated from DGT) and of toxicity follow similar patterns and thus to demonstrate if DGT can be a good surrogate for predicting chelatant effects. As a final result, our study provides a tool to optimize resin quantities with respect to the sediment characteristics and to optimize TIE protocols.

### TU 075

**Optimization of accelerated solvent extraction (ASE) of wide range of endocrine disrupting chemicals (EDC) in sediment**

N Creusot[1], MH Dévier[2], JM Porcher[1], H Budzinski[2], S Aït-Aïssa[1]
[1]INERIS, VERNEUIL EN HALATTE, France
[2]ISM, LPTC, TALENCE, France

Aquatic sediments are the sink for thousands of chemical pollutants. Among them, EDCs encompass a wide diversity of chemical classes from natural and anthropogenic origins, acting on various signaling pathways, and the use of in vitro bioassays is now widely accepted as an integrative method for their detection in complex samples. However, the diversity of EDC chemical properties makes difficult their common extraction and validation of extraction method for bioanalysis is still weakly documented. Hence, the aim of this study was to optimize and validate a method allowing a rapid and efficient extraction of a broad range of active chemicals.

A mixture of 12 EDCs (i.e. estrone, 17β-estradiol, bisphenol A, o,pDDT, 4-tert-octylphenol, fenofibrate, triphenyl phosphate, clotrimazole, PCB-126, 2,3,7,8 TCDD, Benzo[k]fluoranthene and dibenzo[a,h]anthracene) with wide range of polarity (2<logKow<8) at known active equipotent concentrations was used to spike a blank sediment. These chemicals are ligands of estrogen receptor (ER), Pregnane X receptor (PXR) or Aryl hydrocarbon Receptor (AhR). Several extraction solvents (acetone, methanol, dichloromethane, heptane, dichloromethane/acetone (50:50, v/v), dichloromethane/methanol (50:50, v/v), heptane/acetone (50:50, v/v), heptane/methanol (50:50, v/v)) were compared and chemical recoveries were determined on the basis of

both biological and chemical analyses. The same approach was applied to a natural sediment for native EDCs including polycyclic aromatic hydrocarbons, polychlorobiphenyls, organochlorides pesticides, alkylphenols, pharmaceuticals, steroids and more polar pesticides.
In spiked blank sediment, bioassay-based recoveries showed that mixtures such as DCM/MeOH or Heptane/MeOH yielded the best rates (> 80 %) whereas the heptane was the less efficient (50-60 %). First results obtained with chemical analyses were in accordance with bioassay data. Finally, similar results were obtained in natural sediment.
In conclusion, this study reports a comprehensive assessment of extraction conditions before application in different in vitro bioassays, which has been rarely studied. Although there was no marked differences between extraction solvant, mixture of polar and non-polar solvent were shown to offer the best extraction of a wide range of active EDCs.

[10]University Bordeaux 1, UMR CNRS 5805 EPOC, LPTC group,, TALENCE, France
Aquatic sediments are well known sinks for numerous persitent pollutants such as POPs and heavy
metals. Pollutants accumulated in sediments can be partially bioavailable and may represent a threat
for aquatic ecosystems.
In order to study time-course of pollution in the Seine estuary and also toxicity of accumulated pollutants in bottom sediments, a 110 cm-depth sediment core was sampled in the Seine estuary in a
disused dock in Rouen harbor in april 2008 (Rhapsodis project). The core was splited in twenty 5 cmthick
slices which were analyzed for size grain, organic carbon, sulfurs, metals (13 elements), PAHs and persitent organic pollutants (PBDEs, OCPs, PCBs). Toxicity of sediment organic extracts was
measured by using a large panel of in vitro toxicity assay: Microtox®, ER and DR-Calux®, SOS Chromotest and AChE inhbtion assay.
For all analyzed chemicals except Be, Mo and Cd a clear increase of pollutant concentrations was observed with depth. Strinkingly, peak of concentration for various polluants (PCBs, PAHs, sulfured
PAHs, OCPs, Hg and Pb) was observed at 92.5cm depth. All sediment extracts exhibited high toxic
potency. Acute toxicity (Microtox®) was shown to increase with depth. DR-Calux® activity (dioxine-like
activity) was also increasing with depth while ER-Calux® activity related to estrogen-like compounds
was globally low. AChE inhibition activity and genotoxicity (SOS-Chromotest) were mainly measured
in surface and sub-surface sediments.
This study brings first evidences of global pollution decline in the Seine estuary during the last three or
four decades notably for heavy metals, PCBs, OCPs and PAHs. It also highlighted the high toxic potency of accumulated pollutants and putative risk they could represent for aquatic organisms living
in the Seine estuary.
This study was supported by the Seine-Aval program.

**TU 077**
**Genotoxicity of sediments from river Bosna**
A Marjanovic[1], J Djedjibegovic[1], M Sober[1], K Sinanovic[1], M Grung[2], C Harman[2], E Fjeld[2], S Rognerud[2], SB Ranneklev[2], T Larssen[2]
[1]Faculty of Pharmacy, University of Sarajevo, SARAJEVO, Bosnia-Herzegovina
[2]Norwegian Institute for Water Research (NIVA), OSLO, Norway
Among others toxic effects that can posses persistent organic pollutants, for the certain PAHs is well documented their mutagenicity and genotoxicity. In this study we have investigated genotoxic potential of river sediment as risk indicator, primarly for aquatic ecosystem. Having this in mind according to previously performed analysis, repeated sampling of sediment in River Bosna from heavily contaminated and reference site was performed. Genotoxicity was determined by use of the Cytokinesis blocked micronucleus assay (CBMN), method developed by Fenech and co-workers, with and without metabolic activation with S9 microsomal fraction. This technique consists in adding to cell cultures cytochalasin-B (Cyt-B), an inhibitor of the mitotic spindle that prevents cytokinesis. As a consequence, cells that have completed one nuclear division are identified by their binucleated appearance. It is a very sensitive and simple indicator of chromosome damage, which also provides information on cell cycle progression, it is less time-consuming in respect to chromosomal aberrations and slides scoring is relatively easy.
Genotoxic evaluation with in vitro CBMN assay of investigated river sediments shows presence of substances with clastogenic/aneugenic potential. Sediment from the reference site shows direct clastogenic activity, while heavily polluted sediment have dose-dependent clastogenic activity after metabolic activation. According to clastogenic profile of sediment from heavily polluted site it can be concluded that this activity is caused by PAHs present in sample. For the reference site it can be concluded that clastogenic activity is only partly due the PAHs present in the sample, and that there are obviously other substances with direct genotoxic potential. Minimal clastogenic concentration (MCC) of sediment from the polluted site was 10 fold higher than the MCC for the reference site, which correlates with concentrations of PAHs previously determined.
Our results pointed on significant clastogenic/aneugenic activity of sediments from River Bosna, which indicates chronic hazard for aquatic organisms. Risk for human health by consumption of contaminated fish can be assumed, but for the risk assessment additional separate studies should be performed.

**TU 078**
**Effect-directed analysis of potentially genotoxic compounds in sediments collected from Laguna Lake (The Philippines) using the Ames Fluctuation assay**
M Macherey[1], T Schulze[2], G Streck[2], W Brack[2], K Bluhm[1], AV Hallare[3], H Hollert[1]
[1]RWTH Aachen University, AACHEN, Germany
[2]Helmholtz Centre for Environmental Research (UFZ), LEIPZIG, Germany
[3]University of the Philippines, MANILA, Philippines
Waters from lakes and rivers, which are being used in irrigation activities and as potential sources for drinking water, are repositories for many hazardous chemicals. Even more alarming are the sediments beneath the waters which possess high potential to accumulate contaminants that have damaging impacts on human health and ecosystems. Previous studies also reported that Laguna Lake, one of the largest aquatic resources in the Philippines, is under stress as a result of excessive pollution. The presence of high levels of perylene and other polycyclic aromatic hydrocarbons (PAHs) could be identified as potential carcinogens, inducing frameshift mutations. Addition of liver homogenates (S9) can induce mutagenicity by metabolic activation of several PAH´s. The objectives of the study were (1) to assess the mutagenic potential of sediment extracts from Laguna Lake using the Ames fluctuation assay and (2) to identify the bioactive fractions and compound groups that are responsible for the observed genotoxic responses using the strategy of Effect directed analysis (EDA). Samples from Central Bay and East Bay were investigated. Central Bay may contain effluents from highly industrialized metro Manila, whereas East Bay is mainly surrounded by agricultural areas. For an efficient evaluation of sediment toxicity, a fractionation of the complex sediment extracts of both sampling sites was accomplished using a recently developed multicolumn HPLC technique and each fraction was tested in three replicates.
Results of all fractions measured from Central Bay with TA 98 and activation by S9 detected the highest induction in fraction 14 with an induction factor (IF) of 2.0. Without S9 supplementation, the highest induction factor was found in fraction 1 with an IF of 4.6. Results obtained with the tester strain TA 100 and supplementation of S9 revealed an IFmax of 2.08 in fraction 13. In the absence of S9, inductions were found in fractions 1, 11 and 15 with induction factors between 1.64 and 2.23. The sample from East Bay showed the highest induction in fraction 12 with an induction factor of 2.78 when using TA 100 and S9 supplementation. Without activation by S9, inductions were found in fractions 4, 11 and 12 with a range of induction factors between 1.97 and 2.38. Investigations with TA 98 and metabolic activation revealed maximal induction in fraction 3 with an IF of 2.78. Without S9 supplementation, the highest induction factor was detected in fraction 8.

**TU 079**
**Application of the transthyretin binding assay in effect-directed analysis of sediments: identification of thyroid hormone disrupting compounds**
MH Lamoree[1], T Hamers[1], E Simon[1], P Leonards[1], J Weiss[2]
[1]Institute for Environmental Studies, VU University, AMSTERDAM, The Netherlands
[2]Joint Research Centre - European Commission, ISPRA, Italy
In Effect-Directed Analysis (EDA) studies, various bioassays have been implemented that have an endpoint related to endocrine disruption, with the emphasis on estrogenic and androgenic effects. To extend the scope of EDA, we have used the radioligand T4*-TTR binding assay (shortly, TTR assay) to determine the thyroid hormone like (TH-like) activity to direct our fractionation for the identification of unknown thyroid hormone disrupting environmental contaminants. From a human and animal health perspective, the thyroid function is vital for the normal development of the central nervous system of the fetus.
To assess what classes of environmental toxicants are capable of interfering with the thyroid hormone system, an inventory of the different classes of compounds with reported TH-like activities was made. Compounds that are known to influence the thyroid system are, among others, hydroxylated polybrominated diphenyl ethers, hydroxylated polychlorinated biphenyls and triclosan. More recently, also polyfluorinated compounds were shown to have moderate TH-like activities.
In the framework of the EU funded Modelkey project we have carried out EDA studies at several locations connected with European river systems using a variety of bioassays. Sediment extracts were fractionated using sequential reversed and normal phase liquid chromatography.
In the course of this project, we identified several different classes of environmental toxicants in fractions of the responsive sediment extracts, by conventional gas chromatography coupled with mass spectrometric detection as well as liquid chromatography coupled with high resolution mass spectrometry. A selection of these compounds was tested in the TTR assay in order to assess whether they were responsible for the observed TH-like activity in the fractions of the sediment extracts.

**TU 080**
**Biochemical biomarkers applied on benthic species with different feeding strategies: Improvements in a weight-of-evidence approach for sediment quality assessment**
GV Aguirre-Martínez, J Ramos-Gómez, ML Martín-Díaz, TA del Valls
University of Cádiz, CÁDIZ, Spain
Weight of evidence approach for sediment and dredged material quality assessment provides more complete knowledge, which facilitates decision making. Suitability of biochemical biomarkers measured in species with different feeding strategies as potential line of evidence was studied. Sediment pollution of Cádiz Bay (SW Spain) and Algeciras Bay (S Spain) was assessed. Lipid peroxidation, DNA strand breaks and activities of biotransformation and antioxidant enzymes were analyzed as health status indicators in Arenicola marina (deposit feeder), Ruditapes decussatus (filter feeder) and Carcinus maenas (predator) after a field assay based on organism caging and transplantation. Sediment metals and PAHs significantly ($p < 0.05$) induced biomakers compared with day 0 mostly in organisms caged at Saladillo dock (Algeciras Bay), but chemicals only provoked significant ($p < 0.05$) lipid peroxidation increase in crab tissues. Sediment metals, especially Ni, caused antioxidant enzyme significant ($p < 0.05$) induction regarding day 0 in lugworms and clams from rivers Guadarranque and Palmones (Algeciras Bay) and lipid peroxidation significant ($p < 0.05$) increase only in clams from these sites. Most biomarkers measured in Cádiz Bay and Algeciras Bay caged organisms, including lipid peroxidation and DNA damage, were not associated with contaminants analyzed in this research, what suggested the presence of other xenobiotics in the environment, presumably lipophilic, which provoked severe alterations in the exposed animals. A WOE approach which includes multi-specie biochemical biomarker measures allows a more comprehensive sediment quality assessment covering a wider range of biota sensitivities and offers more thorough information for ecological risk evaluations

**TU 081**

**Optimization of the SPE step in the analysis of β-blockers and β-andenomimetics in natural water samples by SPE-GC technique**

ME Caban, A Michalak, M Czerwicka, N Migowska, M Kwiatkowski, P Stepnowski, J Kumirska
Univesiti of Gdansk, GDANSK, Poland

Environmental water sample matrices, especially sewage and marine-water samples are complex and often contain interfering elements that can mask or interfere with the analysed pharmaceuticals. In this situation direct analysis these samples may not be possible. Additionally, the low concentrations in which the pharmaceuticals are generally found cause that an initial stage of concentration and purification of the analytes prior to their analysis is necessary. The solid phase extraction (SPE) is the most common sample preparation technique used in environmental areas. Choice of sorbent is a crucial in SPE because it can control such parameters as selectivity, affinity and capacity. This choice depends strongly not only on the target analytes and the interactions of the chosen sorbent through the functional groups of the analytes, but also on the kind of sample matrix and its interactions with both the sorbent and the analytes. This work describes the application of the different kinds of SPE sorbents: C18 bonded silica gel (Strata C18), copolymers (Oasis HLB, Strata X, and Lichrolut EN), functionalized copolymers (Isolute ENV+), mixed-mode ion-exchange (Strata C-X, Oasis MCX) and a three-function sorbent (Strata Screen C) for extraction of six β-blockers (acebutolol, atenolol, metoprolol, nadolol, propranolol, pindolol,) and two β-adrenomimetics (terbutaline, salbutamol) from natural water samples. Parameters such as pH of the loading samples, the amount and the kind of solvents used in conditioning, washing and eluting steps, were selected and optimized. The obtained extracts were evaporated to dryness, subjected to silylation using BSTFA, and finally analysed by GC-FID technique. The recovery of the analytes form natural water samples in the mentioned above SPE conditions will be discussed.

**TU 082**

**Mutistep fractionation based on normal phase SPE and reverse phase HPLC (RP-HPLC) for isolation of endocrine disrupting chemicals in environmental extracts**

N Creusot[1], JM Porcher[1], H Budzinski[2], S Aït-Aïssa[1]
[1]INERIS, VERNEUIL EN HALATTE, France
[2]ISM, LPTC, TALENCE, France

Effected Directed Analysis (EDA) approach aims to identify adverse pollutants by reducing the complexity of environmental matrices. Single hyperfractionation combined to bioassays is usefull to isolate known active chemicals and to direct chemical analyses to these "classical"pollutants. However, although the emergence of promising chemical tools (e.g. Orbitrap®), identification of unknown active chemicals is still time and cost consuming due to the complexity of each active fraction (e.g. mixture effect). Hence, further fractionation steps are often needed. The aims of this study was to develop and to test the use of a first pre-fractionation step on SPE that will be followed by a RP-HPLC fractionation. First the separation of 12 EDCs have been evaluated with several elution conditions. Silica cartridges with 4 step elution - heptane, heptane/dichloromethane (50/50, v/v), ethyl-acetate and methanol/water (50/50, v/v) - allowing the best and reproductible isolation of chemicals, have been chosen for further investigations. For these conditions, recoveries were assessed for the mixture alone and for a blank sediment extract spiked with this mixture. Finally, a natural sediment known to exert estrogenic, PXR-like, anti-androgenic and dioxin-like activity was fractionated following these conditions. Good mixture recoveries (74-110 %), were obtained. The fractionation F1 contained only the PCBs and the PAHs, while 4-tert-octylphenol, triphenyl phosphate and fenofibrate were detected only in F2. Finally, steroids, bisphenol A and clotrimazole were found in F3 while F4 contained more polar chemicals.

Fractionation on natural sediment allows isolation of TCDD-like activity in F1 and F2 while PAH like activity was detected in F1, F2 and in F3. Then estrogenic compounds were only detected in F2 and F3. Interestingly, the sum of the estrogenic activity found in these 2 fractions is higher than the activity found in the crude extract, sugggesting the occurrence of anti-estrogenic chemicals. Finally, PXR-like activity was mainly detected in F3.

this pre-fractionation protocol allows, in the present case study, the isolation of several biological activities. Based on this first isolation directed hyperfractionation has then been undergone, RP-HPLC hyperfractionation on C18 has been calibrated for the separation of 35 EDCs with broad range of chemical properties and will be readly used for the isolation of active chemicals in the polar and semi-polar pre-fractions.

[3]Linköping University - Clinical and Experimental Medicine, LINKÖPING, Sweden
[4]Environmental Institute, KOŠ, Slovak Republic

The identification of unknown compounds in environmental samples isolated during non-target screening or effect-directed analysis (EDA) is often a challenge on the way to the successful outcome of theses studies. Gas chromatography - electron ionisation mass spectrometry (GC-EI-MS) is frequently used to generate mass spectra due to its potential to produce many fragments and therefore unique and/or easily identifiable spectra. This technique is commonly used and a lot of commercial and a few free mass spectra libraries are available to support identification. The advancement of database search strategies and publishing of online databases has improved tentative identification of many compounds in recent years, but many chemicals and their transformation products are still not included in such databases.

Improvements in the analytical technology and tools such as accurate and multidimensional mass spectrometry (e.g. QToF-MS, ToF-MS, FTICR, Orbitrap) in combination with liquid chromatography and soft ionisation techniques such as electro spray ionisation (ESI) and atmospheric pressure chemical ionisation (APCI) allow the analysis of a broad range of compounds including polar one (or polar substances) and the restriction of the elemental composition in many cases to one or few formulae. However databases containing accurate mass spectra generally contain relatively few spectra and are not yet widely used, as many compounds relevant in environmental samples are still absent from these databases. One obstacle is the comparability of mass spectra generated with different settings, ionisation and spectrometric techniques due to increased instrument specificity, compared with the relatively reproducible EI-MS spectra.

Our aim is to improve the identification of unknowns in environmental samples using a common and open access mass spectra database including MS data from all instrument types and with sophisticated data evaluation tools. The web-based database MassBank [1] was developed within a metabolomics consortium [2] and is a possible tool to achieve this target The database is free and allows the storage of a wide variety of spectra including EI-MS, ESI-QToF-MSMS and ESI-FTI-CR-MS. Different tools are available to process the raw data and upload the data to MassBank including a spreadsheet based record editor for the addition of metadata.

[3]Ben Gurion University of the Negev, BEER SHEVA, Israel
[4]Biodetection Systems, AMSTERDAM, The Netherlands

To ensure safe drinking water it is critical to have a reliable toxicity monitoring system. Although there are several chemical and biological detection methods, there is no suitable system yet for the real-time monitoring of toxicants in water, taking endpoints into account with human relevance. This gap may be partly bridged by a sensor that applies genetically modified bacteria that respond to specific groups of toxicants by emitting luminescence. These bacteria carry a plasmid with a promoter-gene that is known to be activated in case of exposure to certain types of toxicants, for example DNA damaging agents or heavy metals. This promoter gene is coupled to a luminescence gene-set, so that luciferase is formed when the promoter is activated. The resulting production of light can then be detected and used as a measure of the toxic stress the bacteria were exposed to.

A new prototype of a flow-through sensor for on-line water monitoring based on these modified bacteria is being developed at KWR. The bacteria are fixed on an optic fiber or a glass slide and placed in a continuous water flow. The light generated by the bacteria is then measured by photomultiplier tubes. The current prototype is highly adjustable and allows control of pH, temperature, flow, and pressure. Additionally, it is possible to add nutrients as well as test compounds to the water. This sensor prototype is being tested in both the laboratory and at monitoring stations along Dutch rivers. The ultimate aim is to develop a sensor that measures several types of toxicity and that can be applied continuously in the field, both at surface water inlets and in the distribution network.

**Toxicity of coastal waters: use of a quick algal bioassay**

SB Sjollema[1], P Booij[2], H van der Geest[1], R Laane[1], P Leonards[2], M Lamoree[2], W Admiraal[1], D Vethaak[2], P de Voogt[1]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]Institute for Environmental Studies (IVM), VU University, AMSTERDAM, The Netherlands

Primary production by microalgae embodies the carrying capacity of marine ecosystems and is primarily linked to nutrient availability and light. However, recent studies indicate that certain industrial chemicals may have a direct impact on coastal plankton communities and hence on the carrying capacity of estuarine and marine ecosystems. At the same time the frequency and intensity of toxic algal blooms in the coastal zone are increasing globally, resulting in increased levels of toxins prospected to affect coastal ecosystems. These different chemical stressors are hypothesized to disturb regulatory mechanisms within algal communities, modifying the competitive abilities of individual species and resulting in shifts from highly nutritious to unfavourable algal species that destabilize the food chain. It remains however difficult to quantify the toxic effects of these chemicals: the relative contribution of anthropogenic and natural chemicals on the total chemical pressure is unknown. Also insight in the potential synergistic action of toxicants and toxins is lacking, while in the field many confounding factors (e.g. changing nutrient and light regimes) may mask effects.

The first step to unravel the complex interaction between algae and toxic pressure is to provide knowledge on chemical compounds causing phytotoxic effects. In this study we use passive samplers which extract the freely dissolved concentration in the water during a period of 6 weeks to take episodic events into account. The concentrated extracts are tested in an algal bioassay with different marine algal species (e.g. Dunaliella tertiolecta, Phaeodactylum tricornutum) to include differences in algal sensitivity. Use of Pulse Amplified Modulation (PAM) fluorometry provides a quick (4.5h) method to determine toxicity to algae based on changes in photosynthetic efficiency. An Effect Directed Analysis (EDA) will be performed to unravel which chemical compounds are responsible for the toxic effect on the algae. In 2010-2011 passive samplers are exposed at Hansweert (Westerscheldt, The Netherlands) and collected every 6 weeks to include the seasonal dynamics of both anthropogenic as well as natural compounds. Here, first results of this sampling campaign are presented and discussed. The results of the EDA analysis will be used in experiments where mixture toxicity, multi stress and community effects are taken into account to describe the overall toxic effect under relevant field conditions.

**TU 086**

**Dissolved and intracellular microcystins in lake waters during a Planktothrix rubescens algal bloom: HPLC quantification and crustacean acute toxicity test**

L Guzzella, L Ghislanzoni, F Pozzoni, D Copetti
CNR-IRSA, BRUGHERIO, Italy

Microcystins, highly toxic cyclic peptides, are a group of hepatotoxins produced by a number of aquatic species of cyanobacteria, such as Microcystis, Anabaena and Planktothrix. Worldwide contamination in water has prompted the development of detection methods for their identification and quantification. A massive seasonal development of Planktothrix rubescens in a reservoir destined for crop irrigation located in Southern Italy has lead to quantify algal toxin content in the lake water to verify the possible health risk. Microcystins dissolved into the water were separated from intracellular ones by filtering raw samples. Filters were extracted by methanol/water solutions after frozen/defrozen treatment over night. Water samples were concentrated and extracted by SPE-C18 cartridges. Toxin content was detected and quantified using high performance liquid chromatography (HPLC-DAD). The only microcystin detected was [d-Asp3] microcystin-RR. It was identified by retention time and spectrum comparing with a certified standard. Quantification was made by means of a calibration curve obtained at 238 nm. Microcystin extracellular concentration was never above the WHO limits for drinking waters (1 μg/L). Maximum level as dissolved microcystin was 0.7 μg/L on April 2009 sample. In the same sample the highest endocellular concentration (30.8 μg/L) of [d-Asp3] microcystin-RR was measured. As predictable, endocellular toxin was 90-95% of the total microcystin content; the endocellular content ranged from 10 to 40 times greater that the dissolved content. Probably it depends on the physiological state of the alga; for example the extracellular content of microcystin is different, if the samples are collected from a fresh or aged population of P. rubescens; the lysis of dead cells can release endocellular toxins into water environment. Acute toxicity tests (24 h exposure) with Thamnocephalus platyurus were carried on using endocellular and extracellular water extracts. Only the endocellular extract, 10 times concentrated, obtained from April 2009 sample, showed a measurable inhibition (12.5%); it means that the acute toxicity effects on T. platyurus appeared starting from a concentration of about 300 μg/L of [d-Asp3] microcystin-RR. The 24 h dose-response curve showed that the EC50 of desmetyl-microcystin-RR to T. platyurus was 845 μg/L. Comparing with literature results, this microcystin is less toxic than microcystin-LR, but 3 times more toxic than microcystin-RR.

**Integrating biological indicators and geochemical markers to evaluate contamination in an organic matter enriched area on South Brazilian coastline**

CC Martins, L Hadlich, AM Barboza, C Lana
Universidade Federal do Paraná, PONTAL DO PARANÁ, Brazil

Paranaguá Bay (S Brazil) is one of the largest and best preserved estuarine complexes along the western South Atlantic. It houses approximately 19% of the Brazilian Atlantic forest remnants and was considered a biosphere reserve by UNESCO in 1995. The city of Paranaguá has approximately 140,000 inhabitants and one of the largest harbours of the South Atlantic. More than two thirds of local domestic sewage is discharged into the estuary without any treatment. The contamination associated with the input of heavy metals, hydrocarbons, sewage and the development of anoxic conditions may lead to changes in macrofaunal associations. In order to find reliable biological proxies of contamination levels, we evaluated the composition and abundance of local polychaete assemblages. Sediment samples were collected by SCUBA diving at 11 stations around Paranagua in a grid spaced up to 2 km from the main contamination sources. Nutrients, fecal sterols, hydrocarbons and metals were analyzed in the surface sediment layer. A PCA analysis showed that the stations adjacent to the city and the Port of Paranaguá are in fact characterized by high concentrations of nutrients (P, N, TOC), metals, fecal sterols and PAHs. The total density and species number of polychaete assemblages were significantly lower ($p < 0.001$) at stations closer to the harbour and sewage discharge points, Most of the differences reflected the low polychaete abundance and diversity in two hypoxic stations, with high concentrations of total PAHs (3786 $ng.g^{-1}$), metals, nutrients and coprostanol (16 $ug.g^{-1}$). Occurrence patterns of the species *Magelona papilicornis*, *Glycinde multidens*, *Chaetozone sp.*, *Capitella sp.*, *Aricidea taylori* and *Poecilochaetus australis* differed significantly among stations. This set of species can be used as early indicators of organically enriched areas.

**TU 088**

**Assement of contamination of watershed for waste produced by the rice fields**

HL Soares, E Baptista
Universidade Federal de Santa Catarina, FLORIANOPOLIS, Brazil

The southern region of Brazil is dominated by wetlands, which are attractive ecosystems for irrigated rice production. This type of farming is generally practiced in the vicinity of water sources, and requires intensive use of chemical inputs resulting in serious risk of water contamination. For these studies three sites were chosen along the Cachoeira do Sul river (nº 2, 3 and 4), from which water is pumped for the management of the rice fields. In order to define a possible site to be used as a reference, without contamination, another sampling site(7) was chosen on the basis of its clear water, without the turbidity found at the other sites. The samples were collected in November 2008, during the rice cultivation period and therefore during the application of pesticides to crops. The water samples were examined for toxicity using Scenedesmus subspicatus (microalga) and Daphnia magna (Microcrustacean) as bioindicators. The tests with the microalgae showed that the sample of water coming from the tables of the rice field (site 1) and the sample from the Rio Cachoeira do Sul (site 4) in direct contact with rice cultivation, exhibited the highest growth inhibition rates, 44% and 37% respectively. Typically, samples 2 and 3 also presented a toxic effect as indicated by the reduced algal growth rate of 31%. The control sample from the Cachoeira River showed a growth inhibition rate of 4%. Therefore, comparing the various values of the rate of inhibition for the samples, the inhibitory effect appears to be related to exposure to or contact with rice crops and the application of pesticides in connection with rice cultivation. The toxicity tests using Daphnia magna also showed that samples from sites 1, 2, 3 and 4 were associated with lower numbers of neonates and therefore the highest rates of reduction of the reproductive capacity of organisms tested.

**TU 089**

**The integration of chemical, ecotoxicological, and ecological data obtained from an extended study carried out in an industrialized area**

MA Pukalchik, VA Terekhova, TO Poputnikova, VM Vavilova, MA Kaniskin
MSU, MOSCOW, Russian Federation

The aim of the project was to study urban soil by chemical, ecotoxicological and ecological methods and to assess the environmental risk index for each soil samples. Four sites have been selected on the basis of the predicted patterns of chemicals deposition.

Soil samples were took from depths of 5-20 cm at five locations along the main industrial region of the Kirov, Russia (Latitude: 45° 5' 20 N, Longitude: 40° 16' 11 E) in May 2010. The soil samples were air-dried and sieved into coarse and fine fractions. The labile fraction of heavy metal to determine the concentration by Atomic Absorption Spectrophotometry SpectrAA-220FS (Varian, USA) by flame Atomization.

The six bioassays evaluated were 1) Crustacean Daphnia magna- acute toxicity 96-hour, 2) Higher plant Sinapis alba - seed germination, growth rough 4-day, 3) Algae (Scenedesmus quadricauda acute toxicity 72-hour, 4) Protozoan Paramecium caudatum - acute toxicity 24-hour, 5) E. coli (with gene-modified luciferase) - bioluminescence, 30-min and 6) Micromycetes Fusarium oxysporum - the rate of radial growth of colonies, 5-day.

Ecological monitoring includes measures of function and structure of different populations and communities in the soil. The composition of the microbial community was determined by molecular techniques of gas chromatography - mass spectrometry (GC-MS). Analysis was performed on GC-MS system HP-5973 Agilent Technologies (USA).

The present study show that chemical data was input principal investment to assessed EnvRI. The battery of toxicity tests and ecological monitoring data point out the important information about the resistance soils community to heavy metal pollution. The greatest sensitivity of structure microbial community to pollution was shown by the ecological monitoring. Bioluminescent bacteria E. coli and micromycete F.oxysporum were found as the most sensitive test-species to HM polluted.

Estimation of ecological risk have been proposed follows the Triad approach and integrates data by computing different indexes which contribute to the final estimation of the EnvRI (Environmental Risk Index). The highest weight is assigned to parameters describing the effects at population-community level. An intermediate weight is applied to bioassays, measuring ecotoxicological effects at organism level and to data which describe bioavailability of pollutants. The lowest weight in EnvRI computation is assigned to ChemRI.

**TU 090**

**Multi-biomarker approach to investigate the state of contamination of the R. Lambro / R. Po Confluence (Italy)**

A Binelli, D Cogni, M Parolini, A Provini
University of Milan, MILAN, Italy

The response of Zebra mussel (Dreissena polymorpha) to chemical pollution derived from the R.Lambro/R. Po confluence, one of the most polluted European aquatic environments, was assessed by using a wide battery composed by eight different biomarkers: the single cell gel electrophoresis (SCGE) assay, the apoptotic cell determination, the micronucleus test and the Neutral Red retention assay (NRRT). Moreover, we measured the activity of three antioxidant enzymes: catalase (CAT), superoxide dismutase (SOD) and glutathione peroxidase (GPx), as well as the activity of the detoxifying enzyme glutathione transferase (GST). We exposed mussels at laboratory conditions to water sampled in spring and fall at three sampling sites located both upstream and downstream the confluence and directly on River Lambro. We measured each end-point every 5 days for a total time exposure of 15 days, when mussel soft tissues were also taken to evaluate the bioccumulation of several organic pollutants (PAHs, PCBs, DDTs, HCHs and HCB).

Biomarker responses revealed a heavy genotoxicity of the pollutant mixture at all the sampling stations with significant increase of DNA strand breaks, apoptosis and micronuclei with no significant seasonal differences. We obtained a clear induction of the enzyme activities measured in spring that showed the increase of oxidative stress, but also a very complex enzymatic activity trend in fall with several end-points that showed a parabolic slope that bring back the activities to baseline levels, suggesting a possible seasonal change in chemical mixture characteristics. This study confirmed the utility of a wide biomarker battery in biomonitoring studies and the suitability of Zebra mussel as bioindicator organism also for river basins.

**TU 091**

**Stage-dependent β-naphtoflavone-induced cytochrome P450 1A (CYP1A) activity in medaka (Oryzias latipes) embryos using an in vivo quantitative approach**

M González-Doncel, LS San-Segundo, SS Sastre, CF Fernández
INIA, MADRID, Spain

Worldwide continuous increase in chemical production has prompted the development of chemical management programs for a correct assessment of their risk to human health and to the environment. Examples are in the US with the US EPA HPV Challenge Program and here in the EU with the recent REACH Program. Within the environmental assessment, there is a strong current towards the development of alternatives to existing ecotoxicity tests without reducing the validity of the risk assessment. In this context the use of fish embryos and eleutheroembryos are promising alternatives. These stages also provide the application of in vivo techniques for the evaluation of biomarkers indicative of exposure/toxicity. Here, we propose original methods for a non-invasive quantification of the CYP1A activity and its stage dependent β-naphtoflavone (BNF) induction (up to 5 developmental stages were selected) over medaka (Oryzias latipes) embryonic/larval development. CYP1A activity was measured from fluorescent images from metabolite resorufin using intact embryos and at two observational levels: specific induction in gallbladder (vesica biliaris), and non-specific induction in the whole embryo. A battery of analytical procedures is also proposed to quantify BNF in small volume of aqueous samples from biological assays reaching limits of detection up to 30 ppt. This work was made possible by Spanish Government Grants RTA2010-00004-C02 and CTM2010 19779-C02

**Hormonal control of HSP70 and apoptosis in sea bream cells**

YS Woo, E Deane
The Chinese University of Hong Kong, HONG KONG, China

Evidence as to whether heat shock protein 70 (HSP70) chaperones life (stress-tolerance) or death (apoptosis) is equivocal, as HSP70 can either inhibit or promote apoptosis, depending on cell type. Underlying these observations is the tripartite relationship between hormones, HSP70 expression and apoptosis and using a range of in vitro models we have been investigating this in silver sea bream (*Sparus sarba*). Using whole blood preparations it was found that camptothecin-induced apoptosis, as determined by elevated DNA fragmentation. However, exposure of whole blood preparations to growth hormone was found to attenuate the occurrence of DNA fragmentation in parallel with increased HSP70 family gene expression. In a sea bream macrophage primary culture and a fibroblast cell line it was found that chemically induced HSP70 expression (via azetidine treatment) protected against camptothecin-mediated apoptosis, as assessed by lowered caspase 3 activity and reduced DNA fragmentation. When these cells were treated with cortisol different responses were found as macrophages were more prone to apoptosis and had decreased HSP70 amounts whereas fibroblasts were protected against camptothecin- mediated apoptosis with a concomitant increase in HSP70 levels. Also in sea bream gill cell preparations, prolactin was found to protect gill cells against camptothecin-induced apoptosis, an effect that occurred alongside increased HSP70 amounts. It appears from these data that HSP70 may play a central role in mediating apoptosis under the influence of key hormones such growth hormone, prolactin or cortisol. (This research was supported by a General Research Fund (CUHK 4783/09M) from the Research Grants Council, Hong Kong).

**Comparison of bioassays for screening dioxin-like activities in food samples**

AS Schiwy[1], TBS Seiler[1], IT Thiem[2], HH Hollert[1]
[1]RWTH Aachen University / Institute for Environmental Research Bio5, AACHEN, Germany
[2]Lower Saxony State Office for Consumer Protection and Food Safety, BRAUNSCHWEIG, Germany

In our environment we encounter a large number of hazardous substances almost on a daily basis. Knowledge about the toxicity of these substances is important to ensure human health as well as integrity of the ecosystems we live in. Polychlorinated dibenzo-para-dioxins (PCDDs or dioxins), polychlorinated dibenzofurans (PCDFs or furans) and polychlorinated biphenyls (PCBs) are highly ubiquitous toxic substances. They enter the food chain and become health hazards. This has caused the European Commission in 2001 to limit the presence of dioxins in food and feed. Strict but feasible maximum limits had been implemented at the beginning of 2002. Any food or feed exceeding these maximum limits is considered unsuitable for human consumption. Hence, monitoring of dioxin levels is of high importance and should be of primary relevance. Bioassays are a valuable pre-screening tool to investigate dioxin like activity. A newly introduced method to test food and feed is the Micro Ethoxyresorufin-O-deethylase (EROD) bioassay with H4IIe cells. The Micro EROD bioassay is an aryl hydrocarbon receptor based assay to detect the receptors interaction with dioxin-like compounds. In this study the feasibility and application characteristics of this bioassay for food testing were evaluated. A comparison with the H4IIE-Luc and RTL-W1 bioassays was conducted, and acidic column chromatography as sample clean-up methodology to gain fat free samples was characterized. Additionally, a review of alternative methods was performed. The acidic column chromatography in combination with the Micro EROD bioassay revealed to be a promising tool to pre-screen food and feed samples. It can be integrated as a pre screening technique to determine dioxin-like activity. High levels detected should then be further analyzed by instrumental analysis. Nevertheless, further investigation and modification of the Micro EROD bioassay is recommended for streamlining and improvement of the protocol to achieve a sophisticated, integrated pre-screening tool for dioxin-like activity in food and feed samples.

**TU 094**

**Changes of AhR-mediated toxicity of hydrophobic organic compounds after UV-VIS irradiation**

P Macíková[1], J Ospalík[1], M Bittner[1], JP Giesy[2], L Bláha[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]University of Saskatchewan, SASKATOON, Canada

Hydrophobic organic compounds (HOCs) were shown to cause many adverse effects in organisms. Arylhydrocarbon receptor (AhR) activation is among the frequent mechanisms of toxicity of these pollutants. They are present in all environmental matrices, thus, it is almost impossible to avoid the exposure of the organisms to this type of chemicals. HOCs can be degraded and removed from the environment by many processes, such as volatilization, adsorption to solid-phase particles, leaching, bioaccumulation, biodegradation, chemical oxidation or photooxidation. Direct photolysis of HOCs evoked by solar irradiation is a very important way of degradation in the aquatic environment. The aim of this study was to assess (i) changes of AhR-mediated toxicity of benzo[a]pyrene (B[a]P), dibenz[a,h]anthracene (DB[a,h]A), 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and a mixture of the three chemicals in the aquatic solution, and (ii) changes of concentration of each compound after UV-VIS irradiation. The chemicals were dissolved in ethanol, ethanol was evaporated under a gentle stream of nitrogen and distilled water was added. The water solutions were irradiated by a low pressure mercury lamp. AhR-mediated toxicity was assessed using *in vitro* assays based on the H4IIE-*luc* transgenic cell line. Chemical analysis of B[a]P, DB[a,h]A and TCDD was performed using GC/MS(MS). We observed a significant decrease of HOCs concentrations in samples after irradiation which corresponded well with the decrease of AhR-mediated activities of irradiated samples. Therefore, we suppose that there had not been created any AhR-active photooxidation products of HOCs. Supported by projects GACR 525/08/P464 and CETOCOEN (European Regional Development Fund no. CZ.1.05/2.1.00/01.0001).

**TU 095**

**Application of EDA to identify hydrophobicity causing compounds in olive oil mill waste waters**

N Bandow[1], GE Schaumann[2], SE Egerer[3]
[1]University Koblenz-Landau, LANDAU, Germany
[2]University Koblenz-Landau, Environmental and Soil Science, LANDAU, Germany
[3]University Bochum, Geographic Intitute, soil science/ soil ecology, BOCHUM, Germany

In the Mediterranean region waste waters as olive oil mill waste waters (OMWW) are widely applied at agriculturally used soils due to positive properties as high nutrient content. This application is often accompanied with negative effects as increasing phytotoxicity and hydrophobicity of the soils and thus, decreasing field capacity. Although several studies investigated the composition of OMWW, the compounds or class of compounds responsible for this process are still unknown. To facilitate the identification of the responsible chemicals a fractionation procedure was validated for typical OMWW substances as model compounds. The different classes of compounds as e.g. polyphenols, aliphatic hydrocarbons and carboxylic acids are separated by extraction at different pH values and the use of selective solvents. The optimised method was used to fractionate OMWW samples from Palestine. For prioritization of fractions the phytotoxicity in germination tests and hydrophobization potential using the sessile drop method was evaluated.

**TU 096**

**Eco design of environmental benign ionic lubricants: assessment of toxicity and biodegradability**

S Steudte[1], P Stepnowski[1], A Igartua[2], S Stolte[3]
[1]University of Gdansk, GDANSK, Poland
[2]Tekniker Foundation, EIBAR, Spain
[3]University of Bremen, BREMEN, Germany

The philosophy of green or sustainable chemistry is the development of high efficient technical processes and applications using chemicals with a reduced or eliminated hazard potential for man and the environment. Therefore the development of chemicals with optimised technical properties should run in parallel with the minimisation of (eco)toxicological hazard potentials. In the field of designing chemicals, ionic liquids represent an excellent model substance class. Ionic liquids are salts with melting points below 100°C or even room temperature. Their physicochemical properties like high thermal stability or low vapour pressure raised the interest of this substance class for their application as lubricants in resent years. Additional the high structural variety is an advantage of these compounds. By changing the anion or modifying the fine structure of the cation it is possible to define attributes like viscosity or density, which allows for an optimized application-related design of ionic liquids. Beside the optimization for application also the environmental impact should be considered. Therefore studies on toxicity and biodegradability have been performed for selected ionic liquids. The compounds, mainly ammonium based cations, were chosen according to structure-activity-relationships and their potential applicability as lubricants. Toxicity was tested with several model organisms varying from isolated enzymes, mammalian cells, marine bacteria and algae to higher organisms like crustacean. Data about biodegradation are discussed as well. The present study shows that the design of environmental benign ionic lubricants is- with limitations- feasible.

**TU 097**

**Prospective hazard assessment of new industrial chemicals: the case of ionic liquids as high performance lubricants**

P Stepnowski[1], S Steudte[1], M Skup[1], S Stolte[2]
[1]University of Gdansk, GDANSK, Poland
[2]University of Bremen, BREMEN, Germany

The interest in ionic liquids for their potential in different chemical processes is increasing, as they are claimed to be environmentally benign and very good non-volatile solvents for a wide range of applications. Responsible product design however should always take into consideration not only technological demands but also the risks arising out of possible (eco)toxicity. This contribution presents our strategy where technical properties of ionic liquids, potentially used as lubricants, are investigated in parallel with the examinations of (eco)toxicological hazard potentials. Toxicological studies of imidazolium, ammonium and choline based ionic liquids presented here using test systems at different level of biological complexity, such as isolated enzymes, mammalian cell lines or algae. In addition data about biodegradation and sorption of selected ionic liquids to different types of soil and marine sediment are also discussed. A set of instrumental methods for analyzing ionic liquids in environmental and biological samples is presented as well.

## EP05 - Plastic pollution - polluted plastics: Fate, effects and life cycle assessment

**TU 100**

**Distributions of marine microplastics in the Puget Sound estuary**

JE Baker[1], J Masura[1], GD Foster[2]
[1]University of Washington, TACOMA, United States of America
[2]George Mason University, FAIRFAX, VIRGINIA, United States of America

Marine microplastic debris are particles composed of plastic polymers with dimensions between 0.33 and 5 mm. Early reports of pre-production resin pellets in Northwest Atlantic waters suggested losses during manufacturing or shipping may supply plastics to the oceans. Since those initial studies in the 1970's there have been very few reports of microplastics in the oceans. Recently, we have developed standarized protocols to sample and analyze microplastic particles in surface waters, sediments, and beach sands. The goal of our study is to make the first systematic characterization of microplastics in the Puget Sound estuary. Nets with 0.33 mm mesh size were towed horizontally through surface waters using standard plankton sampling conditions and tow durations in several locations throughout the Puget Sound, ranging from highly urbanized, stormwater-dominated embayments to relatively unimpacted open waters. Samples were oxidized with hydrogen peroxide to remove marine carbon. Samples from nearshore that contained more recalitrant terrestrial carbon were oxidized with a sulfuric acid/potassium dichromate solution. After oxidation, inorganic solids were separated from the plastic by density gradient and the remaining solids were isolated and weighed to determine the total quantity of microplastic mass. Concentrations of solid material collected from Puget Sound surface waters in the 0.33 to 5 mm size range vary widely from 1.5 x 10-5 to 0.11 g/m3, and the geometric mean plastic content of this material is 1.8% (range 0.008 to 27% plastic). Strong temporal and spatial gradients indicate a significant source from urban stormwater.

**TU 101**

**Analysis, occurrence and aerobic biodegradation of polyethylene glycols of different molecular weights in seawater, wastewater and sludge**

P Knepper, M Bernhard, P Eubeler, S Klein
Hochschule Fresenius, IDSTEIN, Germany

The biodegradation of polymers plays an important role because polymers are used in high amounts in our daily life. Biodegradation is a major topic today in risk assessment strategies. Mostly, the focus is set on freshwater systems because in generally the direct entry of chemical substances is through these systems.

There are major differences between freshwater (WWTP activated sludge, OECD 301) tests and those in marine (synthetic and native marine water) tests. The differences span from the time of biodegradation of the same substances to differences in the biodegradation graphs of reference substances and also to differences in the metabolic pathway. The potential of biodegradation in freshwater and marine tests will be presented for the group of poly(ethylene glycols) ranging from 200 to almost 60'000 g-mol-1. Specific parameters such as molecular or structural properties of the polymers do have influence on the biodegradation in different environments such as an influence by molecular weight, number of hetero atoms in the chain, specific behavior of groups that hydrolize but do not biodegrade. Possible pathways of biodegradation have been confirmed applying different mass spectrometric (MS) methods, such as matrix assisted laser desorption ionization MS as well as electrospray MS following liquid chromatographic and size exclusion separation techniques. Beside these water soluble polymers examples of unsoluble as well as well as per se biodegradable polymers will be given. Additional methods for the determination in the aquatic environment will be presented.

**TU 102**

**Environmental and health hazards of chemicals in plastic polymers and products**

D Lithner, G Dave, Å Larsson
University of Gothenburg, GOTHENBURG, Sweden

Many of the chemicals used to produce plastic polymers and products are hazardous to human health and the environment. Considering the extensive use of plastics in society and the rapidly increasing accumulation in the environment (both the marine and terrestrial), there is a need for assessing toxicity hazards and risks. In this project the environmental and health hazards of chemicals in plastic products and polymers were investigated. One part includes a survey of the chemical composition of more than 50 different plastic polymers. A hazard ranking and hazard assessment was made based on EU (CLP) hazard classifications of the chemicals that are needed to produce the different polymers. This shows which polymers that are made of the most hazardous chemicals, and the need for substitution of polymers/and or chemicals. The other part deals with the toxicity of water leachates from plastic products to Daphnia magna. In four separate studies leachates from various plastic products, synthetic (plastic polymer) textiles, and discarded electronic products were tested. Toxicity Identification Evaluations were also made to identify which group of toxicants that was causing toxicity. Some overall conclusions are that carcinogenic, mutagenic and/or reproductive toxins (category 1) substances are used to make several of these plastic polymers. Acute toxic substances were found to be leached from several products to water even during the short term leaching period of 1-3 days. Hazardous ranking systems and toxicity testing of product leachate can be useful tools in the assessment of products.

**TU 103**

**Organochlorine pesticides in plastic pellets from Santos, southeastern coast of Brazil**

FI Colabuono, S Taniguchi, PS Dias, MGM Batista, R Oliveira, M Fisner, A Turra, MC Bícego,

RC Montone
Instituto Oceanográfico - Universidade de São Paulo, SÃO PAULO, Brazil
Hydrophobic pollutants such as organochlorine pesticides (OCPs) are adsorbed to the plastic pellets from seawater due to the hydrophobic nature of the plastic surfaces. In this study, the occurrence of OCPs was evaluated in plastic pellets sampled in 30 points on the sand surface in Santos Bay (23°58'06"S and 46°20'33"W), located close to an important industrial complex (Cubatão) and the biggest port of Latin America (Porto de Santos). Pellets (approximately 1 g) were extracted by soxhlet apparatus and the extract was cleaned up by chromatographic adsorption column with 5% deactivated alumina. Twenty-five OCPs were analyzed by gas chromatograph with electron capture detector (GC-ECD). The concentrations of OCPs found in plastic pellets were in ng $g^{-1}$: Dieldrin (<0.61 to 5.75), HCHs (<0.24 to 87.1), DDTs (12.6 to 3545), heptachlor (<0.33 to 39.6), $\gamma$-chlordane (0.47 to 121), endosulfan (<0.46 to 6.20), HCB (1.92 to 557) and mirex (0.73 to 692). OCPs concentrations in plastic pellets varied considerably (more than two orders of magnitude for some compounds) in a single site. Variability can be associated with several factors such as the residence time of the pellet in the environment. The proximity of an industrial area can contribute to the presence of contaminants (e.g. HCB) in this region. The occurrence of HCB, one of the predominant chemicals in the samples, can be associated either with improper disposal occurred in the past and/or with waste from chemicals production or with other sources far from the sampling sites. DDT showed higher concentrations than DDD and DDE in 47% of the samples, which can be attributed to a recent contamination. However, studies about DDTs contamination in several compartments of Santos ecosystem showed low concentrations of DDT and the predominance of the metabolites DDE and DDD. Therefore, plastic pellets can be mainly an important source carrying hydrophobic pollutants coming from different places and OCs concentrations found in plastic pellets may reflect not only local sources of contamination, once the pellets float on the ocean and are in contact with the pollutants along the entire transport pathway before reaching the beach.

**TU 104**

**Sorption of Bisphenol A to poly(methyl methacrylate) in aquatic environment measured by MALDI-TOF-MS**

S Klein[1], E Worch[2], TP Knepper[1]
[1]Hochschule Fresenius, IDSTEIN, Germany
[2]TU Dresden, Institut für Wasser Chemie, DRESDEN, Germany

Plastic debris is one of the most significant pollutants of the marine environment. Depending on their hydrophobic character plastics are acting as carriers for organic pollutants [1]. Thus, ingested plastic particles can play an important role in the uptake of organic pollutants by organisms [2].
For better understanding of contaminant sorption to polymers poly(methyl methacrylate) (PMMA) samples of different molecular weight distributions were exposed to synthetic fresh and salt water contaminated with Bisphenol A. All samples were measured by solvent-free matrix assisted laser desorption ionization/time of flight/mass spectrometry (MALDI-TOF-MS) to observe Bisphenol A sorption according to molecular weight of PMMA. The solvent-free sample preparation was compared to solvent based preparation with regard to the observation of Bisphenol A sorption to PMMA. With this information it is planned to investigate sorption and desorption of other relevant aquatic pollutants.

**Sorption of two antifouling compounds (Irgarol 1051 and Diuron) into plastic pellets**

PS Tourinho
University of Aveiro, AVEIRO, Portugal

Plastic pellets, the raw material for plastic objects, are commonly lost to the aquatic environment and abundantly found worldwide. In the environment, the pellets are able to retain organic contaminants through sorption process. This process is defined as the interaction between the solute and the sorbent, occurring in the sorbent's surface (adsorption) or in the sorbent's matrix (absorption). Here, the sorption process of two antifouling compounds, Irgarol 1051 and Diuron, were chosen to be analyzed, because these compounds were the main substitutes of Tributyl Tin (TBT) in antifouling paint for ships, and there are no studies concerning the sorption of these compounds into plastic pellets. Thus, the aim of this work was to assess the concomitant sorption of Irgarol 1051 and Diuron in polypropylene plastic pellets, evaluating the effects of solute concentration and water salinity. For the solute concentration test, solutions containing 10, 100 and 1000 ng.mL-1 of each compound were tested. For the salinity test, ultrapure (salinity 0) and salt water solutions (salinity 15 and 30) containing 100 ng.mL-1 of each compound were tested. The solutions were introduced to beakers and 1g of plastic pellets was added. All tests were conducted in triplicates along with a triplicate blank. After 7 days, the pellets were removed and extracted with methanol (ultrasonification). The extract was analyzed by high-performance liquid chromatographyðtandem mass spectrometry (HPLC-MS/MS). The increase of solute concentration affected significantly the sorption of both Irgarol (Kruskal-Wallis, H= 11,35, p=0,00) and Diuron (Kruskal-Wallis, H= 7,94, p=0,01). Also, the sorption of Irgarol was relatively lower than Diuron. The salinity variation affected the Irgarol sorption (ANOVA, F=40,75, p=0,00), but did not affect the Diuron sorption (ANOVA, F=1,87, p=0,24). It is known that salinity only affects superficial processes (adsorption). Thus, the present results may indicate that adsorption was the main process occurring for Irgarol 1051, while absorption was the main process occurring for Diuron. Moreover, the greater sorption of Diuron also indicates the occurrence of absorption. The sorption of Irgarol and Diuron into plastic pellets can pose an environmental risk, since the pellets are ingested by aquatic organisms and easily dispersed in aqueous media.

**Using three-dimensional solubility parameters as a screening tool for prioritizing types of plastics and pollutants most likely to lead to elevated exposure**

T Gouin, R van Egmond, C Hastie, C Sparham
Unilever, SHARNBROOK, United Kingdom

The presence of plastics in the environment has been linked with increased exposure of organisms to certain pollutants through ingestion of contaminated plastics. Here we present the use of a screening tool based on calculations of Hansen solubility parameters for a wide range of common plastics and pollutants of environmental relevance. Results suggest that non-polar organic chemicals with log $K_{OW}$ > 5.5 have the potential to have significant sorption capacity to plastic polymers, such as polyethylene and polypropylene. These observations are supported by the use of Hansen solubility parameters, which indicate that non-polar organic chemicals have a greater potential for dissolution in polyethylene, than do polar organic chemicals. Surface interactions for polyethylene and polypropylene are characterised by van der Waals interactions, which help explain the strong dissolution capacity of these polymers for non-polar organic chemicals. Plastic polymers with hydrogen-bonding capacity and polar functional groups, however, have lower sorption capacity for non-polar organics, but may represent sources/sinks of polar organic chemicals. Understanding the interactions between PBT substances and different types of plastic material in the environment, and their relative abundance, is thus an important component towards quantifying potential exposure pathways.

**TU 107**

**Inventory of the presence of plastics in the digestive track of North Sea fishes**

EM Foekema[1], MT Mergia[1], M Kotterman[1], JA van Franeker[1], AJ Murk[2], AA Koelman[2]
[1]IMARES, DEN HELDER, The Netherlands
[2]Wageningen University, WAGENINGEN, The Netherlands

Plastic debris can be found in seas and oceans all over the world and ingestion of smaller plastic parts by marine birds, turtles and mammals has been reported by various researchers. As far as we are aware of, an inventory of the presence of plastics in the digestive track of North Sea fishes has never been made. In 2010, IMARES started such an inventory using fish samples from various positions in the North Sea.
After being measured and weighted, the complete content of the digestive system of each individual fish was collected. The organic matter was chemically digested and the remaining material was searched for any plastics by stereo microscope. This method allows the detection of even very small plastic particles. When drafting this abstract small plastic fragments have been found in 1% of 500 individual Herrings from the Northern North Sea that were processed. Other species like Mackerel, Grey gurnard and Hake were sampled in smaller numbers (45-170 individuals) without plastics being found. Samples of Horse-mackerel and Whiting have been collected and other species and locations are planned to be sampled the coming months. Plastics found in these species (if in significant amounts), plastics retrieved from stomach content from Northern fulmars and plastics collected during surveys with bottom trawling in the North Sea will be chemically analysed by GC-GC-MS. Comparing contaminant levels and profiles also with sediment and fish data, gives a first insight in the importance of plastic debris as carrier of organic contaminants in the North Sea.

**Influence of ingested micro-plastics on the bioaccumulation of organic substances in fish - a model approach**

C Ehling, C Zarfl, J Klasmeier, M Matthies
Institute of Environmental Systems Research, OSNABRÜCK, Germany

Marine waters are polluted with plastic litter, which can cause severe adverse health problems for marine organisms when they are taken up through ingestion or filter feeding. They can contain organic substances ad-/absorbed from surrounding water body or as additives, which might pose an additional chemical risk due to bioaccumulation in the marine food chain [1]. Of particular concern are small particles of less than 1 mm in diameter (micro-plastics), which were recently found in mussels and other organisms [2]. A simple equilibrium model predicts lower bioaccumulation for lipophilic compounds if plastics material is added as separate compartment. To enable a more realistic consideration of the effect of ingested plastics on bioaccumulation in fish, we developed a dynamic bioaccumulation model to investigate the influence of ingested micro-plastics on the bioaccumulation in fish.
We modified the dynamic Gobas fugacity model [3] taken from the well-acknowledged bioaccumulation model ACC-Human [4] which describes the bioaccumulation of pollutants by baltic herring growing from birth to the age of 5 years. To model the influence of plastic ingestion on bioaccumulation of organic substances additional assumptions were made:
i) In addition to plankton herring ingests micro-plastics. Ingested plastics material is completely excreted such that there is no plastic accumulation.
ii) Micro-plastics and the fish at birth are in equilibrium with the surrounding water. Within the gastrointestinal tract plankton and micro-plastics are homogeneously mixed.
iii) It is assumed that ingested micro-plastics consist of low-density polyethylene. The fugacity capacity of micro-plastics is determined by the content of organic carbon.
The additional body burden due to ingestion of organic pollutants with micro-plastics depends on the substance properties. For compounds with fast metabolic transformation ingestion of plastics increases pollutant accumulation, while for persistent compounds it decreases the mean body burden. This study provides first insights into how ingested micro-plastics may influence the bioaccumulation of aquatic organisms.

**Polyethylene microplastics select for 'plastiphilic' bacterial assemblages in coastal marine sediments**

P Harrison[1], M Sapp[2], M Schratzberger[2], AM Osborn[3]
[1]The University of Sheffield, SHEFFIELD, United Kingdom
[2]The Centre for Environment, Fisheries and Aquaculture Science, LOWESTOFT, United Kingdom
[3]Department of Biological Sciences, University of Hull, KINGSTON-UPON-HULL, United Kingdom

Synthetic plastics constitute the majority of anthropogenic debris in the Earth's oceans. Recently, microplastics (fragments of ≤ 5 mm) have been highlighted as emerging pollutants in coastal sediments. Despite the potential for this debris to impact upon macrobiota, our understanding of the interactions between microplastics and microorganisms is negligible. This study initiates characterisation of the ecological interactions between bacteria and microplastics within coastal sediments. Specifically, this research aims to determine whether and how rapidly sediment bacteria colonise microplastic pollutants and to investigate the structure, diversity and successional dynamics of plastic-associated bacterial assemblages over time and across different types of sediment.
Fourteen-day laboratory microcosms were established using sandy and silty sediments from three sites within the Humber Estuary (United Kingdom). The microcosms were spiked with polyethylene as a model plastic. Changes in the structure and diversity of bacterial assemblages at the plastic-sediment interphase and within sediments were investigated by terminal restriction

fragment length polymorphism and sequencing analyses of 16S ribosomal RNA genes. Plastic-associated bacterial assemblages formed in all sediment types with the onset of colonisation varying from six to 48 hours. The plastic-associated bacterial communities were distinct from those in sediments (ANOSIM $R = 0.5$, $P < 0.001$). Successional changes occurred in the structure of the plastic-associated bacterial communities, with increasing convergence in the structure of these communities across different types of sediment. Epsilon- and gamma-proteobacteria were identified as dominant classes within the plastic-associated bacterial communities. Whilst temporal variability in the structure of the sediment bacterial communities was found, convergence of these communities between sediment types was not observed.
This study provides the first evidence for the potential for rapid bacterial colonisation of microplastics in marine sediments and for the formation of microplastic-associated bacterial assemblages whose composition differs from those in bulk sediments. The results also provide insight into the existence of 'plastiphilic' bacterial taxa that may become selected for in the presence of plastic across several types of sediment. These findings have opened an avenue for microbial research into the ecological impacts of microplastics.

**TU 110**
**Environmental impact of treatment processes for plastics and composites at the end-of-life vehicles in Spain**
C Muñoz[1], EM Moliner[1], DG Garraín[1], VF Franco[1], RV Vidal[1], DJ Justel[2]
[1]Universitat Jaume I, CASTELLÓN, Spain
[2]Departamento de Mecánica y Producción Industrial, EPS Mondragón, MONDRAGÓN, Spain
From an environmental perspective, the automotive sector is currently faced with two major challenges:
- Reduce the energy demand.
- Reduce the amount of waste generated.

Reducing the vehicles' weight -among other factors- will reduce the energy demand. In this sense and in a similar way as has happened in other transport sectors, the increased use of lighter materials such as plastics, composites and light alloys is postulated as part of the solution.
In order to meet the second challenge -reducing the amount of waste- Directive 2000/53/EC on end-of life vehicles states that no later than 1 January 2015, the reuse and recovery shall be increased to a minimum of 95% by an average weight per vehicle and year, for all the end-of-life vehicles. Directive 2000/53/EC focuses on the reduction of waste dumped into landfills, but expresses no limits on the emission levels of the treatments applied to achieve this objective.
In this work, the Life Cycle Assessment methodology has been used in order to assess the environmental impact of all the emissions of the different treatments applied to the plastics of the end-of-life vehicles in Spain. This assessment will be useful as a reference document to analyze the improvements in the environmental impacts that the future compliance of Directive 2000/53/EC will mean and it will also show the influence of the use of plastics and composites. In addition, the emission levels obtained through this assessment will be useful to check which end-of-life treatment is the most environmentally sustainable.

**TU 112**
**Stepwise D-Optimal design based on latent variables**
S Brandmaier[1], U Sahlin[2], T Öberg[2], IV Tetko[1]
[1]HelmholtzZentrum-Muenchen, NEUHERBERG, Germany
[2]Linnaeus University, KALMAR, Sweden
In the course of REACH, each chemical compound produced in or imported into the EU in amount of more than 1 ton has to be registered according to a number of environmental endpoints, including bioaccumulation and toxicity. Experimental determination of these properties requires a high number of animal tests. Apart from ethical reasons, animal experiments are expensive and time consuming. Therefore, the number of these tests should be kept as small as possible. This can be achieved by testing only a small representative subset of compounds, using them to build QSAR models and predict the remaining compounds.
There are several standard approaches for the selection of diverse sets of compounds for model purposes, such as factorial or D-Optimal design. The later method is frequently considered to be a better choice. The D-optimal design selects compounds using principal component analysis (PCA) of molecular descriptors. The analysis is done in one step and does not take into account the target property. Therefore, the selected compounds may not be optimal for modelling of the given property. Moreover, most labs, e.g. because of restricted capacities, test compounds not in parallel but in a stepwise procedure. The question is whether there is a better strategy that could provide better selection of compounds by taking into consideration the target property and available data.
We introduce a stepwise solution for experimental design, that utilizes the D-Optimal approach and combines it with partial least squares techniques to iteratively refine the descriptor space for the compound selection. This refinement is realized by the usage of the PLS latent variables, that are correlated with the target property, instead of principal components to extend the initially selected set of compounds. We show, that especially for global datasets, this approach can significantly increase the quality of a model, built on compounds suggested for testing, compared to a model, based on the compounds selected by the traditional D-Optimal design approach. The developed methodology was applied to predict several important endpoint required for REACH. We show that the new approach significantly decreased ($p < 0.01$, binomial test) the average RMSE about 0.05 log units and increased R2 and Q2 of the models compared to the traditional D-Optimal design.

**TU 113**
**Hormetic effect of textile wastewaters to sea urchin early development**
R Oral[1], G Pagano[2], F Koçbas[3]
[1]Ege University, IZMIR, Turkey
[2]Federico II Naples University, Department of Biological Sciences, NAPLES, Italy
[3]Celal Bayar University, Faculty of Art and Sciences, MANISA, Turkey
The relevance of hormesis has been recognized leading to increasing concern in ecotoxicology. We applied an experimental design (optimal and sub-optimal control quality) for evaluating the occurrence of hormesis in wastewaters of textile industry, physico-chemical parameters were analyzed. We used sea urchin (Paracentrotus lividus) bioassays to assess toxic vs. hormetic effects. Sea urchin embryo cultures were exposed to untreated and treated (chemical and biological) textile wastewater at dilutions ranging from 0.1 to 10% in seawater. A total of eight culture repeats showed "optimal"cultures with normal larvae in controls >70%, and "suboptimal"cultures with <70% larvae in controls. The results showed that both untreated and treated wastewaters of textile industry at all dilutions, up to 10%, failed to induce any increase in developmental defects in sea urchin larvae in the cultures with optimal control quality (94.1% normal larvae). In contrast, developmental defects were significantly decreased in larvae reared in either untreated or treated wastewaters at levels ranging 0.1 to 0.3% when tested against control cultures displayed suboptimal quality (66.1% normal larvae). Increasing concentration-related toxicity was detected in cultures reared in either untreated or treated wastewater at concentrations ranging from 1 to 10%. These findings provide evidence that suboptimal control quality is needed for detecting hormetic effect of environmental agents in an ecosystem. Moreover, the data cast doubt about effective removal of toxic components along with wastewater treatment at the facilities investigated in this study.

**Optimization of fertilization and larval development toxicity tests using two marine sea urchin species. Study of salinity influence.**
GV Aguirre-Martínez, C Carballeira, ML Martín-Díaz, TA del Valls
University of Cádiz, CÁDIZ, Spain
Embryo larval development (ELD) and fertilization tests with sea urchin have been widely used in ecotoxicity studies to assess pollution of marine ecosystems, and included in a regulatory framework due to their sensitivity and reproducibility. Salinity could act as a confounding factor when determining the mentioned toxicity responses, since these biological processes properly occur in a salinity range which depends on the species. In an attempt to determine the optimum salinity range, ELD and fertilization bioassays were performed at different salinities (15 to 40.5 "ð) using two species of Atlantic sea urchin: Arbacia lixula and Paracentrotus lividus. A. lixula embryo larval development assay showed wider optimum salinity range (from 29 to 35 "ð) compared with P. lividus (from 29 to 31 "ð). Regarding fertilization assay using P. lividus as bioindicator species, the highest percentages of fertilization (90 %) were measured when the salinity ranged from 29 to 31 "ð. More research is needed concerning A. lixula, since the fertilization success did not show higher values than 50 %. In the present study it has been demonstrated that salinity could be a confounding factor when interpreting ecotoxicological results, consequently this parameter should be controlled in order to optimize the described toxicity tests.

**Comparing the response of neonates, juvenile and adults of Daphnia exilis (Herrick, 1895) exposed a toxic metals**
A Sobrino-Figueroa
Universidad Autonoma Metropolitana Iztapalapa, MEXICO D.F., Mexico
In this study an sensibility evaluation in neonates, juvenile and adults (5 days) of *Daphnia exilis* exposed to the metals Cd, Cr, Cu, Mn, Ni, Pb, Va and Zn was carried out in order to determine their response and propose the use of *D. exilis* like alternating method for to evaluate the toxicity of water and sediments samples of aquatic systems. Static bioessays, were done with neonates and juvenile exposed during 48h to five concentrations of each metal (0.625, 0.156, 0.078, 0.039, 0.018 mg/ L) and control without toxic. With the gathered data the lethal concentration 50 ($LC_{50}$) were determined for probit method. Lethal tests showed that neonates and juvenile were more sensitive to copper. $LC_{50}$ obtained were 0.013 mg/L, and 0.010 mg/l respectively . No significant differences ($p > 0.05$) were observed between $LC_{50}$ of Cd, Cr, Cu, Mn, Ni and Zn obtained in the neonates and juvenile assays. This data suggest that the response observed in the Daphnia exilis neonates is similar to juvenile.

**TU 116**
**Evaluation of sensitive of veliger and pediveliger larvae of Catarina scallop Argopecten ventricosus (Sowerby II, 1842) exposed a toxic metals**
A Sobrino-Figueroa, CC Cáceres-Martínez
Universidad Autonoma Metropolitana Iztapalapa, MEXICO D.F., Mexico
In this study an evaluation of the effects of Cd, Cr, Pb and mixtures in veliger and pediveliger Catarine scallop larvae and their settlement was carried out. Bioessays, lasting 48 hours, were conducted with 5 concentrations of each metal and of their mixture (1:1). Lethal Concentration 50 ($CL_{50}$), and larvae settlement percentage were determined. Significant differences between control and exposed organisms were observed at 24 and 48 hours ($p < 0.05$). Cadmium was the more toxic metal for veliger and pediveliger larvae, The Cd+Cr + Pb mixture interaction was boosted, with a magnification value of 1X. A reduction in the larvae settlement was observed 80% in Lead tests, 71% with Cadmium, 83% with Chromium and 88% with the mixture. *A. ventricosus* larvae are more sensitive to metals in comparison with *Artemia franciscana* nauplii organisms utilized to evaluate the residual waters toxicity that are spilled in the coastal zone, it is important to continue carrying out research to detect the possible damage in the scallops populations.

**TU 117**
**Sub-lethal toxicity of zinc to Mysidopsis juniae (Crustacea: Mysidae)**
LF Pitombeira, AQ Silva, J Nilin, LV Costa-Lotufo
Universidade Federal do Ceara, FORTALEZA, Brazil
In aquatic environments, due to the great dilution factor, organisms are exposed to sub-lethal concentration of pollutants, such as metals resultant from industrial activity. Long-term exposure to this waste may cause physiological or behavioral disturbances. These effects are not detectable in acute toxicity tests, and so, the use of chronic assays poses as such a relevant approach. In this sense, the present study investigated the toxicity of zinc in a short-term chronic bioassay using a microcrustacean, *Mysidopsis juniae*, as the experimental model. Since the Brazilian legislation has yet to regulate bioassays such as this, the study aims to validate this species and this method as a viable ecotoxicological routine. The methodology used herein was modified from the norm proposed by the United States Environmental Protection Agency for *Mysidopsis bahia*. Concentrations of the test compound varied from 0.0375 to 0.60 mg/L, in 200 mL quadruplicates on 5 organisms younger than 24h per group. Two static 7-day experiments were conducted at $24 \pm 1$°C and 35 ppm salinity. Mortality, dry weight and length of organisms were evaluated. Mean LC50 was $0.22 \pm 0.11$ mg/L. Variation of length was significant reduced at the highest tested concentration, however, for the dry weight, no statistical differences were observed between exposed and control organisms. As there is only little information concerning sub-lethal effects in *M. juniae*, it is adequate to state that this method still requires adjustments for its effective standardization. However, based on this data, is reasonable to conclude that length, rather than weight, is a sensitive parameter to evaluate sub-lethal effects of zinc toxicity.

**TU 118**
**Antioxidant action of two polyphenols, resveratrol and piceid, on a biological model in vitro.**
S Manente, A Zuin, M Bragadin, G Ravagnan
Ca' Foscari University of Venice, VENICE, Italy
Among natural antioxidants found in many natural foods and beverages, the flavonoid resveratrol and piceid have been proven to be effective against a broad range of diseases whose origin can be

attributed to oxidative damage. Resveratrol is a phytoalexin, a secondary metabolite synthesized by Spermatophytes in response to stress conditions caused, for example, by exposure to UV radiation or fungal infection. Piceid, called also polidatina, is the glucosylated form of resveratrol, and, as its parental compound, also shows two isomers *cis* and *trans*; it is more resistant to enzymatic oxidation of resveratrol, enters the cell through an active transport mechanism that uses the glucose transporters, and, because of its higher solubility in water, is more efficiently absorbed from the mammal's intestine. This work was planning to evaluate the antioxidant action of these polyphenols on a biological model *in vitro* and to assess, then, any protective action of these stilbenes when the same organelle are exposed to toxic environmental substances known to give rise to a state of oxidative stress. The choice of using a mitochondria-based bioassay was determined by the need to clarify the biochemical mechanisms underlying the antioxidant effect of resveratrol and piceid on natural membranes. In particular, starting from some studies conducted to date on model membranes (<i*e*. synthetic organelles like micelles or liposomes), we tried to investigate resveratrol and piceid antioxidant action performed at mitochondrial membranes, using frozen beef heart mitochondria. Initially, they has been utilized with the classical mitochondrial endpoint, <i*e*. respiratory chain inhibition. Then, because it is reported that the antioxidant activity of polyphenols is linked to their ability to block or slow down the lipid peroxidation, reacting with peroxy radicals formed in the propagation phase, we investigated the ability of resveratrol and piceid to interact with initiator radicals, since the possibility exists that oxidation is inhibited at the stage of initiation. Indeed, the action of resveratrol and piceid as a scavenger against radical initiators and propagators of membrane oxidation, and its effectiveness in preventing the lipid peroxidation in different types of substrates, is well known.

**TU 119**

**Genotoxicity induced by amorphous silica powders in murine alveolar macrophages (RAW 264.7) and human epitelial lung cells (A549). Effect of dimension and superficial morphology**

P Guidi, M Bernardeschi, V Scarcelli, P Lucchesi, M Nigro, G Frenzilli
University of Pisa, PISA, Italy

No sufficient evidence exists about the health hazards caused by nanosized amorphous silica, nor as regard its superficial conformity. The aim of the study is to investigate the potential genotoxic effects of silica particles with different superficial morphology (mesoporous and dense spheres) and dimension (250,500 nm), by in vitro experimental models. Pure quartz, vitreous silica and imogolite (1 nm diameter) were also investigated. Murine alveolar machrophages (Raw 264.7) and human epitelial lung (A 549) cell lines have been used as representative of occupational and environmental exposure. Genotoxicity was evaluated by Comet Assay (4 and 24 hrs exposure) and Micronucleus Test. Cytotoxicity was tested using Trypan Blue method. Cell lines have been treated with 5-10-20-40-80 μg/cm2 of different silica-based compounds. The same doses of exposure were tested by Micronucleus test. MMS was used as positive control in Comet assay, Mytomicin C for micronucleated cells.

Cell suspensions exposed to the lowest dimension of porous particles show a particular distribution of these particles inside the cell, with respect to the one across the slide. When observed with TEM, cells treated with smaller porous powders showed enlarged vacuoles filled with the particles, indicating an active endocytosis process.

Data analyses confirmed crystalline particles to possess genotoxic activity. Interestingly, amorphous silica particles were also found to possess genotoxic activity.

In particular, physical characteristics like superficial porousity and dimension seem to play a role in modulating the genotoxic potential.

Even in absence of clear dose-effect trends, an effect of superficial morphology was found to modulate genotoxic and cytotoxic potential of amorphous particles in both cell lines: increased MN frequencies, increased degree of DNA fragmentation and decresed viability were induced by particles with porous surface in comparison with dense ones. On the other hand an effect of particle dimension was found as well: smaller dense particles induced higher frequencies of MN, higher amount of DNA migration and loss of viability.

Vitreous silica and imogolite were not found to possess genotoxic activity at the tested doses. Future research directions are going to extend the study to pure amorphous silica particles at nano-metric scale and to investigate the mechanisms of cell damage induced by amorphous SiO2.

**TU 120**

**Possibility to use porcine cumulus oocyte complexes (COCs) as in vitro toxicology assessment of heavy metal environmental pollutant bioavailability**

M Areekijseree, C Thepsithar, W Mettasart
Department of Biology, Faculty of Science, Silpakorn University, Sanamchan Palac, NAKORN PATHOM, Thailand

This work aimed to study the possible method to culture female porcine cumulus complexes (COCs) for use as in vitro toxicology assessment of heavy metal contamination. The oocytes isolated from ovaries were round in shape and surrounded by zona pellucida with layers of cumulus cells ranging between 90-400 micrometer in diameter. COCs were classified into intact-, multi-, partial-, completely denuded oocyte, and expanded cumulus cell layer at the percentage composition of 53.86%, 14.32%, 4.32%, 19.20%, and 8.30%, respectively. COCs classified as Type I and II were further investigated for morphological changes by culturing at 37°C with 5% CO2, 95% air atmosphere and high humidity for 48 h. in culture medium with and without hormones induction. On the early stage of culture, the oocytes were still in a round shape, and surrounded with zona pellucida and several cumuli cell layers. Expansion of the cumulus cell layers was observed when the cells were cultured for longer periods. Compared to the COCs induced with hormones, the groups that were cultured without hormone appeared in a spherical shape with process of sticking granular end point into the zona pellucida of oocyte. Meanwhile, at the cumulus cell surface, they were many microvili communicating with the surrounding cumulus cells. Interestingly, morphological changes of the complexes were observed after culturing for 24-48 h. In the groups supplemented with hormones (FSH, LH, and estradiol), the COCs showed the expanded cumulus layers, where the cumulus cells were peel off from the oocyte surface. For the round-shape cumulus cells, they adapted themselves into either an elongate shape or a columnar shape, and no communication between microvilli of cumulus cells. As a result, peel off, expansion and elongation of the cumulus cells from the oocytes occurred to allow oocyte maturation after culture with hormones. The further study is to use COCs culture cells to assess cadmium and copper toxicity.

**Soil health assessment through primary coelomocyte culture of Eisenia fetida: In vitro exposures to elutriates of artificially contaminated soils and real soils**

A Irizar, N Garcia, D Buey, M Soto, I Marigomez
UPV/EHU, LEIOA, Spain

Exposures to contaminated soils of individuals *Eisenia fetida* are widely used to assess soil health, being some of the tests applied with such a purpose well stablished and standarized by the OECD. However, recently a protocol for coelomocyte primary culture of *E. fetida* have been designed, and it was validated through the exposure of cells in vitro to different metals and performing the Neutral Red Retention (NRR) assay to assess cell viability. Although the *in vitro* exposures of coelomocytes to a single metal compound was tested, the soils are usually polluted with mixtures of different contaminants, and therefore the coelomocyte primary cultures should be also tested with real soils to validate them as a tool for soil health assessment. Elutriates of OECD soils artificially contaminated with Cd as well as elutriates of mine soils were extracted and primary coelomocyte cultures were exposed to elutriates for 24 h. The cell viability was assessed by the NRR assay and riboflavin content and the activity of the MXR were also measured to detect the effect of the elutriate exposure. The results showed that elutriates of the contaminated OECD soils decreased the NR retention of coelomocytes in a dose-dependent manner, and the riboflavin content was also reduced. This response seemed to be a general stress signal since the decrease was not dose-dependent. In addition, the activity of the MXR decreased, indicating a possible inhibition of the transport of toxic compounds outside the cell (i.e.damaged detoxification). The exposures to elutriates of mine soils showed also a decrease of the NRR capacity, and a similar decrease of the riboflavin content was also detected. The results of these experiments indicate that the *in vitro* exposures of coelomocyte primary cultures could be a useful tool for assessment of soil health.

**Application of the modified Comet assay (Fpg) to three fish cell lines for genotoxicity assessment of pollutants**

AE Kienzler[1], S Bony[2], X Tronchère[1], A Devaux[2]
[1]ENTPE, VAULX-EN-VELIN, France
[2]INRA-ENTPE, LSE, VAULX-EN-VELIN, France

In a context of growing regulatory pressure, the need for in vitro model in genotoxicity assessment is currently increasing. This apply to the need for genotoxicity testing of new and existing chemicals (REACH), to the monitoring programs of water quality recommended in the Water Framework Directive and responds to the societal demand to avoid testing on whole organism. Amongst the known genotoxicity biomarkers frequently used to assess genotoxocity potential of pollutants, the modified Comet assay using restriction enzyme allows an increased sensibility of the Comet Assay. Thus, in this work, it has been chosen to detect genotoxicity at environmentally relevant concentrations, since most of the aquatic genotoxic contaminations are characterized by chronic exposure at low levels of concentration. The Fpg restriction enzyme has been chosen, amongst other, for its capacity to detect various lesions such as base oxidation or alkylation, therefore broadening the type of DNA damage detected by the Comet assay.

First a Fpg modified comet assay has been applied to three piscine cell lines (RTL-W1, RTG-W1, PLHC-1) exposed to various model genotoxicants exhibiting known mode of actions (MMS, H2O2[3DOTS]).This allowed to assess and compare the feasibility of the modified comet assay with cell lines currently used in ecotoxicological studies ( DNA damage basal level, cell aggregation, response to genotoxicants). Second, the genotoxicity potential of different classes of environmental chemicals (phytosanitary products, heavy metals, pharmaceuticals[3DOTS]) was tested on some of those cell lines.

The German mirror committee of ISO TC147 SC 5 WG 9 'Genotoxicity' organised an international round robin study on the Ames fluctuation test (ISO DIS 11350). Nineteen laboratories from seven countries participated in the study. The laboratories had to test four coded water samples. Sample one, a river water sample, was used as a negative control water sample and for spiking with strain-specific mixtures of mutagens (samples two and three). Sample four was an effluent from an industrial waste water plant. Validity criteria were fulfilled in 86 to 100 % of all test conditions (bacterial strain / ± S9-mix). The overall test sensitivity was 100 %. The test specificity ranged from 80 to 100 % depending on the test condition. For statistical evaluation an arcsin-square-root transformation was applied to generate a metric data set. An ANOVA was performed to identify samples with a significantly higher numbers of revertants. A threshold value derived from a large set of negative controls was used in a final step to exclude results of individual tests with unexpected low numbers of spontaneous revertants. The lowest ineffective dilution values (LIDs) were then determined by this new approach. The variability of the LID values among the laboratories amounted in most cases to no more than two dilution steps around the median. The data produced in this round robin study proved a sufficient reproducibility of the test procedure and provide validity data for the finalization of the ISO standardization process.

**Improvement on frozen mitochondria bioassay: a methodological remark.**

S Manente, A Zuin, A Iero, M Bragadin, G Ravagnan
Ca' Foscari University of Venice, VENICE, Italy

The protocol for the bioassay with the mitochondria of beef heart frozen at -22 ° C, developed by Iero et al. (2003) requires that the reaction cell is thermostatically controlled at 25 ° C: this value was chosen because it is used as a reference for the state environmental standard (Standard Ambient Temperature and Pressure, SATP). The choice is not, therefore, been supported by assessments on the effectiveness of the test at this temperature, but was dictated by the practice of reporting results to a standard temperature value. Finally, it was decided to make a comparison between the working temperature of 25 °C and 37 °C, chosen as close to the body temperature of cattle (estimated to be 38.6 °C) then working temperature 'normal' mitochondria extracted from ox heart. In the first phase, a series of tests only for the basal respiration were carried out in order to compare respiration rates and the quality of the regressions obtained, and subsequently mitochondria have been tested for toxicity using some known mitochondrial toxic substancesthe (e.g. Pb (NO3)2) to compare the trend of effect to the two temperatures. Running the tests at 37 °C, it can therefore calculate the toxic effect of the compound at concentrations lower than those attainable with the test at 25 ° C: it can be concluded that the bioassay with frozen beef heart mitochondria is more sensitive and accurate at 37 °C. This reason, together with considerations concerning the rate of respiration higher (due to higher enzyme activity) and increased signal stability, lead to the conclusion that in order to optimize the performance of the test is preferable to control the temperature of the cell reaction at 37 °C.

**TU 125**

**A novel contact bacterial bioluminescence assay with Photorhabdus luminescens for testing of freshwater samples including sediments**

I Rusová, P Masner, P Macíková, L Bláha
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Testing of the bioluminescence inhibition with *Vibrio fisheri* has become a world standard in rapid screening of ecotoxicity. However, ecological relevance of using this marine bacteria for assessment of freshwater samples has been disputed. Further, use of the bioluminescence assay for colored or turbid samples is limited with respect to possible false positive results (attenuation of the luminescence by the colour). Here we present development of a novel assay with the luminescent bacteria *Photorhabdus luminescens* originally isolated from soil, which aims to overcome both above mentioned limitations. Low-salt media are used for the culture of *P. luminescens*, and the rapid kinetic design (also known as 'Flash-test' at *V. fisheri*) allows contact toxicity testing of the turbid and coloured samples such as sediment suspensions. Experimental protocol and the sensitivity has been tested with a number of various samples including model chemicals and complex sediments and compared with *V. fisheri* test. The results demonstrate good applicability of the novel test for direct toxicity assessment in complex field samples. Supported by the projects INCHEMBIOL (Ministry of Education C.R. - MSM0021622412) and CETOCOEN (European Regional Development Fund no. CZ.1.05/2.1.00/01.0001).

**Effects on cholinesterase activity in erythrocytes of wild birds exposed in vitro to lead, cadmium and their binary mixtures**

A Hernández-García[1], D Romero[1], C Gravato[2], L Guilhermino[2], AJ García-Fernández[1]
[1]University of Murcia, MOLINA DE SEGURA, Spain
[2]Centro Interdisciplinar de Investigação Marinha e Ambiental (CIIMAR), PORTO, Portugal

Lead and cadmium effects on erythrocytes have been widely reported, including calcium and potassium homeostasis alteration, changes in cell membrane, osmotic alterations and mechanical fragility of the membrane, synthesis inhibition of haem group, interferences in oxygen exchange, alterations in carbohydrates and energy metabolism, cholinesterase inhibition, and oxidative stress induction due to reactive oxygen species (ROS), as well as alterations in antioxidant mechanisms. Although cholinesterase inhibition by metals is still a controversial topic in scientific literature. The aim of this study was to evaluate the lead and cadmium-induced effects in mallard (Anas platyrhynchos), Eagle owl (Bubo bubo) and Eurasian buzzard (Buteo buteo) erythrocytes exposed in vitro to cadmium, lead and cadmium:lead combination (1:10) in propotiortions equal to those previously found in wild birds. After determination of cell viability with Propidium Iodide, different concentrations were selected in order to evaluate cholinesterase activity in haemolysates. Cholinesterase activity was measured according to Ellman's method. Variations in this enzyme system after exposure to these metals depended on the species used. In general trends, mallard erythrocytes showed a decrease in this activity. In Eagle owl erythrocytes, a great increase in this activity was observed. In buzzard erythrocytes no significant changes were observed following lead exposure, whereas cadmium provoked an increase in this activity in all doses, and metal mixture produced an increase at EC25 and EC50. Little is known about the effects of these metals on cholinesterase activity in erythrocytes, although a decrease in rodents exposed in vivo to lead was observed. On the other hand, no variations were found in workers exposed to lead. For cadmium, it has been observed an enzyme inhibition in human and rodent erythrocytes exposed in vitro. However, activation on cholinesterase activity has been related with membrane alterations in human erythrocytes. In conclusion, the increase in cholinesterase activity in raptor erythrocytes exposed to cadmium and/or lead, especially in Eagle owl, could be a sign of structural membrane damage. Acknowledgments: Work supported by the Spanish Government (CGL2004-5959/BOS, CGL-2008-4318/BOS, NOVEDAR-CSD00C-07-22204) and Seneca Foundation (08758/PI/08). Special thanks to P. María-Mojica for his help in sampling.

**Acute and chronic toxicity testing of pharmaceutical compounds on primary cultures from the zebra mussel (Dreissena polymorpha)**

B Quinn[1], M Parolini[2]
[1]Irish Centre for Environmental Toxicology, GALWAY, Ireland
[2]University of Milan, MILAN, Italy

There is growing concern over the potential toxic effects of emerging contaminants, particularly pharmaceuticals, being released into the aquatic environment. There is much renewed interest in alternative toxicity test methods, and the use of alternative (invertebrate) animal species owing to the recent REACH legislation. *In vitro* techniques are one such alternative method and are an important tool in investigating the mechanisms of action of toxins on individual cells or tissues removed from the process of the entire organism. A recently developed method for the *in vitro* culture and maintenance of cells and tissues from the zebra mussel (*Dreissena polymorpha*) was used in toxicity tests to investigate the acute (cytotoxicity) and chronic (glutathione S-transferase (GST) induction) effects of the non-steroidal anti-inflammatory drug diclofenac and the lipid regulator gemfibrozil. This technique offers a screening evaluation method providing information on both the cytotoxicity and mode of action of these contaminants on cells in suspension and tissue explants (respectively) on the three most common targets of environmental pollutants in the zebra mussel: hemocytes, gill and digestive gland. Both compounds showed similar levels of cytotoxicity with gill and hemocyte cells show a significant decrease in viability at 0.001 mg/L. The trypan blue exclusion test was found to be more sensitive than the mitochondrial MTT reduction assay. An increase in GST expression was seen in both gill and digestive gland explants after a preliminary 24h exposure to 1 and 10 mg/L gemfibrozil indicating their potential biotransformation capacity. Toxicity results from these acute and chronic *in vitro* exposures shall be presented along with their comparison to in vivo whole animal tests to assess their sensitivity.

**TU 128**

**Novel approach for ecotoxicological assessment of pesticides: Nnn-invasive neural and vascular responses in aquatic oligochaete, Lumbriculus variegatus, exposed to pyrethrins**

SR Gooneratne[1], CD Drewes[2]
[1]Lincoln University, CHRISTCHURCH, New Zealand
[2]Iowa State University, AMES, United States of America

Oligochaete worms are key non-target macroinvertebrates in terrestrial and freshwater ecosystems. Aquatic and terrestrial pollution has attracted much public interest in the past two decades. Yet despite a major research thrust in this field, a non-invasive sensitive biomarker that would allow repeat measurements to monitor both onset and recovery from toxic insults has not emerged. Sub-lethal effects of agricultural pyrethrin pesticides [commercial formulations and pure permethrin (PMT) and fenvalerate (FEN)] on nervous and vascular functions of the freshwater oligochaete Lumbriculus variegatus were studied non-invasively following immersion (upto 6 h) in aqueous concentrations ranging from 0.001 to 10 ppm. Neurotoxicity effects evaluated included conduction velocity (CV) of the medial giant fibers (MGF), helical swimming, and body reversal behavior. Vascular system effects included blood pulsation rate in tail segments. Both PMT and FEN induced a significant ($P < 0.05$) dose-dependent decrease in the CV of the MGF, loss of swimming and reversal reflexes, and increased frequency of blood pulsations. Results indicated that FEN was more toxic than PMT and that commercial preparations of both pyrethrins were more toxic than the respective pure compounds. Effects of commercially prepared FEN occurred at doses as low as 0.001 mg/L and usually within 3 h of chemical exposure. Thus pyrethrins caused marked nervous, behavioral and vascular effects even at very low concentrations. The CV technique reported here is sensitive, gives accurate and reproducible results, does not require anaesthesia or immobilization, and allows quantification of neurotoxic effects with non-invasive repeat measurements in the same oligochaete. This novel technique could be used as an early-warning biomarker to monitor toxicity of pesticides and other chemicals in non-target aquatic and also terrestrial (earthworms; not reported here) organisms.

**TU 129**

**EROD as a biomarker in zebrafish embryo**

BK Kais, TB Prof. Dr. Braunbeck
University of Heidelberg, HEIDELBERG, Germany

The present study is part of the joint research project "DanTox" funded by the German Federal Minister of education and Research (BMBF). The overall aim of this project is to develop a eukaryotic test system which can be used to investigate the ecotoxicological effects of contaminated sediments. In addition to native sediments and sediment extracts, selected model chemicals from the list of priority substances of the European Water Framework Directive (EWFD) will be tested. These substances are methylmercury(II)chloride (heavy metal), chlorpyrifos (organophosphate insecticide) , aroclor 1254 (polychlorinated biphenyl, PCB) and Bisphenol a (diphenylmethane derivative). The visualization of specific activation of the aryl hydrocarbon receptor (AhR) via live cell imaging is one of the bioassays that will be developed. The measurement of ethoxyresorufin-O-deethlyase (EROD) activity in fish is a well-established in vivo biomarker of AhR-mediated induction of cytochrome P450-dependent monooxygenases (CYP1) and is a highly sensitive indicator of specific planar polycyclic aromatic hydrocarbons (PAH) as well as of structurally related compounds. The CYP-induced fluorescence signal results from the ability of CYP1A to convert the substrate 7-ethoxyresorufin to the fluorescent product resorufin. The transparency of the zebrafish embryo allows a direct detection of an EROD-induction via epi-fluorescence microscopy and confocal laser scanning microscopy (CLSM) according to Otte 2010. The aim of this study is to develop a stable and easy-to-handle EROD-assay by elucidating the spatio-temporal pattern of basal and induced CYP1 activities in zebrafish embryos. β-Naphtoflavone (10 µg/L) is used as a positive control and shows CYP1 induction at any time of inspection after 24, 48, 72, 96 and 120 hours post-fertilization. Due to their molecular structure, methylmercury(II)chloride and chlorpyrifos showed no EROD-induction. Aroclor 1254, on the other hand, is a well-known inducer of CYP1A and interesting spatio-temporal patterns can be expected. The role of Bisphenol a as an inhibitor of CYPs, however, has still to be clarified. In order to ensure that there is no toxic effect related to the substances that influences EROD activity, fish embryo toxicity tests (FET) are carried out. Semi-static exposure systems turn out to be well-suited to ensure a constant distribution and uptake of heavy metals as well as of hydrophobic PAHs.

**In vivo and in vitro hepatic transcriptional and proteomic response in Oncorhynchus mykiss exposed to ethinylestradiol and benzo(a)pyrene**

MT Hultman[1], Y Song[1], K Petersen[1], B Salbu[2], BO Rosseland[2], KT Tollefsen[1]
[1]Norwegian Institute for Water Research (NIVA), OSLO, Norway
[2]University of Life Sciences (UMB), ÅS, Norway

The European Union (EU) established in 2007 the chemical regulatory legislation Registration, Evaluation, Authorisation and Restriction of Chemical Substances (REACH) with the objective to improve the human and environmental health status. Through performing assessments, early identification of potentially hazardous chemical compounds could be made, thus prohibiting or regulating their production and use. It is estimated that approximately 30,000 chemicals are in need of risk assessment due to their production volume, persistent and/or bioaccumulation potential (vPvB). REACH rely on using aquatic organisms, foremost fish as a test organism in these assessments resulting in the potential use of millions of fish for regulatory testing. Besides the high costs, the implementation of the 3Rs (reduction, refinement and replacement) are of con-

siderable ethical importance. Therefore, search for and evaluation of alternative or non-animal testing methods to serve as surrogates for whole fish tests are of high priority.
This study has evaluated the hepatic transcriptional responses in *Oncorhynchus mykiss* exposed *in vivo* and *in vitro* to benzo[a]pyrene (BaP) and ethinylestradiol ($EE_2$), as to determine whether primary hepatocytes may serve as an (alternative) non-animal test method. Analyses focused on characterising the global transcriptional changes and determining whether the cellular responses where manifested at the protein level in both *in vivo* and *in vitro* experimental models. In addition, bioassays involving cytotoxicity (metabolic activity and membrane integrity) were measured on *in vitro* samples. Results presented will determine whether primary hepatocytes exhibit comparative responses to that of native liver cells in rainbow trout.

[2]Norwegian School of Veterinary Science (NVH), OSLO, Norway
[3]Liverpool John Moores University (LJMU), LIVERPOOL, United Kingdom
[4]University of Life Sciences (UMB), ÅS, Norway
[5]Swiss Federal Institute of Aquatic Science and Technology (EAWAG), DÜBENDORF, Switzerland
[6]Helmholtz Centre for Environmental Research (UFZ), LEIPZIG, Germany
The Registration, Evaluation, Authorisation and Restriction of Chemical Substances (REACH) is the European Union's chemical regulatory legislation for new and existing chemicals. The REACH legislation requires that chemicals, considered to be persistent, bioaccumulative and/or toxic (PBT), have to undergo regulatory testing using aquatic vertebrates. Estimates are that about 30,000 single chemicals may require testing with up to three million fish using currently available and validated methods. With the strong drive towards implementing the 3Rs (reduction, refinement and replacement) into ecotoxicological testing, the need for developing and evaluating alternative (non-animal) experimental methods is clearly warranted. This multi-disciplinary project, involving various international research groups, intends to meet this challenge through the development and evaluation of alternative test methods to carry out rapid, reproducible screening for the bioaccumulative and toxic properties of chemicals. Ecotoxicological testing using zebrafish (*Danio rerio*) embryos, complimented by *in silico* quantitative structure-activity relationship (QSAR) models, *in vitro* methods (cell cultures) and toxicogenomics, will be assessed. Results will then be compared to findings from *in vivo* experiments to evaluate whether these approaches may be applied as part of the regulatory testing within REACH.

### TU 132
**Alterations in gene expression after exposure of zebrafish (Danio rerio)embryos to sediment extracts**
JE Bräunig[1], S Peddinghaus[1], S Wiseman[2], M Hecker[2], JP Giesy[2], S Keiter[1], H Hollert[1]
[1]RWTH Aachen University, AACHEN, Germany
[2]University of Saskatchewan, Toxicology Centre, SASKATOON, Canada
The present study is part of the joint research project DanTox, which has the objective of developing a combined vertebrate-based sediment contact assay to investigate mechanism-specific endpoints indicative of the exposure to sediment bound pollutants. Specifically, this study focused on the analysis of changes in gene expression patterns in embryos of zebrafish (*Danio rerio*) after exposure to contaminated sediments. Together, these goals will contribute to the development of a targeted cDNA-microarray which will be useful for environmental screening.
Three sediment samples, one from a contaminated site located in the outer Vering Canal in Hamburg-Wilhelmsburg and two from the Rhine River, each representing a different level of contamination, were used. After freeze-drying, the sediments were extracted with acetone in a Soxhlet apparatus. Fertilized zebrafish eggs were exposed to the extracts for 48 hours according to a standardized fish embryo toxicity test guideline (DIN 38415-6). Subsequently, mRNA was extracted from the embryos and subjected to quantitative real-time polymerase chain reaction (Q-RT-PCR) to analyze the transcript abundance of selected genes. Specifically, a battery of phase I and II metabolism genes (CYP1A1, AHR2, GST and UGT1A1) as molecular biomarkers of dioxin-like exposure as well as MT1 and MT2 as markers for metal exposure were measured. Clear increases in the transcript abundance of CYP1A1, GST and UGT1A1 were observed. The greatest fold changes, up to 600-fold, were observed in embryos exposed to the extract from the Vering Canal. Dose-response relationships for CYP1A1, GST and UGT1A1 were observed in embryos exposed to extract from the least contaminated Rhine site, Ehrenbreitstein. No comparable dose-response relationships were observed in embryos exposed to extracts from either the Vering Canal or the second Rhine site, Altrip. This was likely due to already maximal induction of transcript abundance in embryos exposed to the least concentration of both sediment extracts. Transcript abundance of MT1 and MT2 was not significantly altered in embryos exposed to extracts from any of the sites. Based on the results it appears that dioxin-like pollution may be more prevalent than metal pollution in these areas.
A goal for the future is to correlate results from gene expression analysis to results obtained with in vitro biotests such as the EROD assay and the H4IIE assay for the same samples.

### TU 133
**Embryotoxic and Ah-receptor-mediated effects of sediment extracts from the Vering Canal of Hamburg and the Rhine River in Danio rerio embryos**
S Peddinghaus, J Bräunig, T Hoen, K Winkens, H Hollert, S Keiter
Institute for Environmental Research, AACHEN, Germany
The European Water Framework Directive (EWFD) aims to achieve a good ecological and chemical status in the surface water of European rivers until 2015. However, there is still need for basic research in order to fulfill this legal obligation. In particular, since sediments and particulate matters are well known for being sinks and secondary sources for pollutants, applied sediment toxicology is of major relevance in achieving the objectives set by the EWFD.
The present study is part of the joint research project DanTox, which - among other specific endpoints - investigates embryotoxic and AhR-mediated effects of sediment extracts from the Rhine River and the outer Vering Canal of Hamburg-Wilhelmsburg using Danio rerio embryos. Sediment samples were collected from three sites, two from the Rhine River (Altrip (A) and Ehrenbreitstein (EB)) and one from the outer Vering Canal of Hamburg (VC). Freeze-dried sediments were extracted with acetone in a Soxhlet apparatus. In order to investigate dioxin-like activity in embryos of Danio rerio a combination of the fish embryo toxicity test (FET) and the cell culture based EROD-assay was applied.
Exposure to the sediment extracts led to different malformations in zebrafish embryos. The LC50 values ranged from 1.3 mg SEQ/ml (VC) to 25.8 mg SEQ/ml (EB) Moreover, the results showed a clear increase of the acute embryotoxicity over time (24, 48, 72 and 96 h) for all three samples. Exposure to TCDD led to a decrease in EROD activity below basal level of the negative control. This was unexpected, since TCDD is one of the strongest EROD inducers and used as a positive control in the cell culture based EROD assay. These results indicate that the barrier function of the chorion prevents TCDD from entering and harming the embryo. In contrast to TCDD, the exposure to sediment extracts showed an EROD induction above the basal level of the negative control.
To achieve the goals of the EWFD it is of particular interest to establish a combined vertebrate-based sediment contact assay with different biological endpoints (e.g. embryotoxicity, teratogenicity, and AhR-mediated toxicity). Therefore, the present study is a first step for establishing such specific biomarkers to determine the ecotoxicological effects of sediment-bound pollutants. However, there is still need for research to improve and standardize the measurement of dioxin-like activity and embryotoxicity in sediments using zebrafish as a vertebrate-based test model.

### TU 134
**Evaluation of epigenetic DNA modifications in a zebrafish (Danio renio) cell line model**
E Farmen[1], MT Hultman[1], KJ Macrae[1], M Vandegehuchte[2], G Stentiford[3], MA d'Auriac[1], JH Sønstebø[1], KE Tollefsen[1]
[1]Norwegian Institute for Water Research, OSLO, Norway
[2]Ghent University, GENT, Belgium
[3]Centre for Environment, Fisheries & Aquaculture Science, WEYMOUTH, United Kingdom
Influences of environmental factors, subsequent epigenetic DNA modifications and potential development of diseases emphasize the importance of epigenetics and its application as a potential environmental biomarker. However, the study of multigenerational epigenetic DNA modifications is a novel approach in ecotoxicology which can be both time and labour consuming. Therefore the potential of a high throughput in vitro screening method were assessed by exposing a zebrafish cell line to model substances 5-azacitidine, ethinylestradiol, diethylstilbestrol and arsenite. Methylation of CpG islands of selected genes were monitored by bisulphite conversion and high resolution melt analysis after short term exposure to sub-lethal concentrations. The genes selected for targeted CpG methylation analyses were DNA-methyltransferase 1, vitellogenin 1 and c-Myc. Results will be compared to existing in vivo data for validation of a high throughput in vitro alternative zebrafish model.

### TU 135
**Combining the acute Danio rerio embryo toxicity test with the assessment of endocrine disruption endpoints**
A Jonas, B Jedlickova, I Sovadinova, L Blaha
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
Effluents from the wastewater treatment plants (WWTP) are important sources of pollution in the natural water bodies. Whole effluent toxicity tests evaluate the overall toxicity of chemical mixtures present in these effluents. One of these tests is the fish embryo toxicity (FET) test with zebrafish (*Danio rerio*) which is a modern test recently standardized by ISO. Nonetheless, the embryo mortality, which is evaluated in the standard test, may miss more subtle endpoints such as endocrine disruption, which is a known environmental problem for fish populations and other ecosystem components. In the present work, we combine the standard FET test with determination of the estrogen-controlled genes by PCR method. WWTP effluent samples have been collected across the European Union (the FATE-SEES project coordinated by the JRC, Ispra, Italy), and tested (i) by the in vitro reporter gene test for estrogenicity and (ii) by the modified FET test. We evaluated the applicability of the PCR within the standard test, and compared the results of both in vitro and in vivo methods. Outcome of the currently running work will be presented.
Supported by Brno PhD Talent Financial Aid to Adam Jonáš and the projects INCHEMBIOL (MSM0021622412) and CETOCOEN (CZ.1.05/2.1.00/01.0001).

### TU 136
**Tweaking the fish embryo test with zebrafish (ZFET) for a refined alternative toxicity evaluation of pesticides**
AFM Wichmann[1], V Schiller[1], R Kriehuber[2], C Schäfers[1], H Hollert[3], M Fenske[1]
[1]Fraunhofer IME, AACHEN, Germany
[2]Forschungszentrum Jülich, JÜLICH, Germany
[3]RWTH Aachen, AACHEN, Germany
Great efforts have been made to develop the zebrafish embryo toxicity test (ZFET) as an alternative to ethically questionable and costly animal experiments. The recently revised European directive on the protection of animals used for scientific purposes (DIRECTIVE 2010/63/EU) now specifically tolerates the use of not yet independently feeding embryonic and larval stages of non-human vertebrates for testing, what will further promote the development of methods to broaden the scope of the ZFET within the regulatory framework. A large number of chemicals have already been tested in the ZFET, but pesticides were found to be underrepresented and a lack of mode-of-action (MoA) specific testing is apparent. As for many other substances, pesticide effects on the zebrafish embryos often occur only after 48hpf, thus outside the time frame of the standard ZFET to date. In line with current validation activities towards a OECD guideline for the ZFET, we tested several pesticides in the 48h-ZFET and in an extended 120h-ZFET to investigate the consequences of a prolonged test period on the toxicity and the sensitivity compared to the acute fish toxicity. Additionally, embryos exposed for 48h to a selection of pesticides at morphological effect concentrations below the EC20 were subjected to microarray analyses to study potential MoA specific responses of the transcriptome. As anticipated, the first 48hpf were found not to be the most sensitive exposure period for the majority of pesticides tested and morphological effects were often confined to minor, non-lethal effects. Exposure beyond 48h led to either delayed or failed hatching or to severe and often lethal effects. However, differentially expressed genes at 48h relate to molecular functions, which can be linked to the morphological effects observed and to the given MoA of the pesticide, even at the very low concentrations investigated. These findings provide strong evidence, that the application of transcriptomics to a mode-of-action specific testing of pesticides in the ZFET can increase the sensitivity and improve the mechanistic understanding without prolonging the test period.

### TU 137
**Acute and chronic zebrafish embryotoxicity toxicity for two narcotic chemicals using a passive dosing exposure system**
B Butler, DJ Letinski, EJ Febbo, TF Parkerton, MA Lampi
ExxonMobil Biomedical Sciences, Inc., ANNANDALE, NJ, United States of America
Recent computational models, such as the target lipid model, have been used to derive envi-

ronmental quality objectives that are intended to be protective of chronic toxicity endpoints. However, reliable experimental chronic/early life stage (ELS) effects data for fish are limited and further test data are needed to confirm this prediction. An effort has been underway for the past several years to develop a zebrafish embryotoxicity (zFET) OECD Test Guideline, currently in draft form, to meet various drivers to Reduce, Refine and Replace the use of vertebrates in animal testing. Here we present an adaptation of this method using a closed system to allow for longer-term embryo toxicity testing of sparingly soluble or volatile substances. A passive dosing system using test substance-saturated silicone oil in silicone tubing was employed to generate constant test concentrations without carrier solvents. We present acute and ELS endpoint data for 1,2,3-trichlorobenzene as well as phenanthrene, two narcotic compounds of differing aqueous solubilities. The observed acute and chronic effect concentrations and the empirical acute to chronic ratios are compared to predictions derived using the target lipid model. Implications of this comparison and need for further research are discussed.

[6]OECD, PARIS, France

The OECD Acute Fish Toxicity Test Guideline (TG 203) is an integral component in the environmental safety assessment of industrial chemicals, agrochemicals, pharmaceuticals, feed stuffs, and biocides. One of the most promising alternative approaches to the acute fish toxicity test is based on the use of zebrafish embryos. In 2005, the German Federal Environment Agency submitted the draft TG on 'Fish embryo toxicity (FET) test' to the OECD Test Guideline Program and a supportive Background Paper. Subsequently, OECD established the ad hoc Expert Group on the Fish Embryo Toxicity Test. Based on the outcome of expert meetings, OECD decided to perform a validation study (coordinated by ECVAM and steered by a validation management group). The validation study aims to evaluate the transferability, and the intra/interlaboratory reproducibility of the Zebrafish FET (ZFET). Newly fertilised zebrafish eggs (20/concentration and control) are exposed for up to 96h to chemicals. 4 apical endpoints are recorded daily as indicators of acute lethality in fish: coagulation of embryo, lack of somite formation, non-detachment of tail bud from the yolk sac and lack of heart-beat. LC50 values are calculated for 48h and 96h exposure. 20 chemicals are tested at 5 different concentrations in 3 independent runs in at least 4 laboratories with appropriate controls. The presentation will give an overview on 1) the validation study design, 2) preliminary results 3) positive and negative controls and 4) the correlation of the ZFET with acute fish LC50 data.
"Disclaimer: The opinions expressed and the arguments employed herein are those of the authors and do not necessarily reflect the official views of the OECD or of the governments of its member countries'"

The ILSI Health and Environmental Sciences Institute (HESI) held a workshop June 2010 on the "Development of alternatives to chronic ecotoxicity tests: predicting early-life stage and endocrine-mediated toxicity in aquatic vertebrate species."The meeting was attended by over 50 scientists representing industry, academia, government, and NGOs from North America, Europe, and Japan and was aimed at examining critical science needs related to the development of alternatives to chronic fish toxicity and endocrine disruption tests. It is estimated that demands for long-term (chronic) fish toxicity testing represents approximately 6% of the total animal testing needs for REACH, and there is a great need to develop scientifically-sound alternative methodologies that can accurately predict chronic toxicity and endocrine disruption while maximizing the use of limited resources. Various approaches such as the use of fish cell lines, modeling, and new technologies (such as 'omics) are promising strategies to improve testing and should ultimately result in reducing animal use. However, their application to chronic toxicity and endocrine disruption tests hinges on a fundamental understanding of chemical's adverse outcome pathway. By focusing on the concept of adverse outcome pathways in reviewing new and existing data and methodologies, the workshop participants began the design of a long-term platform to address animal alternative testing strategies for chronic toxicity and endocrine discuption.
Discussions at the workshop led to eight major recommendations that will aid to focus and refine the development of alternative methodologies for ecotoxicology: 1) Focus on and further develop adverse outcome pathways; 2) Perform critical evaluations of existing tests; 3) Increase global coordination of test development across disciplines & sectors; 4) Create centralized data repositories for fish & amphibian data; 5) Develop standard reference chemical lists for chronic ecotoxicity & EDC testing; 6) Promote increased use of fish and amphibian embryo-based toxicity tests to predict chronic toxicity; 7) Modify current EDC tests for use in quantitative risk assessment & promote the development of robust alternatives; and 8) Consider mixture toxicity and effluent discharges when designing alternative strategies. This poster will highlight these conclusions and provide an update on the ongoing HESI committee activities.

**Molecular assays enabling 'animal-free' toxicology tests**

CA Morris[1], GA El-Hiti[1], I Weeks[1], JS Woodhead[2], P Kille[1]
[1]Cardiff University, CARDIFF, United Kingdom
[2]Invitron, WYASTONE LEYS, MONMOUTH, United Kingdom

The exploitation of genetic endpoints provides the potential to develop in vitro screening procedures. The resulting high throughput toxicology screens would have utility for rapid compound assessment within pharmaceutical pipelines and in tiered frameworks for the assessment of industrial and agro-chemicals.
We have developed a molecular assay for gene expression analysis based on chemiluminescence which utilises the high signal output from acridinium-ester (AE) and has the potential to measure changes in gene expression without amplification technologies. AE-labelled probes bind in a sequence-specific manner to RNA and light output is directly proportional to the number of transcripts present. A homogenous assay format can be achieved by exploiting the way the AE is protected by the nucleic acid duplex. Unbound probe can be removed by a chemical means which leads to very low background levels hence simplifying the assay format.
This technology is capable of achieving 0.1fmol sensitivity with a dynamic range of 4 orders of magnitude and has previously been exploited to measure endocrine disrupting chemicals in aquatic toxicology applications1,2,3. We are currently optimising assays for genotoxicity (RAD51C, Cystatin A, p53) and steroidogenesis (CYP21A2, CYP19A1 and HSD2) endpoints in order to demonstrate broader application to toxicology testing.
The assay requires only a tube luminometer and waterbath and has the potential to provide a cheap and precise alternative to qPCR. Development of novel AE molecules will allow dual measurement of control and marker genes in a single measurement and use of target capture using magnetic beads covalently modified with streptavidin will also further improve sensitivity. When combined, these technologies will provide a powerful toolkit to measure steriodogenesis and genotoxicology markers.

**A review of freshwater fish sublethal tests over the past 60 years**

J Norberg-King[1], SE Belanger[2], MR Embry[3], M Halder[4]
[1]USEnvironmental Protection Agency, DULUTH, United States of America
[2]Procter and Gamble, CINCINNATI, United States of America

[4]European Commission Joint Research Centre /ECVAM, ISPRA, Italy

Pressure on animal testing has traditionally been the purview of mammalian toxicological science, but in the past few years, more attention is given also to environmental safety. As with higher vertebrate animal alternatives, balance between reduce animal use without impairing or increasing uncertainty in risk assessment is needed. Testing demands for long-term (chronic) fish toxicity is anticipated to be the third largest pool of needs following 2-generation mammalian developmental toxicity test (OECD TG 416) for REACh. In 1984, in a review of sublethal tests, Woltering suggested that that the growth endpoint could be deleted from the sublethal fish tests, without affecting the predictive nature of the tests. As this endpoint has not been excluded and other endpoints have been added (e.g., biomass), we evaluated toxicity data from years of fish life cycle chronic, partial chronic and early life stage tests to assess the utility of the standard fish chronic toxicity endpoints, in particular the sublethal response. Approximately 500 studies involving >100 fish species were summarized using several databases, literature and unpublished industry sponsored reports. We found the most sublethal tests have been performed with the fathead minnow, rainbow trout, zebrafish, Medaka, and bluegill. The fathead minnow has the greatest frequency of use over a wide variety of research applications and use of bluegill has become uncommon since the 1990's. With the additional development of shorter tests, i.e., the 7-d growth and survival test and 21-day reproduction tests, a review of the tests and their endpoints is due. The choice of species and method is often based on what makes it a strong model for addressing new challenges in aquatic toxicology, including the identification of sensitive life-stages/endpoints or chemicals with differing modes/mechanisms of action, predicting population-level effects based on data collected from lower levels of biological organization, and exploring/understanding the emerging role of genomics in research and regulation. Much of the ability to application to chronic toxicity hinges on an understanding of chemical mode of action. A summary of the most common methods, species, and duration and will be presented, and endpoints for the tests will be explored.
KEYWORDS: Aquatic toxicity, freshwater, early life stage, fish, sublethal toxicity

**Evaluation of the efficiency of the industrial effluent treatment using the luminescent bacteria toxicity bioassay**

RA Lourenço[1], DP Oliveira[1], EA Savazzi[2]
[1]Faculdade de Ciências Farmacêuticas de Ribeirão Preto - FCFRP/USP, CRAVINHOS, Brazil
[2]Companhia Ambiental do Estado de São Paulo (CETESB), RIBEIRÃO PRETO, Brazil

Introduction: The toxicity assay with the luminescent bacterium Vibrio fischeri is recommended in the assessment of environmental quality, being the only one that can be used to evaluate the toxicity of effluents before and after the treatment, due to the bacterium's ability to tolerate low concentrations of oxygen; it can also be used to evaluate the efficiency of effluent treatment applied by the industries. Considering that the release of industrial effluents containing toxic substances is a major responsible for the contamination of water bodies, control of release of these wastewater is extremely important for the supply of quality water for the population. Objective: To determine the acute toxicity of industrial effluent samples collected in the region of Ribeirão Preto, using the test with luminescent bacteria. Methods: Samples of effluent from two industries (one food and a tannery) were collected before and after treatment of the effluents, following the CETESB collection protocol. The analyses were performed using luminometer coupled to the computer with specific software Microtoxð and culture of lyophilised Vibrio fischeri, following

the protocol recommended by the manufacturer. The assay was performed after 5 and 15 minutes of contact. A sample was considered positive when it caused an inhibition of luminescence of 20% compared to negative control. Results: In both industries studied, the raw effluent was considered toxic. However, at the output, after treatment of these industries, no toxicity was detected under the tested conditions. Conclusion: The study showed that the treatment evaluated by both industries has been effective in removing of the toxicity in relation to toxicity for Vibrio fischeri, thus contributing to preserve the environment. Information on the type of treatment used by these industries was not provided by them.

**Application of Hg specific biosensors to soils: a laboratory to field study**

B Zhang[1], YG Zhu[2], GI Paton[1]
[1]University of Aberdeen, ABERDEEN, United Kingdom
[2]RCEES, Chinese Academy of Sciences, BEIJING, China

The development of assays using a range of environmentally relevant bacterial-based biosensors for the assessment of metal bioavailability in soils and water has advanced over the past decade. In this study, two Hg specific sensors were calibrated using aqueous Hg doses for application to Hg amended and historically contaminated soils. A constitutively-marked biosensor was used to assess the presence and effect of other soil attributes. The response of the Hg specific sensors to Hg amended soil water and soil enabled a dose response to be developed allowing a prediction of Hg dose. However, when the sensors were applied to soils historically contaminated with Hg, the predictive capacity was poor, regardless of the soil solution extraction used. The presence of co-contaminants greatly constrained the applicability of the Hg specific sensors and this was validated both by the response of the constitutively-marked sensor and chemical analysis. Bacterial biosensors may well perform effectively in solutions but this application to historic soil will require further development at the interface between the test medium and the sensor.

**In vitro biological responses to 1D and 2D nanomaterials: carbon nanotubes and graphene**

VC Sanchez, MA Creighton, AB Kane, RH Hurt
Brown University, PROVIDENCE, United States of America

Carbon-based nanomaterials are one of the most important and variable families available. They have geometries that range from spherical (as particles), to fibrous (as one-dimensional nanotubes), and sheet-like (as two-dimensional graphene) forms. Evaluation of potential adverse health effects of these diversely engineered materials requires expensive and long-term in vivo toxicological testing. We have developed an alternative 3D in vitro culture using non-adherent macrophages in order to assess the potential of these materials to induce inflammatory responses and granulomas.

Macrophages are phagocytic cells specialized in recognition, internalization and destruction of a wide variety of stimuli including foreign bodies. They play a central role in the development and maintenance of chronic inflammation, granulomas and fibrosis. Although carbon nanomaterials are non-antigenic and may persist in biological systems, it is suggested that their different geometric structures determine the induction of pathological outcomes. In this model, THP-1 cells were transferred to cell culture wells previously coated with 3% agarose and exposed for up to 14 days to sub-lethal doses of the different carbon nanomaterials. Behaviour in biological systems, cellular interaction and internalization were evaluated.

The CB, MWCNT and FLG were characterized by high-resolution transmission electron microscopy. The capacities of these ultrahigh surface area materials to adsorb biological molecules and alter cell culture media were characterized by adsorption studies and spent media analysis. Vitamins such as pyridoxine HCl and nicotinic acid present in cell culture media were adsorbed in a dose-dependent manner; depletion of other vitamins was material specific.

Macrophages internalize CB particles and MWCNT as well as FLG up to 5 μm in lateral dimension; though they do not internalize the larger FLG, they do interact and tightly adhere to their surfaces. Both the carbon nanotubes and the graphene samples appear to induce the formation of stable cell-material aggregates in the 3D microwells. In the case of nanotubes it will be shown that the cell-material aggregates show the characteristic morphological features and biomarkers of granulomas, such as those observed in recent in vivo studies. The 3D cell culture model could become an attractive alternative to in vivo testing for the prediction of granuloma formation and inflammatory responses to 1D and 2D carbon nanomaterials.

## ET02 - Assessing the exposure, effects and risks of Pharmaceuticals and Personal Care Products (PPCPs) in the environment

[4]College of Natural Sciences, Yongin University, YONGIN, South-Korea
[5]College of Natural Sciences, Soonchunhyang University, ASAN, South-Korea

Abstract
As a part of efforts to address contamination of pharmaceutical residues in Korean waters, we evaluated potential risks of fourteen major pharmaceuticals in Korea. The study pharmaceuticals, i.e., acetaminophen, acetylsalicylic acid, chlortetracycline, cimetidine, ciprofloxacin, diclofenac, erythromycin, ibuprofen, lincomycin, mefenamic acid, oxytetracycline, sulfamethazine, sulfathiazole, and tylosin were chosen based on their occurrences and potential risks in Korea. We reviewed literatures to identify data gap in aquatic toxicity, and conducted appropriate toxicity tests to derive predicted no effect concentrations (PNECs). Occurrence levels of the study pharmaceuticals were also gleaned from available literatures. As test organisms, freshwater invertebrates (Daphnia magna and Moina macrocopa) and fish (Oryzias latipes and Danio rerio) were employed. The PNECs of acetaminophen, acetylsalicylic acid, chlortetracycline, cimetidine, ciprofloxacin, diclofenac, erythromycin, ibuprofen, lincomycin, mefenamic acid, oxytetracycline, sulfamethazine, sulfathiazole, and tylosin were determined 100, 100, 10, 110, 10.6, 100, 1, 10, 7, 0.2, 18.3, 66, 44, and 20.6 μg/L, respectively. The 95% upper confidence limits of the average of measured environmental concentrations (MECs) for acetaminophen, acetylsalicylic acid, chlortetracycline, cimetidine, ciprofloxacin, diclofenac, erythromycin, ibuprofen, lincomycin, mefenamic acid, oxytetracycline, sulfamethazine, sulfathiazole, and tylosin in Korea were determined 0.023, 0.037, 0.050, 0.217, 0.006, 0.013, 0.008, 0.067, 0.059, 0.036, 0.009, 0.024, 0.103, and 0.011 μg/L, respectively. Hazard quotients derived from MECs and PNECs for 14 pharmaceuticals were less than 1, suggesting no potential environmental concerns in Korea. Potential impact of mixture exposure, however, may not be ruled out.

**Risk assessment and management of active pharmaceutical ingredient emissions from manufacturing facilities**

JA Baird, VT Coombe, P Mccormack, RJ Murray-Smith, J Robinson, PF Robinson, JR Snape
AstraZeneca, MACCLESFIELD, United Kingdom

Active Pharmaceutical Ingredient (API) residues have been found to be widespread in the aquatic environment, albeit in most cases at trace levels, with the route to the environment predominantly being via therapeutic use and subsequent excretion to sewer. Whilst manufacturing discharges may be a low overall contributor to environmental concentrations, they need to be managed effectively so that they do not adversely affect the local receiving environment. In order to achieve this, AstraZeneca has developed a risk based approach that identifies the long and short-term concentrations, referred to as the Environmental Reference Concentration (ERC) and Maximum Tolerable Concentration (MTC) respectively, of an API which should not be exceeded in the local aquatic environment receiving the effluent from a pharmaceutical manufacturing site. Performance against these standards has been measured across AstraZeneca's global manufacturing sites through evaluation of process operations and batch scheduling, targeted determination of effluent API concentrations using LC-MS/MS and an understanding of the off-site dilution and fate of effluents.

This poster presentation provides an overview of the ERC and MTC concept, the techniques and challenges in the application of the analytical chemistry and assessment methodologies applied and summary results of the assessments of the effluent quality discharged from AstraZeneca's manufacturing sites.

[8]F. Hoffmann-La Roche Ltd, BASLE, Switzerland

The environmental release of ionisable organic compounds (where behaviour depends on pH, ionic strength, etc.) represents a number of challenges for risk assessors who must select relevant and appropriate test endpoints using methods that have historically been used with more neutral lipophilic compounds. ECETOC have thus established a Task Force to review the current understanding and available literature on partitioning property data of ionisable organic compounds at environmentally relevant pHs, including estimation methods for these properties. It is anticipated that the output of the task force will lead to suggestions and recommendations for improved methods for predicting the environmental concentration of ionisable organic compounds in aquatic environments. To date, the work of the Task Force has emphasised the need for better generic environmental fate models, with appropriate soil and water properties, and other parameters required for effective environmental risk assessment of ionisable compounds. Preliminary findings include identification of the key parameters needed to better predict the bioavailability of ionisable organic compounds, which are shown to be strongly influenced by the physical-chemical properties of the substance, for instance, pKa and log Kow, as well environmental properties such as pH. Modelling activity is supported from data assembled for a physical-chemical property database for ionisable organic compounds used as pharmaceuticals. Using the best available property data a sensitivity analysis has been performed using a number of environmental fate models to determine how variability in environmental input parameters influence the predicted environmental concentration and ultimately the bioavailabilty of a substance.

**TU 150**

**Sediment toxicity assessment and PNEC derivation for cyclic volatile methylsiloxanes**

D Redman
HydroQual, PROVIDENCE, UTAH, United States of America

Cyclic volatile methyl siloxanes (cVMS) are important consumer materials that are used in personal care products as well as industrial applications. These compounds have gained increased attention in recent years following the implementation of chemical legislation programs worldwide (e.g., REACH). Industry-wide research programs are being conducted to characterize the persistence, bioaccumulation and (eco)toxicity properties (e.g., PBT) for cVMS compounds. As part of this larger effort, sediment effects data (acute and chronic) were compared to effects data for other non-polar organic chemicals using the target lipid model (TLM) framework and equilibrium partitioning (EqP) theory. The TLM provided a data-rich framework that was well suited for evaluating potential effects from CVMS compounds based on structures and probable toxic mode of action (e.g., narcosis). Many of the reported acute and chronic effects data for CVMS compounds (D4, D5, D6) were above the measured aqueous solubility when evaluated on a porewater basis using EqP with measured organic carbon partition coefficients (Koc). This suggests that effects observed in laboratory toxicity tests could be due to physical effects (e.g., oiling) in addition to chemical narcosis and have limited relevance since total sediment concentrations of CVMS compounds are relatively very low. Those chronic effects that are below the estimated solubility limit are consistent with the PNEC derived with TLM using bioavailability adjustments for high logKow chemicals (e.g.,logKow>6), which often have reduced bioavailability due to sorption and/or kinetic limitations. The suitability of this adjustment for CVMS compounds was demonstrated by comparing measured biota-sediment accumulation factors (BSAF) to predicted BSAFs using EqP with measured Koc and the bioavailability-adjusted Kow. The TLM-derived PNEC is based on a large dataset of chronic effects data for several organisms from various taxa and is a robust benchmark for evaluating potential risks due to CVMS compounds. This work supports an on-going tissue residue-based risk assessment by evaluating the application of the TLM to CVMS compounds in sediments.

**TU 151**

**An approach to search for potential persistent pharmaceuticals using a multivariate chemical similarity approach**

L Andersson, J Fick, S Rännar
Umeå University, UMEÅ, Sweden
A multidimensional chemical map of drugs was constructed, using principal component analysis, covering 899 drugs described by 67 calculated chemical descriptors. The map of drugs was applied to search for potential persistent drugs using a novel structural similarity tool. The basis for the tool is a selection of anchor molecules (diclofenac, trimethoprim, and carbamazepine) representing drugs of known environmental concern. In addition 12 chemicals listed by the Stockholm Convention on persistent organic pollutants (POPs) were used representing typical environmental pollutants. Chemical similarity was quantified by measuring relative Euclidean distances in the five dimensional chemical map. More than 100 drugs were found within a relative distance less than 10% from each drug anchor, whereas the region of the map closest to the POPs was much less populated. The 15 nearest neighbours (kNNs) of each anchor are presented, showing minor overlaps between the diclofenac, carbamazepine and POP clusters. A literature survey showed that in principal no data is available on the environmental fate characteristics of the identified kNNs except for the non-steroidal anti-inflammatory drug ketoprofen, which was among the diclofenac kNNs. In total 52 individual compounds are identified using the novel read-across tool which could provide a basis for future studies on environmental fate characteristics of drugs.

**TU 152**

**Environmental risk assessment for ancillary substances in biotechnologcal production**

JO Straub, D Gysel, U Kastl, J Klemmer, M Studer
F.Hoffmann-La Roche Ltd, BASEL, Switzerland
More and more pharmaceutical active substances are produced through biotechnological processes. For sustained, safe growth and high yield the organisms need an optimised environment, which is attained through the use of buffers, chelators and antibiotics, beside actual nutrients. These ancillary substances are drained with the wastewater to a wastewater treatment plant (WWTP) and are eventually released to receiving waters. Potential risks of such substances to WWTPs and surface waters were investigated.
Three buffers (MES, MOPS, PIPES), one very common chelator (EDTA) and one antibiotic (Gentamycin) were literature-searched or tested for biodegradability and inhibition of activated sludge as well as toxicity to algae, daphnids and fish. Based on documented use amounts of the ancillary substances in the biotechnological production plants of F.Hoffmann-La Roche Ltd in Basel (CH) and Penzberg (D), actual wastewater fluxes through the WWTP as well as realistic dilution factors for the surface water, site-specific predicted environmental concentrations (PECs) for the respective WWTP and receiving water in Basel and Penzberg were extrapolated. These were compared with predicted no effects concentrations (PNECs) for the wastewater treatment and surface waters, derived from the toxicity results.
PEC/PNEC risk characterisation ratios for the five ancillary substances are presented.

[4]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal
The liver is crucial in detoxification and, consequently, the study of functional and structural liver impacts serve as indicators of toxic exposure and effects. Still, toxicopathological effects in liver after exposure to pharmaceuticals are not yet characterized in fish. So, our purpose was to analyze qualitatively and quantitatively the liver structure of adult zebrafish after exposures of pharmaceuticals, while looking at their estrogenicity. For the latter, vitellogenin (Vtg) induction was assessed by immunohistochemistry. In parallel, a histological and stereological approach was made at light microscopy, in the last case to estimate the so-called volume-weighted mean volume of the hepatocyte nucleus, a potential liver biomarker of environmental stress. Thus, a sub-acute exposure of 21 days was carried out, at a breeding optimal temperature using a selection of five pharmaceuticals (carbamazepine, fenofibric acid, propranolol, trimethoprim and sulfamethoxazole), previously quantified in the Douro River estuary. These compounds, with different modes of action and belonging to distinct therapeutic groups, were tested individually and in mixture. The mixtures corresponded to the maximum levels found in the estuary and to 10,000 times higher.
The immunohistochemistry evidenced that individual exposures to fenofibric acid, propranolol, and both mixtures had potential to induce Vtg expression. This is in line with recent data uncovering surprising estrogenic effects of certain pharmaceuticals. Our results disclosed sex specific reactions and distinct responses depending on the type of exposure. For instance, males had the need to increase the hepatic mass (most likely) to face the higher metabolic demand, while females overcome it quite well (using the baseline hepatic mass and organelle machinery they already had for ovary maturation). Also, the nuclear volume of hepatocytes increased in males after both mixture exposures, which is logically related to a higher metabolic demand and activity. This pattern was not seen after individual exposures.
The study confirmed the usefulness of nuclear volume increases as a general marker of toxicant exposure and highlighted the importance of studying the effects caused by distinct (non-steroidal) pharmaceuticals in mixtures, including realistic environmental levels and considering both sexes.

**The toxicity potential of pharmaceuticals found in the Douro River estuary (Portugal) - Part II: Assessment of impacts in the maturation of zebrafish gonads after sub-acute exposures**

TV Madureira[1], MJ Rocha[2], C Cruzeiro[3], MH Oliveira[4], RAF Monteiro[4], E Rocha[4]
[1]ICBAS - U.Porto, CIIMAR - CIMAR LA, ISCS-N, PORTO, Portugal
[2]ISCS-N and CIIMAR-CIMAR LA, PORTO, Portugal
[3]CIIMAR - CIMAR LA, PORTO, Portugal
[4]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal
The inherent biological activity of pharmaceuticals, nowadays commonly detect in aquatic compartments, together with their potential to interact with similar targets in aquatic species, may induce changes in biological key functions, such as reproduction. Some effects may negatively affect individual and even also the sustainability of a wild fish population. As in aquatic environments the fish are exposed to a great variety of compounds, and there is a currently lack of data concerning the toxic effects caused by non-steroidal pharmaceuticals, this study included carbamazepine, fenofibric acid, propranolol, sulfamethoxazole and trimethoprim as selected compounds. We hypothesized that pharmaceuticals other than those classically associated with reproductive physiology disruption may also affect the gonads, directly or indirectly. Thus, the main goal herein was to assess, using histopathological and stereological analyses, the impacts of these man-made chemicals on the maturation stages of female and male gonads of zebrafish exposed during 21 days. Individual and mixtures of the above referred pharmaceutics were tested, including a low environmental mixture of the five compounds at ng/L levels, as previously quantified in the Douro River estuary (Portugal).
Overall, the stereological analyses of volumes showed a tendency for a diminishing of the most mature cell compartments, namely spermatozoids and late/mature oocytes after individual and mixture exposures and when comparing with controls. Moreover, an increase in spermatocytes and primary oocytes was obtained suggesting, at least, a slow-down in maturation. Nevertheless, a distinct pattern was observed between sexes. The females seemed to be more sensitive to pharmaceutical mixtures, while in males the pronounced differences were registered in the individual exposures. The histological analyses were clearly in line with the quantitative results and evidenced a follicular atresia phenomenon that occurred in female gonads after both mixture exposures.
The present study demonstrates the potential of pharmaceuticals from various therapeutic classes to disrupt the normal kinetic of ovary and testis maturation compartments in zebrafish and, consequently, alerts for the importance of studying the reproductive effects caused by these compounds which are not connoted as endocrine disruptors.

**The toxicity potential of pharmaceuticals found in the Douro River estuary (Portugal) - Part III: Experimental assessment of gross developmental defects using the zebrafish embryo test**

TV Madureira[1], C Cruzeiro[2], MJ Rocha[3], E Rocha[4]
[1]ICBAS - U.Porto, CIIMAR - CIMAR LA, ISCS-N, PORTO, Portugal
[2]CIIMAR - CIMAR LA, PORTO, Portugal
[3]ISCS-N and CIIMAR-CIMAR LA, PORTO, Portugal
[4]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal
The fish embryos are now pointed out as one of the most promising and viable animal alternative tests in environmental toxicology and the zebrafish embryos are particularly advantageous as they allow an easy identification of potential teratogenic and embryotoxic effects. Thus, this study aimed to assess the toxicological effects caused by two distinct mixtures of pharmaceuticals using the zebrafish embryos as experimental model. One mixture corresponds to an environmental realistic scenario found in the Douro River estuary (Portugal) and the other mimics an overestimated mixture of pharmaceuticals. The studied mixtures included five pharmaceutical compounds which were the following: carbamazepine, fenofibric acid, propranolol, sulfamethoxazole and trimethoprim. The assay targeted developmental toxicity.
The mixtures of pharmaceutical compounds proved to induce several physiological and morphological alterations during the embryonic stages. The anatomical changes were mainly spine deformities and yolk-sac edemas. Moreover, a significant diminishing of heart rates and of tail lengths was noted even at ng/L levels. The results showed that the toxic effects are concentration dependent. Other parameters evaluated as mortality, hatching time and spontaneous movements were not affected by mixture exposures.
Even dealing with environmental low concentrations of pharmaceuticals relevant embryotoxic effects were observed. If we face the effects on the zebrafish embryos as proxies of fish embryotoxicity or even of general toxicity potential, the data suggests that risks seem to exist locally for the biota at the current levels of pollution by those pharmaceuticals. According to other data presented at this meeting, the concentrations of compounds tested seem to be able to disturb the gonads and the progeny, indicating that these low levels are potentially more harmful than we could predict.

**Evaluation of whole toxicity of the river waters sampled in urbanized area of Japan, Mainly contaminated by treated and/or untreated sewage.**

H Yamamoto
The University of Tokushima, TOKUSHIMA, Japan
In European and North American countries, bio-assays have been used for the management of industrial and municipal wastewater discharged into the natural aquatic environment. Following the introduction of whole effluent toxicity (WET) regulation using acute Daphnia magna test by South Korea projected to be started in 2011, Japan also started their research on possible introduction of the system similar to USEPA's WET to Japan but information had been limited about the toxicity of the industrial and municipal wastewater in Japan. Thus, our research group has examined the aquatic toxicity of some industrial and municipal wastewater in Tokushima, Japan using the short-term chronic test in USEPA's WET Test Methods with slight modification and found significant adverse effects on the growth of green algae (*Pseudokirchneriella subcapitata*), on the reproduction of *Ceriodaphnia dubia* and/or germination/survival of eggs of Japanese medaka (*Oryzias latipes*) or zebrafish (*Danio rerio*) for several samples. On the other hand, we have been investigated on ecological risk of pharmaceuticals and personal care products and found some PPCPs including some antimicrobial agents and UV filters might be a possible threat for the aquatic organisms.
In present study, the short-term chronic toxicity tests were used to evaluate the distribution of toxicity of river waters sampled in approximately 10 urbanized sites of Tokushima, Kyoto, and Saitama, Japan, where the untreated or treated sewage water is the major source of the contaminants. The reproduction of *Ceriodaphnia dubia* was significantly inhibited in the river waters sampled in at least seven sites while the growth of green algae was significantly inhibited in those sampled in at least three sites. Some potential toxicants, mainly PPCPs, were measured for the water sampled using GC-MS or LC/MS/MS for the water samples in addition to the toxicity tests for twenty individual PPCPs. Toxicity unit (TU) for each individual PPCP was calculated based on NOEC values and compared with the TU of the whole river waters. Relatively higher concentrations of most of PPCPs were found in Tokushima compared to Kyoto and Saitama. Triclosan and other antifungal agents slightly or moderately contribute the whole toxicity of the water samples for algae but the factors other than PPCPs may play important role for daphnid.

**Biologicaly treated Latvian municipal and industrial waste water toxicity to crustaceans D.magna and A.salina**

I Putna, M Balode, S Purvina, S Strake, M Pfeifere
Latvian Institute of Aquatic Ecology, RIGA, Latvia
One of the main reasons of the Baltic Sea pollution is leaching waste water from the waste water treatment plants. With HELCOM Baltic Sea Action Plan the Baltic Sea countries have commit-

ted themselves to achieve Baltic Sea with life undisturbed by hazardous substances hence reaching good environmental quality status.
The aim of this study was to evaluate Latvian municipal and industrial waste water toxicity after their treatment in the waste water biological treatment plants using freshwater (*D. magna*) and saltwater *(A. salina)* crustacean tests.
Tested biologically treated waste water samples were collected in the time period from May 2009 until August 2010 from two industrial and two municipal waste water treatment plants. Toxicity was determined by using two different acute toxicity standard methods: freshwater - ISO *Daphnia magna* immobilization test (EN ISO 6341:1996) and saltwater - *Artemia salina* test (ArtoxKit M standard method).
The acquired results showed that *A. salina* is more sensitive against biologically treated municipal and industrial waste water than *D. magna*. Both test results indicates that Latvian industrial waste water toxicity has a seasonal character showing higher toxicity in autumn and winter while municipal waste water is none or slightly toxic during all seasons. According to test results success of treatment process of Latvian municipal waste waters depend from inhabitant amount in the area the waste water is collected. Study revealed that biological waste water treatment is not sufficient for Latvian industrial waste waters.
This study was performed in the frame of project INTERREG COHIBA (Control of hazardous substances in the Baltic Sea region).

**TU 158**

**Global hepatic gene expression in fish exposed to sewage effluents: a comparison of different treatment technologies**

FG Cuklev[1], E Kristiansson[1], L Gunnarsson[1], C Rutgersson[1], B Björlenius[2], DGJ Larsson[1]
[1]Sahlgrenska Academy, University of Gothenburg, GOTHENBURG, Sweden
[2]Stockholm Water Co., STOCKHOLM, Sweden

Effluents from sewage treatment plants (STPs) contain complex mixtures of pollutants. The addition of more advanced treatment steps to existing plants with conventional treatment has been suggested to enhance the reduction of chemicals, including pharmaceuticals. To assess how effluents treated with different technologies affect biological responses in fish, we have performed in vivo studies with rainbow trout over two weeks. The treatments evaluated include conventional activated sludge alone or in combination with activated carbon, ozone, ozone plus a moving bed biofilm reactor or UV/H2O2 treatment. The study was performed at a semi-large scale pilot plant with parallel treatment lines at Henriksdal STP (Stockholm, Sweden). Fish were also exposed in cages up- and down-stream from another STP with conventional activated sludge treatment (Stadskvarn STP, Skövde, Sweden) to allow a comparison between rigorously controlled exposure conditions and the more realistic field exposure. Previously, we have shown that the conventionally treated effluent induced an increase in liver and heart size. These effects were normalized by several of the advanced treatments. However, we have also shown changes in the blood plasma metabolome upon exposure to e.g. ozone-treated effluents, indicating that advanced treatment steps could potentially produce effluents affecting exposed organisms by unknown modes of action. Here, effects on mRNA expression were studied in order to more specifically identify affected physiological pathways and biomarkers. Quantitative PCR data showed that exposure to conventionally treated effluent induced hepatic zona pellucida glycoprotein 3 (zp3), a marker of exposure to estrogens, and cytochrome P450 A1 (cyp1a), a marker of exposure to dioxin-like chemicals. All advanced treatments reduced the induction of both genes with the exception of cyp1a which was not reduced by UV/H2O2 treatment. Effects on global hepatic gene expression, assessed by microarray, will be reported and related to observed metabolic changes.

**TU 159**

**Assessing fish responses to municipal wastewater in Canadian receiving environments**

M Mcmaster[1], GR Tetreault[1], J Bennett[1], K Shires[1], B Knight[1], C Brown[2], M Servos[2]
[1]Environment Canada, BURLINGTON, Canada
[2]University of Waterloo, WATERLOO, Canada

Municipal Wastewater Effluent (MWWE) is the largest point-source for contaminants to the Canadian aquatic environment. This effluent is a mixture of domestic and industrial wastes, Pharmaceuticals and Personal Care Products (PPCPs). The purpose of this study was to evaluate the potential impacts of these discharges at various levels of biological organization (fish communities and populations and individuals) in the Canadian aquatic receiving environment. In 2005 and 2007, field studies upstream and downstream of two municipal discharges assessed fish communities (diversity and abundance), populations and individual responses in terms of growth (condition factor) and reproduction (in vitro sex steroid production, gonadosomatic indices, and gonad, kidney and gill histopathology). Fish community assessments in 2007 and 2008 demonstrated significant alterations in fish abundance, diversity, and changes in the key species of the river fauna downstream of the MMWE discharges. Fish [Greenside Darter (Etheostoma blennioides) and Rainbow Darter (Etheostoma caeruleum)] collected downstream of the Kitchener and Waterloo municipal wastewater plants had greater condition when compared to reference fish collections. Although fish populations did not display effects to MMWE exposure, individual exposed fish demonstrated physiological alterations in sex steroid productive capacity and male fish demonstrated intersex. Other alterations in histopathology observed included inflammation of tubules in the kidney and stunted gill lamellae.

**TU 160**

**Relationship between Soil Sorption Coefficient (Koc) and Octanol/Water Partition Coefficient (Kow) for Methylsiloxanes**

S Xu, GE Kozerski
Dow Corning Corporation, MIDLAND, United States of America

In environmental modeling, organic carbon normalized soil/water sorption coefficients ($K_{OC}$) of nonionic organic compounds by natural organic matter are often estimated from their octanol/water partition coefficients ($K_{OW}$) using an empirical single-parameter linear relationship. When this approach was used for cyclic methylsiloxanes (cVMS) such as octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), the measured log $K_{OC}$ values for cVMS were found to be much smaller than those estimated based on the empirical model optimized using data for non-siloxane organic compounds as the training set. In order to better understand the relationship between $K_{OC}$ and $K_{OW}$, the measured room temperature values of log $K_{OC}$ and log $K_{OW}$ from literature were analyzed in this study for nonionic (neutral) organic compounds, including volatile methylsiloxanes (VMS). It was found that the aforementioned discrepancy for siloxanes arose from two factors. First, relative to wet n-octanol, wet organic carbon is a more cohesive matrix, stronger H-bonding donor, and more effective at inducing dipoles in polarizable molecules. Secondly, relative to the benchmark non-organosilicon compounds for which the correlation between $K_{OC}$ and $K_{OW}$ was derived, VMS have larger size, strong H-bonding basicity and low polarizability that signify the difference in solvation properties between organic carbon and octanol. Consequently, VMS follow the same scientific principles as other nonionic organic compounds in environmental partitioning, but may not obey the simplified single-parameter relationships.

**TU 161**

**The effects of different synthetic Progestins in fish: potencies vary**

J Runnalls[1], AP Scott[2], JP Sumpter[1]
[1]Institute for the Environment, UXBRIDGE, MIDDLESEX, United Kingdom
[2]CEFAS, WEYMOUTH, United Kingdom

Synthetic progestins are widely used for contraception and hormone replacement therapy. These progestins can be prescribed alone or in combination with synthetic estrogens (for example EE2). In humans, progestins act as contraceptives by inhibiting ovulation. They have been found to be present in the aquatic environment, which is not unexpected given their widespread use. Given the pivotal role that progestins play in human reproduction, it is important to understand the hazard these compounds pose once discharged into the aquatic environment.
Our research has investigated the effects of several synthetic progestins on reproductive performance in the fathead minnow (Pimephales promelas). Using our 45 day 'pair-breeding' assay, we found dramatic effects on reproduction, specifically a complete cessation of egg-laying. Where as some progestogens were active in the low ng/l range, others prevented egg production only when concentrations were above 1ug/l. Other effects seen included induction of secondary sexual characteristics in female fish (tubercles, fin spots and fat pads) and effects on plasma steroid levels. We propose that progestins are potentially a serious threat to aquatic wildlife, perhaps more so than the much-studied estrogens!

**TU 162**

**Dose-response effects of chronic exposure of Fathead Minnows to low concentrations of a synthetic glucocorticosteroid**

S Kugathas, TJ Runnalls, JP Sumpter
Brunel University, UXBRIDGE, United Kingdom

Human pharmaceuticals present in the aquatic environment could adversely affect aquatic organisms, particularly fish. Synthetic glucocorticosteroids (GC) are used in large quantities as immunosuppressive and anti- inflammatory drugs. Many GCs are halogenated to increase the persistence in the human body, so they might be expected to be relatively resistant to degradation and hence present in the aquatic environments. Some reports have quantified the environmental concentrations of GCs in the hundreds of nanograms per litre range. In order to assess the impact of environmental concentrations of GC, an in-vivo exposure experiment was conducted with adult fathead minnows. Fish were exposed (ten male and ten female in each tank in duplicate) to 100ng, 1µg or 10µg Beclomethasone dipropionate /L via a flow through system. Similar duplicate tanks served as control, with no chemical added. After 21days of exposure, all fish were terminally sampled to determine various endpoints. There was a dose-response increase in plasma glucose levels and a decrease in blood lymphocyte counts and plasma cortisol levels. Secondary sexual characters in females suggest a dose-related masculinisation of fathead minnows which is not predicted from the mechanism of GC action. Expression profiles of selected genes (PEPCK, GR and Vtg) in liver via real-time PCR studies also resulted in dose-related effects at all three tested concentrations. Hence, we are not be able to define a no effect concentration for this chemical. The results suggest that GCs could cause effects in very low (as low as 100ng/L) concentrations that could be environmentally-relevant. Therefore, studies to determine the environmental concentration of GCs and to determine no effect concentration are needed to assess if GCs pose a risk to aquatic environment.

**TU 163**

**Effect of azole fungicides on testicular steroidogenesis in vivo and ex vivo in zebrafish (Danio rerio)**

D Baudiffier, N Hinfray, JM Porcher, F Brion
INERIS, VERNEUIL-EN-HALATTE, France

The occurrence of several azole fungicides in aquatic environment has been recently reported but their endocrine effects in fish are poorly studied. The aim of the present study was to assess the effect of clotrimazole, a pharmaceutical fungicide, on expression of key target genes (StaR, cyp17a1, cyp11b2) involved in testicular steroidogenesis as well as on 11- ketotestosterone (11KT) biosynthesis.
For that purpose, we first exposed adult male zebrafish to a wide range of clotrimazole concentrations (from 0.01 µM to 0.3 µM) for 7 days. In vivo exposure to clotrimazole resulted in an increase of cyp17a1 and cyp11b2 gene expressions in testis. To gain further information about the mechanism of action of clotrimazole, zebrafish testicular explants were exposed to similar concentrations of clotrimazole, with or without forskolin (FSK), an activator of the cAMP pathway that stimulates steroidogenesis. FSK (1 µM) strongly up-regulated cyp17a1 and cyp11b2 gene expressions and increased 11KT release in the culture medium. Clotrimazole (0.2, 1, and 5 µM), alone or in combination with FSK (1 µM), did not change basal or FSK-induced expression of cyp17a1 and cyp11b2. However, it inhibited both basal and FSK-induced 11KT release ex vivo, suggesting it acted as an inhibitor of steroidogenic enzymes. In order to determine whether other compounds belonging to the azole family are able to elicit similar effect on testicular steroidogenesis as clotrimazole, two other azole fungicides known to contaminate aquatic environment were tested, fenbuconazole and propiconazole. We showed that exposure of male zebrafish for 7 days to fenbuconazole and propiconazole had no significant effects on steroidogenic gene expressions while ex vivo both azoles was able to inhibit the 11KT release. Overall, our results show for the first time that the pharmaceutical fungicide clotrimazole is able to affect key steroidogenic genes expressions in a fish testis. However, the marked differences observed between in vivo and ex vivo experiments suggest that clotrimazole does not act directly on testes to regulate cyp17a1and cyp11b2 transcription. Whatever, using the testis tissue explants model, we demonstrate a direct action of clotrimazole, and to a lesser extent propiconazole and fenbuconazole, on the gonad which results in inhibition of 11KT synthesis. These original data deserve further studies on the effect of these compounds on fish reproduction

[4]National Institute of Environmental Research, INCHEON, South-Korea
[5]Korea University, SEOUL, South-Korea

[6]Nanjing University, NANJING, China
[7]University of Saskatchewan, SASKATOON, Canada
Pharmaceuticals in the environment are of growing concern for their potential endocrine disruptions in ecosystem. Using a human adrenal H295R cell line and in vivo systems, we investigated the potential endocrine disrupting effects of six pharmaceuticals (diclofenac, erythromycin, ibuprofen, sulfathiazole, chlortetracycline, and oxytetracycline). After exposure to each target pharmaceutical for 48 hr, production of 17β-estradiol (E2) and testosterone (T), aromatase (CYP19) enzyme activity, or expression of steroidogenic genes were measured. Among target pharmaceuticals, ibuprofen, sulfathiazole, oxytetracycline and chlortetracycline enhanced E2 production. This observation was accompanied by increased aromatase activity and up-regulation of CYP17, CYP19, CYP11β2 or 3βHSD2 mRNAs, which are important components of steroidogenic pathways. After the ~120 d chronic exposure ibuprofen, sulfathiazole or chlortetracycline lead to changes in several reproduction related endpoints in Oryzias latipes, including up-regulation of vitellogenin gene level in male fish or fewer broods per pair. In addition, plasma E2 concentrations increased significantly after 14 days of exposure to 50 or 500 mg/L sulfathiazole, or 40 mg/L chlortetracycline in adult male medaka (3-4 monthes old). Based on the results of this study, certain pharmaceuticals could affect steroidogenic pathway, alter sex hormone balance, and eventually damage the reproduction in organisms.

## TU 165
**Sub-lethal effects induced by the non-steroidal anti-inflammatory drug (NSAID) ibuprofen on the freshwater bivalve Dreissena polymorpha**

M Parolini, AB Binelli, AP Provini
University of Milan, MILAN, Italy

Pharmaceutical compounds are considered emerging environmental pollutants, since hundreds of these molecules are commonly revealed in the aquatic environment in the high ng/L to low µg/L range worldwide. Non-steroidal anti-inflammatory drugs (NSAIDs) are a group of therapeutic molecules that share similar pharmacologic properties and are widely used for control of pain and inflammation. Among these, ibuprofen (IBU; ((+/-)-2-(p-isobutylphenyl) propionic acid with R and S isomers), being one of the core medicines included in the "Essential Drug List"of World Health Organization, is produced, sold and used in great amount worldwide. Because of its considerable selling, often over-the-counter, large prescription volume, and high excretion degree as parent compound and/or in form of metabolites, IBU has been identified as one of the main pharmaceuticals present in the aquatic ecosystems. Notwithstanding, at present, few studies have evaluated its potential toxicity toward non-target organisms.
Sub-lethal effects induced by this NSAID were investigated by using a multi-biomarker battery applied to the freshwater bivalve *Dreissena polymorpha*. According to a semi-static in vivo approach, zebra mussels were exposed for 96 h to increasing environmentally relevant IBU concentrations (1, 9 and 35 nM), perfectly comparable to those currently revealed in aquatic ecosystems. Cyto-genotoxicity was evaluated by the single cell gel electrophoresis (SCGE) assay, the DNA Diffusion assay, the micronucleus test (MN test), and the lysosome membrane stability (Neutral Red Retention Assay) on mussel haemocytes. In addition, the activity of catalase (CAT), superoxide dismutase (SOD), glutathione peroxidase (GPx) and the phase II detoxifying enzyme glutathione S-transferase (GST) was measured in the cytosolic fraction extracted from a pool of entire bivalves in order to reveal a possible oxidative status unbalance of treated-specimens. The biomarker battery pointed out a slight cyto-genotoxicity on zebra mussel haemocytes at low environmental levels (1 nM), while higher IBU concentrations were able to significantly increase both genetic (apoptotic and MN cells) and cellular damage. In addition, IBU seems to induce moderate effects on the activity of antioxidant and detoxifying enzymes, as shown by the notable oxidative status unbalance of exposed bivalves.

## TU 166
**Ibuprofen: an early life-stage toxicity test with the fathead minnow (pimephales promelas)**

N Maack[1], SP Gallagher[2], O Krueger[2], A Leopold[2], U Rechenberg[1]
[1]Federal Environment Agency, Germany, DESSAU, Germany
[2]Wildlife International, EASTON, United States of America

Human pharmaceuticals are regularly detected in the aquatic environment, especially those produced in very large quantities. The guideline for human medicinal products, finalized in 2006, is used to estimate the environmental risk of human pharmaceuticals and requires data that includes chronic toxicity data for Algae, Daphnia and Fish. Such data are often missing for products with a market authorization before 2006. Alternatively literature data, frequently of poor quality, were used instead, leading to greater uncertainty and often to a debate about the general usage of these data. This is the case for Ibuprofen as well. Therefore we conducted an Early Life Stage Toxicity Test with the Fathead Minnow (*Pimephales promelas*) according to OECD 210. Fathead minnow embryos were exposed to a geometric series of six test concentrations and a negative (dilution water) control under flow-through conditions. The exposure period included a 5-day embryo hatching period, and a 28-day post-hatch juvenile growth period. Mean measured concentrations were 0.0091; 0.029; 0.092; 0.30; 0.93, 3.0 mg/L respectively. Four replicate test chambers were maintained in each treatment and the control group, with one incubation cup in each test chamber. Endpoints measured were hatching success, survival and growth respectively. There were no statistically significant treatment-related effects on hatching success, survival or growth at concentrations ≤3.0 mg/L. Consequently, the NOEC, based on all parameters measured, was 3.0 mg/L, the highest concentration measured. The LOEC was >3.0 mg/L

## TU 167
**Changes in global gene expression profiles and development of biomarker gene(s) in larval zebrafish exposed to selective serotonin reuptake inhibitors (SSRIs)**

JW Park[1], TB Henry[1], HC Reinardy[2]
[1]The University of Tennessee, KNOXVILLE, United States of America
[2]University of Plymouth, PLYMOUTH, United Kingdom

The selective serotonin reuptake inhibitors (SSRIs) are a group of pharmaceuticals used in human medicine to block serotonin reuptake on cell membranes and elevate the levels of the neurotransmitter serotonin. Some SSRIs and their metabolites have been detected (sub to low ppb levels) in surface waters receiving inputs from wastewater treatment plants. In non-target organisms such as fish, SSRIs can act on the neuronal and neuro-endocrine signalling system and potentially influence higher levels of biological organization including reproduction and behaviour. To obtain a better understanding of the biochemical pathways that are influenced by SSRI exposure in fish, we evaluated global gene expression profiles for two representative SSRIs (fluoxetine and sertraline) to determine if the expression pattern of specific genes could be used as indicators of SSRI exposure in fish. Larval zebrafish Danio rerio were exposed to two concentrations (25 and 250 ppb) each of fluoxetine and sertraline for 5 days prior to extraction of total RNA for global gene expression analyses based on the Affymetrix GeneChip® Zebrafish Genome Array platform. No mortality or changes in fish behavoir were observed during the exposure, however alterations in global gene expression indicated treatment effects on gene regulation. The number of genes with significantly altered expresion > 1.5 fold relative to the control was 482 genes for 25 ppb fluoxetine, 242 genes for 250 ppb fluoxetine, 66 genes for 25 ppb sertraline, and 90 genes for 250 ppb sertraline. Ten genes were differentially regulated in all treatments relative to the control, suggesting that both SSRIs share some similar molecular pathways during larval zebrafish exposure. Of particluar interest in GO analysis under biological process of fluoxetine exposure was that many differentially expressed genes identified by microarray were involved with stress responses. The observed quantitative relationship between common or different transcriptional responses among treatments led to identification of potential biomarker genes and these genes include: acetylcholinesterase and FK506 binding protein 5. We are currently investigating changes in expression of these and other genes influenced by SSRI exposure in zebrafish by quantitative reverse transcriptase PCR, and these results will lead to enhanced understanding of the effects of environmental SSRI exposure in fish and development of biomarkers of exposure to SSRIs.

## TU 168
**Cyclic volatile methylsiloxane (cVMS) residues in fat, muscle, and liver tissue of American mink (Mustela vison) obtained from Lake Pepin, Minnesota USA**

KB Woodburn, DE Powell, JA Durham
Dow Corning Corporation, MIDLAND, United States of America

The concentrations of cyclic volatile methylsiloxane (cVMS) materials were measured in mink tissue (fat, muscle, and liver) taken from organisms collected from the marsh areas of Lake Pepin, Minnesota, USA. This large freshwater lake has previously been examined for the trophic magnification behavior of the cVMS compounds octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6) in an aquatic food web consisting of benthic invertebrates and fish. Three male and one female mink were captured on Lake Pepin in November 2008 by a commercial fur trapper. The mink were dissected to remove the liver, perirenal fat, and a portion of quadriceps muscle from a rear leg. The stomach was also removed for content identification to identify dietary preferences immediately prior to death. For D4, Lake Pepin lipid adjusted aquatic organism concentrations ranged from approximately 300 to 900 ng/g-lipid in benthic invertebrates, to ~40 to 350 ng/g-lipid in fish, to <LOD in mink fat. For D5, lipid-adjusted Lake Pepin concentrations ranged from approximately 4000 to 18000 ng/g-lipid in benthic invertebrates, to ~174 to 3000 ng/g-lipid in fish, to a mean value of 44 ng/g-lipid in mink fat. Finally for D6, the Lake Pepin lipid-adjusted concentrations ranged from approximately 150 to 1300 ng/g-lipid in benthic invertebrates, to 10 to ~170 ng/g-lipid in fish, to a mean value of 5 ng/g-lipid in mink fat. The Lake Pepin mink data demonstrate continued trophic dilution of cVMS in higher trophic level species, a trend that is similar to that reported for cVMS in food webs terminating in seabirds (i.e., kittiwakes and eiders) and grey seals.

## TU 169
**Phytotoxicity, persistence and uptake of antimicrobial salinomycin in the plant Brassica rapa**

L Stephenson[1], V Furtula[2], J Liu[2], P Chambers[2], F Wrona[2]
[1]Stantec Consulting Ltd., GUELPH, Canada
[2]Pacific Environmental Science Centre, NORTH VANCOUVER, BC, Canada

The phytotoxicity of the veterinary antimicrobial salinomycin, both in a pure form (96%) and in formulation as Sacox120 (120g of salinomycin/Kg), to the plant *Brassica rapa* and its persistence in soil was evaluated. Plants were grown for 14 days under controlled conditions in natural standard soil (LUFA 2.2) amended with concentrations ranging from 1.6 to 32 mg Sacox120/Kg dry weight of soil (DWS) and 0.095 to 7.68 mg salinomycin sodium /Kg DWS. LCMS analyses of salinomycin in soil was conducted to confirm the concentrations at the beginning and the end of the chronic exposure test as well as to investigate its stability and persistence over a 15-day period with no plant growth. Measurement endpoints included shoot and root length, shoot and root wet and dry mass, seedling emergence, and flower bud formation; assessment endpoints included the interpolated IC50s and IC25s for each endpoint. Growth of plants exposed to pure salinomycin was affected at concentrations between 0.35 and 3.71 mg/Kg DWS. The IC50s for growth of plants exposed to Sacox120 ranged between 23 and 38 mg/kg DWS. When the ICps for Sacox 120 were adjusted for the active ingredient, the ICps ranged between 2.7 and 4.5 mg Salinomycin/kg DWS, indicating that the other constituents in the formulated product had little influence on the efficacy of the active ingredient. Seedling emergence was either less sensitive or comparable to the growth metrics and production of flower buds was the least sensitive. Although toxicity can be soil, chemical, species, and endpoint specific, the effect levels were surprisingly consistent among growth endpoints. LCMS analyses of LUFA 2.2 soil at the beginning of the chronic exposure test confirmed the theoretical concentrations of salinomycin with average recoveries across the whole range of exposure concentrations being 90% and 83% for Sacox120 and salinomycin, respectively. At the end of the 14-day chronic exposure test salinomycin concentration had deceased to 5.8% and 6.2% of theoretical values. Decay curves for Sacox120 and salinomycin in LUFA 2.2 soil for two different concentrations (low and high) with no plants present showed no change in salinomycin concentrations over a 15-d period. These experiments demonstrated that the presence of plants and microbial flora have a significant effect on salinomycin concentrations in soil.

## TU 170
**Assessment of chronic effects of Ivermectin in Danio rerio using several parameters**

R Oliveira[1], Pedro Leal[1], FN Ferreira[2], JB Amorim[1], I Domingues[1], MVM Soares[1]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Universidade de Brasília, BRASÍLIA, Brazil

Ivermectin (IVM), a veterinary pharmaceutical, is widely used in livestock production and is a component of various parasiticides. No information is available about the chronic effect of IVM to fish species, despite the vast literature about IVM effects to non-target organisms. In this study it was performed a chronic test based on the OECD (2008) guideline - Fish Screening Assay for Endocrine Active Substances. The test species Danio rerio was used. Concentrations ranged between 0.25-25µg IVM /L, with a daily medium exchange. At test end, lethal and sublethal endpoints were measured: survival, growth, behaviour (swimming and feeding), biomarkers (catalase-CAT, cholinesterase-ChE, and glutathione-S-transferase-GST), and reproductive markers (gonads histopathology and vitellogenin-VTG levels). Results showed mortality at 25µg IVM/L. IVM affected growth, particularly in males. Swimming behaviour disturbances occurred in all tested concentrations: lethargic movement and erratic swimming, spending more time at the bottom of the aquarium. Feeding behaviour showed that organisms exposed to the highest concentrations were using more time for the first strike and for complete pellet ingestion. GST was inhibited also at the highest concentrations of IVM. Qualitative histophatological analysis showed no alterations in male and female gonads.Vitellogenin levels were affected in females, with an inhibition at the highest concentration. Besides the assessment of effect concentrations of IVM to Danio rerio, the combined use of this series of endpoints contributed to a better understanding of the underlying mechanisms of toxicity of IVM.

### TU 171

**Effects of sequential exposure to Ciprofloxacin and Sulfamethoxazole in marine microbial biofilms**

CH Johansson, KM Eriksson, L Janmar, S Fleiss, T Backhaus
University of Gothenburg, GÖTEBORG, Sweden

Many human pharmaceuticals are emitted into the aquatic environment after usage and antibiotics belong to a commonly detected group. Designed to be effective at low concentrations, it is hence likely that environmentally realistic concentrations of antibiotics directly affect environmental microbes. Also, antibiotic resistance is increasingly recognized as a potential threat to human health. In particular there is concern that resistance will develop in natural bacterial communities and spread to pathogenic bacteria.

To test whether environmentally realistic concentrations of antibiotics affect natural communities and lead to tolerance developments, a flow through microcosm experiment was performed in 2010. Long-term effects of two antibiotics were studied on periphytic biofilms (communities of predominantly microalgae and bacteria), established in aquaria from the indigenous micro-biota found in the natural seawater in the Gullmar fjord on the Swedish west coast.

During the first two weeks the communities were continuously exposed to either Ciprofloxacin (CIP) or Sulfamethoxazole (SMX) at nominal concentrations of 1nmol/L. Afterwards the exposure regimes were changed, so that communities previously exposed to CIP were exposed to SMX (1, 14, 200nmol/L) instead and vice versa for communities originally exposed to SMX. This second phase lasted five days.

At the end of each exposure regime the communities were sampled and assessed with respect to various ecotoxicological endpoints. Chl a content and pigment patterns were used to describe the effects on the algal part of the communities, while effects on bacteria were investigated using bacterial production (3H-Leucin incorporation) and bacterial catabolic profiling (Biolog Ecoplates). Samples were also taken to study the genetic profiles of the exposed communities.

### TU 172

**Toxicity assessment of oxytetracycline at different trophic levels**

R Oliveira[1], S Mcdonough[2], F Pitanga[1], AM Moura[3], R Bhujel[2], MVM Soares[1], JA Nogueira[1], I Domingues[1]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]2AARM (Aquaculture and Aquatic Resources Management), Asian Institute of Technol, PATHUNTANI, Thailand
[3]Instituto Biológico,, CAMPINAS, SÃO PAULO, Brazil

Use of antibiotics in the aquatic environment has become an important concern. Oxytetracycline (OTC) is one of the most common veterinary antibiotics used worldwide. OTC is utilized in fish and shrimp farming, and for other animal intensive farming systems, as a growth promoter or for bacterial disease treatment. Several field studies have showed that OTC can persist in the sediment of aquatic environments for more than180 days. Considering the extensive use and high environmental persistence of OTC, this study aims at assessing the lethal and sublethal toxicity of OTC for species of different trophic levels. To achieve these objectives a battery of acute toxicity tests with algae, rotifers, crustaceans and fish were performed following OECD and ToxKit protocols. Following the acute toxicity assessment, different assays were performed for sublethal effect assessment. Representative biomarkers from different metabolic pathways were chosen (catalase-CAT, lactate dehydrogenase-LDH, cholinesterase-ChE, and glutathione-S-tranferase-GST) and teratogenic endpoints were determined using Danio rerio embryos. The results of OTC acute toxicity show Thamnocephalus platyurus, a freshwater species, as the most sensitive species with a 24h-LC50 of 0.042 mg/l (CI: 0.039-0.044) and Artemia salina, a saltwater species, as the most resistant with a 24h-LC50 870 mg/l (CI: 797-987). No difference was found on morphological development of zebrafish early life-stages but a significant ($p<0.05$) delay in hatching time was found for embryos exposed to concentrations above 150 mg/l. The enzymatic markers analyzed showed inhibition of oxidative stress enzyme (96h-LOECCAT = 5mg/L) and effects of OTC on detoxification phase II (96h-LOECGST =10mg/L) pathways. In comparison with the 96h-LC50 of 330 mg/l (CI: 314-345) for zebrafish embryos the sublethal endpoints analyzed seem to be more accurate in effects assessment of OTC. Linkages between the sublethal (enzymatic and developmental parameters) effects found in this study indicates that with parameters at higher levels of organization are essential for better understanding of the effect of OTC on organisms and the environment. Moreover, studies on environmental risks of OTC, even at lower concentrations focusing on long term effects applying other methods such as chronic toxicity tests, mesocosm assays, and mixture exposures should be carried out.

### TU 173

**Multi-generation life-cycle toxicity assessment of triclosan using Daphnia magna**

K Sibley, B Lucas
University of Guelph, WATERLOO, Canada

Triclosan is a ubiquitous compound in wastewater treatment plant effluents and biosolids and is commonly detected in surfaces waters throughout North America and Europe. The acute toxicity of triclosan (TCL) toward aquatic organisms has been relatively well studied but information on long-term, low level exposures at environmentally relevant concentrations is needed. The objective of the present study was to evaluate the toxicity of triclosan in a multi-generational test with the waterflea *Daphnia magna* in a laboratory exposure. *Daphnia* were exposed to nominal concentrations of TCL ranging from 0.5 to 250 μg/L in 21-d tests for five generations (we have completed the second generation). Brood randomly collected from five replicate beakers after the 21-d exposures were used to seed to next generation. Endpoints measured included survival, number of offspring (total and per adult), and cumulative number of offspring. After the first generation, a 21-day LC50 value could not be calculated due to high adult survival; after the second generation, an LC50 of ~140 μg/L was determined with a NOEC of 100 ug/L suggesting increased sensitivity in pre-exposed animals. Time to first brood increased significantly, and the number of offspring decreased significantly with increasing concentration during each of the first two generations but relative LC50 and NOEC values were comparable. No effects were observed at concentrations <100 μg/L indicating that triclosan may pose minimal long-term risk to aquatic invertebrates at environmentally relevant concentrations.

### TU 174

**Ecological risk assessment of selected antifungal and antimicrobial agents in small urban creeks in Tokushima, Japan, with unsewered drainage area**

I Tamura[1], Y Yasuda[2], S Yoneda[2], K Kagota[1], K Kimura[3], Y Kameda[4], n Tatarazako[5], H Yamamoto[6]
[1]Graduate School of Integrated Arts and Sciences, The University of Tokushima, TOKUSHIMA, Japan
[2]Faculty of Integrated Arts and Sciences, University of Tokushima,, TOKUSHIMA, Japan
[3]Saitama City Institute of Health Science and Research, SAITAMA, Japan
[4]Center for Environmental Sciences in Saitama, SAITAMA, Japan
[5]National Institute for Environmental Studies, TSUKUBA, Japan
[6]Institute of Socio, Arts, and Sciences, The University of Tokushima, TOKUSHIMA, Japan

Pharmaceuticals and personal care products (PPCPs) are widely used in our daily life as drugs and cosmetics. Sewage and household effluent containing PPCPs, which are designed to show certain physiological effects, may have harmful effects on some aquatic organisms. Among these compounds, four antifungal or antimicrobial agents, triclosan, triclocarban, 4-chloro-3-methylphenol (PCMC) and 4-chloro-3,5-dimethylphenol (PCMX), used in products such as antiseptic soaps and cosmetics, were selected and their ecological risk was estimated in small urban creeks in Tokushima, Japan, highly contaminated by treated or untreated sewage. The concentrations of these compounds and other antibacterial and antifungal agents (e.g., chlorothalonil, 2-phenoxyethanol, 3-methyl-4-isopropylphenol) were monitored using a GC-MS using trimethylsilyl derivatization. The sunlight photolysis and river water die-away test were conducted to examine the persistence of these compounds in the aquatic environment in addition to the sorption of these compounds to determine the partitioning between aqueous and sediment phase. Furthermore, acute toxicity of these compounds were evaluated using fish (Oryzias latipes), daphnia (Daphnia magna), green algae (Pseudokirchneriella subcapitata), and chironomid (Chironomus yoshimatsui) while short-term chronic toxicity were evaluated using fish eggs (Danio rerio), daphnid reproduction (Ceriodaphnia dubia), NOEC of green algae, and chironomid.

First, triclosan was detected as high as 155 ng/L. The other antifungal/antimicrobial agents, triclocarban, 3-methyl-4-isopropylphenol and 2-phenoxyethanol were also detected in most of the sampling sites while the other agents were under the detection limit in most of the sampling sites. The results of biodegradation experiments suggest relatively slow biodegradation of triclosan and triclocarban while those of photolysis experiments suggested relatively rapid photodegradation of the two. Triclosan was found to be very strongly toxic for algae with 96h-EC50 of 2.8 μg/L but moderately toxic for daphnid and fish, and the measured concentration/predicted no effect concentration (MEC/PNEC) ratio exceeded 1 in water and the MEC/PNEC ratio was in the range between 0.1 and 1 in sediment. Triclocarban showed the similar trend. For the other antifungal/antimicrobial agents, MEC/PNEC values were far below 0.1 and no severe risk for aquatic organisms is suspected.

### TU 175

**Cytostatic drugs - are they environmentally relevant?**

I Ebert, S Schmitz, I Vogel
Federal Environment Agency, Germany, DESSAU, Germany

Pharmaceuticals are emerging micropollutants of concern. Cytostatic drugs are discussed as high risk substances in regard of human health. In addition they are considered as problematic for the environment. Chemotherapy drugs are of potential environmental relevance due to their poor biodegradability. The toxicity of chemotherapy drugs to humans is well known whereas very little is published about the toxicity to the environment.

The demand for chemotherapy treatment is increasing from year to year. It is expected that the consumption of cytostatic drugs will rise not only for human use but also in veterinary medicine. Therefore, an increase of these substances in the environment is also expected in the future.

The aim of this work is to survey the ecotoxicological potential of this special group of human pharmaceuticals. Since 2006 data requirements for the environmental risk assessment of human pharmaceuticals are mandatory for the authorisation procedure within the EU. So far, applicants have provided a multitude of acute effect data but only a limited number of long term effect and fate data within the authorisation process. Fate and effect data from applicants as well as data from publicly available literature will be analysed regarding acute and chronic toxicity and biodegradability. Furthermore, for some most widely used cytostatic drugs the relevance for the environment will be emphasised based on recent consumption data and measured environmental concentrations.

### TU 176

**The neutral species of the weak base trimethoprim is more toxic to willow trees (Salix viminalis) than the cation**

O Mikes[1], S Trapp[2]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Department of Environmental Engineering, Technical University of Denmark, KGS.LYNGBY, Denmark

The acute toxicity of the veterinary antibiotic trimethoprim (TMP) to willow trees was tested at three different pH levels in hydroponic solutions with TMP concentrations of 1, 10, 100 or 1000 mg/L. The pH variation was achieved by using ammonium (pH 4.3, low) or nitrate (pH 6.4, medium) as nitrogen source, and by additional tritration with KOH (pH 8.15, high). TMP is a weak base that dissociates at pKa 7.2. A statistically significant higher toxicity of the neutral form was observed, i.e. a higher toxicity at medium and high pH than at low pH. A toxic effect of the neutral form was observed at an external concentration of 100 mg/L, while the toxicity of the cation appeared only at the concentration of 1000 mg/L. The result of the study shows that the toxicity of TMP to willow trees is low, but also that the toxicity of weak bases varies with pH.

### TU 177

**Ecotoxicity tests to evaluate the toxicity of some anticancer drugs released in hospital waste water**

NR Mater[1], V Faucet-Marquis[1], C Albasi[1], L Castillo[2], A Pfohl-Leszkowicz[1]
[1]Laboratoire de Génie Chimique, AUZEVILLE-TOLOSANE, France
[2]Water Research Center, MAISONS LAFFITE, France

Most pharmaceutical compounds are excreted partially transformed or even unchanged via urine and faeces of patients under medical treatment. As hospital effluents reach the municipal sewer network generally without preliminary treatment, they can reach environment and affect animals, plants, but also human health via drinking water. The aim of this research is to validate biomarkers to evaluate the potential toxicity of drugs (ciprofloxacin, tamoxifen) frequently used in cancer chemotherapy in range of concentrations found in waste water. In the present study, several bioassays have been optimized : (i) cellular viability of human cell exposed in vitro to ciprofloxacin or/and tamoxifen, (respectively 0.3 μg.L-1 to 0.3 mg.L-1 and 5.6 ng.L-1 to 56 μg.L-1) during 24-72h ; (ii) growth inhibition of the aquatic plant Lemna minor. Plants were exposed during seven days at the same concentration as the cells. Ciprofloxacin and tamoxifen even at low doses are toxic for

human cell and plant models. Effects were different depending on the relative proportion of the drugs applied to cells, suggesting different target and action of these compounds.
Other bioassays will be optimized, in particular the 32P post-labelling technique to determine DNA adduct reflecting genotoxic effect.

**TU 178**

**Cytochrome P450 (CYP) 3A activity in Atlantic salmon (Salmo salar) liver microsomes**

V Zlabek[1], G Zamaratskaia[2]
[1]University of South Bohemia in Ceske Budejovice, FFPW, VODNANY, Czech Republic
[2]Swedish University of Agricultural Sciences, Department of Food Science, UPPSALA, Sweden

Cytochrome P450 3A (CYP3A) is involved in hepatic metabolism of a number of endogenous and exogenous including commercially available drugs. This isoform is well studied in mammals, whereas considerably less information is available on CYP3A in fish. However, the role of fish CYP3A in detoxication of aquatic pollutants and pharmaceuticals potentially implies the possibility of using CYP3A as a biomarker in aquatic pollution monitoring.
This study investigated an applicability of the marker substrates of mammalian cytochrome P450 (CYP) 3A for fish. For this purpose, the effect of a selective CYP3A inhibitor ketoconazole on in vitro metabolism of several substrates was studied. Following compounds were investigated as possible substrates for CYP3A: 7-benzyloxyresorufin (BR), 7-ethoxyresorufin (ER), 7-benzyloxy-4-trifluoromethylcoumarin (BFC) and 7-benzyloxyquinoline (BQ). These substrates were incubated with a pool of liver microsomes from 4 fish (Atlantic salmon) with or without ketoconazole. The concentrations of ketoconazole in the incubations were 1, 10 and 40 µM . The product formation from those substrates was measured by HPLC. The mode of inhibition and inhibition constants (Ki) were determined by a GraphPad Prism version 4.0 for Windows, GraphPad Software (San Diego California, USA).
Ketoconazole was a potent competitive inhibitor of BR (Ki=45.3 µM) and BQ (Ki=1.6 µM) and non-competitive inhibitor of BFC metabolism (Ki=2.3µM) in the microsomes. The results indicate that BFC and BQ can be used as substrates to estimate CYP3A activity in fish liver microsomes.

**Effects of sodium hipochlorite in different trophic levels**

F Pitanga, R Oliveira, I Domingues, M Moura, R Bicho, AMVM Soares
CESAM & University of aveiro, AVEIRO, Portugal

Sodium hypochlorite (SH) is a chemical compound used on a large scale, frequently as a disinfectant or a bleaching agent. It is present in agriculture, chemical, paper, pharmaceutical and waste disposal industries, among others. Chlorine disinfectants in wastewater react with organic matter, giving rise to organic chlorine compounds which are toxic for aquatic organisms and are persistent environmental contaminants.
In this work we assessed the toxicity of SH to organisms belonging to different trophic levels. Effects of SH were evaluated in the growth of the algae Pseudokirchneriella subcapitata and Chlorella vulgaris (concentrations ranging from 0,1 to 100 mg/L), in the survival of Artemia fransciscana and Thamnocephalus platyurus (concentrations ranging from 0,05 to 10 mg/L) and in Danio rerio (zebrafish). Zebrafish assays include acute (concentrations ranging from 0,7 to 10,1 mg/L) and chronic (concentrations ranging from 5 to 500 µg/L) exposure of adult organisms and early life stages test in which embryo development was monitored. The biomarkers lactate dehydrogenase (LDH); GST,glutathione-S-tranferase (GST); Cholinesterase (Che) and catalase (CAT) were measured after zebrafish early life stages and adults exposure to SH.
Most sensitive species was T. platyurusand with a LOEC of of 0,5 mg/L, followed by P. subcapitata (LOEC =1 mg/L), C. vulgaris (3,2 mg/L), A. fransciscana (10 mg/L) and D. rerio (adult) (5,5 mg/L). Moreover, it was observed that SH induced an early hatching in D. rerio embryos exposed to concentrations above 6,4 mg/L. Preliminary results show that D. rerio embryos exposed to concentrations above 7.4 mg/L also presented a higher GST activity.

**TU 180**

**Histology of liver and gills in mosquitofish, Gambusis holbrooki, after long-term exposure to sublethal concentrations of benzalkonium chloride**

AT Correia[1], T Balula[2], H Vidal[1], B Nunes[3]
[1]CIIMAR, PORTO, Portugal
[2]FCS-UFP, PORTO, Portugal
[3]CESAM, AVEIRO, Portugal

Benzalkonium chloride is a detergent with effective germicide and preservative proprieties commonly used in several pharmaceutical and personal care products. The histopathological effects of benzalkonum chloride on the liver and gills of mosquitofish, Gambusia holbrooki, were studied by light microscope in tissues stained with hematoxylin and eosin. The fish were exposed to sublethal concentrations (0,025 mg/l, 0.1 mg/l and 0.4 mg/l) of benzalkonium chloride for 4, 10 and 28 days. Qualitative histological examination of both organs showed a variety of minor cellular alterations (e.g. lifting up of epithelium, intraepithelial oedema, fusion of adjacent secondary lamellae and hepatocytes vacuolization), also present in the control group. Almost changes are of minimal pathological importance, suggesting that the lesions were easily reversible as exposure to irritants ends. In addition, gill morphometrical indices were been used to test any physiological disturbance of the respiratory surface with exposure to benzalkonium chloride. However, statistical analysis did not find any relationship between the concentration and/or duration of exposure and the histopathological alterations, suggesting that benzalkonium chloride as little effect on gambusia.

**TU 181**

**Preliminary risk assessment of organic UV filters and UV light stabilizers in coral reef ecosystems at Okinawa, Japan**

Y Kameda
Center for Environmental Science in Saitama, KAZO, Japan

Organic UV filters are used in personal care products and polymer based products to protect human skin from UV-A and UV-B radiation as well as to maintain the product quality for a longer time. UV light stabilizers (UV absorbers) are used in technical products such as plastics, coatings, adhesives and construction materials. Recent studies have reported that these chemicals are released into aquatic environment and that some of them were detected in surface water, sediment, aquatic organisms and human breast milk. In addition, it was reported that organic UV filters in sunscreens cause coral bleaching by promoting viral infections. The aims of this ongoing research are 1) revealing organic UV filters and UV light stabilizers concentrations in seawater and sediment at coral reef lagoons adjacent to recreational area by passive samplers in order to evaluate impacts from recreational activities, 2) revealing their concentrations in coral reef organisms, especially predators of hard coral to evaluate hard coral exposure to them.

## ET04 - Ecologically relevant endpoints

**TU 184**

**Binding biomarker results with ecologically-relevant parameters in an aquatic macrobenthos community**

A Ippolito[1], P Parenti[1], R Giacchini[1], E Varolo[2], M Vighi[1]
[1]University of Milano-Bicocca, MILANO, Italy
[2]E. Mach Foundation, Innovation and Research Centre IASMA, S. MICHELE ALL'ADIGE (TN), Italy

The effects of plant protection products (PPPs) on a freshwater macrozoobenthos community where studied in a semi-controlled system. The system consists in a series of artificial channels alimented by an unpolluted river (River Fersina, Trentino-Alto Adige region, northern Italy). The channels are filled with stones, creating a substrate comparable to that present in the river and are naturally colonised by a macrozoobenthos community. The structure of the community in the channel and in the river was monitored for a long time before the experiments, indicating a reasonable comparability.
A realistic PPP application scenario was developed in order to reproduce an exposure condition comparable to those likely to occur in the rivers flowing in intensive agricultural basins of the region. For each channel, a section upstream the PPP immission was taken as untreated control. A panel of biochemical parameters (acetylcholinesterase, glutathione-S-transferase, catalase, and alkaline phosphatase activities,) were measured on selected taxonomic groups of the community (Tricoptera and Plecoptera) after each PPP application.
Quantitative samples of the community were collected after the PPP applications in order to assess effects on the populations of relevant taxonomic groups and on the community structure. Biomarker responses were compared with population and community data in order to assess possible relationships between responses at different hierarchical levels.

**TU 185**

**Effects of the pharmaceutical ivermectin on freshwater nematodes at the organismic, population, and community level**

M Brinke[1], W Traunspurger[1], P Heininger[2]
[1]University of Bielefeld, BIELEFELD, Germany
[2]Federal Institute of Hydrology (BfG), KOBLENZ, Germany

Extrapolating effects of contaminants found at lower levels of biological organization to higher levels, such as ecosystems, is important for environmental risk assessments (ERAs), but it is often already difficult to link two proximate levels. Although these extrapolation uncertainties exist, combined studies at different levels provide complementary and ecologically relevant information that is valuable for ERAs.
In this presentation, effects of the veterinary parasiticide ivermectin on free-living freshwater nematodes are shown at three levels. First, single-species bioassays with two nematode species (*Caenorhabditis elegans* and *Panagrolaimus cf thienemanni*) were conducted to investigate how ivermectin's mode of action (interference with transmission of neural stimuli to muscles) affects reproduction of free-living nematodes and to compare their sensitivity towards ivermectin with other freshwater organisms. The derived lowest observed effect concentrations (LOECs) were 2.1 and 0.5 µg/L, respectively. Second, full life-cycle experiments using these LOECs were conducted to estimate the actual impact of ivermectin on life-cycle traits of nematodes, e.g., age at maturity and intrinsic rate of natural increase ($r_m$). A consequence of the mode of action became more obvious than in the bioassays: towards the end of the reproductive period, *C. elegans* juveniles hatched inside 38% of their mothers before the mothers died, because muscle relaxation might have inhibited egg-laying. Third, a microcosm experiment with an ambient meiofauna community was conducted over a period of 224 days to take into account indirect food web effects and bioavailability of ivermectin in sediments. For nematodes a no observed effect concentration ($NOEC_{Community}$) of 0.6 µg/kg dry wt was derived, which is close to predicted environmental concentrations (PECs) of ivermectin in sediments (0.45-2.17 µg/kg dry wt).
Effects of ivermectin could be demonstrated at all observed levels of biological organization. The bioassays and the life-cycle experiments yielded valuable fundamental information, indicating a risk for free-living freshwater nematodes, while the microcosm experiment confirmed the risk under more realistic conditions.

**TU 186**

**Assessment of the reproductive and developmental toxicity of the herbicide Betanal® Expert and corresponding active ingredients on Daphnia spp.**

JL Pereira, T Vidal, N Abrantes, F Gonçalves
CESAM & Department of Biology, University of Aveiro, AVEIRO, Portugal

Pesticides usage is regulated taking into account environmental protection and ecotoxicological evaluation in the aquatic compartment prior placement in the market is generally required. The recommended workflow for ecotoxicological assessment tends to focus on the active ingredients rather than the commercial formulations of pesticides and on demanding references to the acute toxicity of the chemicals rather than considering life-history effects. The herbicide Betanal® Expert is a recently developed herbicide formulation that delivers the active ingredients (a.i.) ethofumesate (systemic benzofuranyl alkanesulphonate acting as growth inhibitor), phenmedipham and desmedipham (systemic bis-carbamates acting as photosynthetic inhibitors). The long-term toxicity of the commercial formulation as well as that of each a.i. to the freshwater cladocerans Daphnia magna and Daphnia longispina was addressed here, and reproductive effects were focused in particular. In this way, this study aimed (i) to provide experimental evidence on the reproduction injury induced by the herbicides; (ii) to compare the sensitivity of the model species D. magna and the indigenous D. longispina. Both the commercial formulation and the a.i.s were able to induce reproductive and developmental effects in both non-target species. Despite no great effects could be depicted in total fecundity (total number of eggs deposited in the brood chamber), concentrations below 1 mg L-1 were generally able to induce massive developmental effects in the progeny, thus the yield of unviable progeny. These include egg abortion, release of undeveloped embryos and release of dead neonates. Ethofumesate was the least toxic herbicide inducing the yield of unviable progeny following exposures to concentrations equal or higher than 1.9 and 4.6 mg L-1. The sensitivity of the standard D. magna was comparable to that of D. longispina as to the production of unviable progeny, being ethofumesate the single herbicide able to induce clearly distinct responses: D. magna and D. longispina released significant amount of aborted eggs following exposure to 1.9 mg L-1 and 4.6 mg L-1, respectively. Based on these results one should conclude that reproduction injury operated by exposure to very low concentrations of the herbicides should translate into serious impairment of population growth. Such impairment could never be predicted on the basis of acute toxicity assessments as required by regulation.

### TU 187

**Gastropod interspecies difference in response to 17a-ethinyl-estradiol: a full life cycle dose-response experiment**

AH Hallgren
Lund University, LUND, Sweden

Effects of 17α-ethinyl-estradiol (EE2) on fish are fairly well documented. However, for lower trophic levels, such as macroinvertebrates, the knowledge is less and the studies that have been performed are over a short period of their life cycle. Accordingly we investigated the effects of EE2 on two common freshwater gastropods, *Radix balthica* and *Bithynia tentaculata*, over a full life cycle. The quantified life history parameters for P-generation were growth, mortality, time and size to first reproduction and for F1-generation, success of hatching. Intrinsic rate of increase was also calculated utilizing the life history parameters. The responses for *B. tentaculata* were of a general negative trend with increased EE2 concentration but for *R. balthica* there was none or even positive trends. *Bithyina tentaculata´s* lower growth rate, longer time to reproduction and decreased reproduction resulted in a lower intrinsic rate but for *R. balthica* there was no response in the intrinsic rate of increase at ecological relevant concentrations. We also analyzed the importance of duration of the treatment on fecundity and found that *B. tenataculata* was significantly affected but *R. balthica* was not. The result from this study showed that the responses not only differed depending on treatment, but also on the sensitivity of the two species and that duration is an important factor when evaluating response from EE2. These results can imply that *R. balthica* may benefit from the effects of EE2 at ecological relevant concentrations by being less negatively affected.

### TU 188

**Ecological endpoints of exposure to toxic substances on interstitial copepods (crustacea, copepoda)**

WD di Marzio[1], D Castaldo[2], ME Sáenz[3], B Fiasca[2], DMP Galassi[2]
[1]CONICET-PRIET-DCB-UNLU, LUJÁN, Argentina
[2]Dipartimento di Scienze Ambientali, University of L'Aquila, L'AQUILA, Italy
[3]CONICET-PRIET DCB UNLU, LUJÁN, Argentina

Poor information on the ecological effects of pollutants on meiofaunal species living in the groundwater environments is presently available. This contribution is aimed at assessing the sensitivity to toxic substances of interstitial copepods living in subsurface porous aquifers, with special reference to the hyporheic habitat. Copepods are by far amongst the most abundant and species-rich groups in the hyporheic habitat and for this reason they have been selected for sediment toxicity assessment, being plausibly predictive of the ecological risk for the hyporheic fauna as a whole. The effects of chemicals, potentially contaminating ground water, i.e. Ammonium ($NH_4^+$) and the pesticide Aldicarb, were assessed by analysing shifts and/or alterations of developmental and population dynamics of copepod species. Four harpacticoid species were selected; namely, *Bryocamptus zschokkei*, *B. minutus*, *B. echinatus*, *B. pygmaeus*. Mono-specific cultures were developed for each species. Harpacticoid copepods have holobenthic life-cycle and pass through six naupliar stages, followed by six copepodite stages, copepodite VI being the adult. The selected species were assayed at sublethal concentration of 13 mg/L and 0.6 mg/L for $NH_4^+$ and Aldicarb, respectively. A developmental, time-dependent, relative index (DRIC) was evaluated for copepods along eight weeks, by scoring each developmental stage, measuring time and number of organisms at each developmental stage. It was calculated as DRIC = ΣSi*Ni, where Si is the stage i and Ni the number of copepodites at the i-stage (n = 6). Data for partial and final DRIC were obtained. Time for reaching the adult stage and sex ratio were also analysed. Data obtained with Aldicarb tests indicated that final DRIC was significantly reduced at values higher than 60% without modify the polynomial trend, adult stage timing ranging from 6 weeks or longer than 6 weeks, if compared to control populations; sex ratio on female basis showed extreme values, ranging from 0 to 100%. Ecological effects of $NH_4^+$ was highly species-specific, being *Bryocamptus zschokkei* the more sensitive to this pollutant, as indicated by the final DRIC reduction close to 50%, and adult stage attained after eight weeks. Experimental results based on copepod species were also evaluated under the perspective of the environmental risk assessment for the hyporheic fauna.

### TU 189

**Age altered sub-organism's responses in chromium exposed Daphnia schodleri (Anomopoda: Daphniidae): sensitivity and antioxidant enzymes**

MA Arzate-Cárdenas[1], R Ortiz-Butrón[2], FF Martínez-Jerónimo[1]
[1]Instituto Politécnico Nacional-Escuela Nacional de Ciencias Biológicas, MÉXICO, DF, Mexico
[2]Instituto Politécnico Nacional, MÉXICO, DF, Mexico

*Daphnia schodleri* is a natural occurring cladoceran in Mexican freshwater bodies, and its relative big size and short life cycle allow its use in ecotoxicological bioassays. Generally, younger and older life stages are considered to be the most susceptible and/or sensitive organisms because of several sub-organisms' level processes, such as ageing, in which antioxidant activity decreases and reactive oxygen species (ROS) cannot be totally neutralized. Moreover, aquatic communities are structured by organisms of different ages, in which physiological and biochemical responses differ in magnitude from each other. According to these statements, seven age groups of *Daphnia schodleri* (0, 3, 5, 7, 14, 21 and 28 d) were exposed to Cr (VI) in acute and non lethal bioassays. The results from acute toxicity bioassays were used to estimate the chromium $LC_{50}$ values for every age group, which ranged from 0.11 to 0.61 mg $L^{-1}$, and a Gaussian distribution pattern was observed. Antioxidant enzymatic activity of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx) and glutathione reductase (GR) was assessed in two different experimental designs: a) using two sublethal concentrations (0.032 and 0.0064 mg $L^{-1}$); and b) two fractions (1/5 and 1/25) of previously determined $LC_{50}$ for every age group. In the first experimental design, SOD and GPx activities showed a decreasing pattern with respect to their control groups; the CAT and GR levels were hardly modified by chromium exposure in neonates, but not in other groups. The second design results were totally different: no pattern was found among the age groups but not only neonates were affected by the toxicant. The two groups that could be considered similarly susceptible are the identified as pre-adults, the ones before the beginning of reproductive activity (5 and 7-d old). These results suggest that organisms' sensibility is not always related to susceptibility at suborganisms' level, since 7-d old organisms were the less sensitive in acute toxicity bioassays.

### TU 190

**Is a higher resistance to copper correlated with a faster recovery in daphnids?**

CAR Venâncio[1], I Lopes[2], R Ribeiro[3], AMVM Soares[2]
[1]University of Aveiro, AVEIRO, Portugal
[2]CESAM & Departamento de Biologia, Universidade de Aveiro, AVEIRO, Portugal
[3]IMAR- Instituto do Mar,Departamento de Zoologia, Universidade de Coimbra, COIMBRA, Portugal

Natural populations are commonly exposed to sequential pulses of contaminants. If the input of a pulse of lethal levels of a contaminant causes the disappearance of the most sensitive genotypes from a population (genetic erosion), then, the ability of the impacted population to withstand a further pulse of the contaminant will largely depend upon recovery rate of the remaining organisms. This study aimed at evaluating if the genetically determined resistance is positively related with a faster recover capacity, which would guarantee a double advantage to the resistant genotypes. To achieve this goal, cloned lineages of Daphnia longispina O.F. Müller, exhibiting different sensitivities to lethal levels of copper, were exposed to sequential pulses of this metal, to evaluate specific recovery rates and their relation to resistance. For each cloned lineage, the intensity of pulses corresponded to the respective concentration of copper causing 30% of mortality after 24h of exposure (LC30,24h). Obtained results showed no positive correlation between genetically determined resistance to lethal levels of copper and recovery rates.

It was also observed that even during the recovery period, mortality continued to occur, suggesting that standard lethal assays sub-estimate toxicity (as endpoints are computed solely based in mortality occurring during exposure to the toxicant). Furthermore, the lack of a positive correlation between resistance and a faster recovery highlights the increased risk at which impacted populations are subject after being exposed to a pulse of lethal levels of a contaminant.

### TU 191

**Cellular energy allocation in Chironomus riparius: sensitivity and relevance**

JAM Pedrosa[1], SCV Santos[1], T Verdelhos[1], M Lemos[1], JLT Pestana[1], C Barata[2], AMVM Soares[1]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Department of Environmental Chemistry Institute of Environmental Diagnosis and W, BARCELONA, Spain

The Cellular Energy Allocation (CEA) methodology was developed as biomarker technique to assess the effect of toxic stress on the energy budget of test organisms. It measures changes in energy reserves (total lipids, protein content and sugar content) and energy consumption (electron transport activity) and thus evaluates the metabolic costs induced in organisms by contaminant exposure. However CEA methodology is not commonly applied to benthic macroinvertebrates. Moreover there is a need for validation of these energetic biomarkers by assessing its sensitivity and reliability measuring it after exposure to contaminants with different modes of action and relevance by comparing it with endpoints measured at higher levels of biological organisation.

In this work we investigated the sublethal effects of the insecticide Movento® (spirotetramat) and Cadmium chloride on the midge Chironomus riparius. After exposure to a gradient of insecticide and metal sub-lethal concentrations, effects on CEA, growth, oxygen consumption rate, burrowing behaviour, emergence and adult size were measured. Results are discussed in terms of the sensitivity of the different endpoints and the advantages of using energetic biomarkers as a early warning indicator of adverse ecologic effects in freshwaters.

**Chitobiase activity as an indicator of altered survival, growth and reproduction in Daphnia pulex and Daphnia magna (Crustacea: Cladocera) exposed to spinosad and diflubenzuron**

L Lagadic[1], CD Duchet[2], MMI Inafuku[3], TC Caquet[1], ML Larroque[4], EF Franquet[5], CL Lagneau[2]
[1]INRA, RENNES CEDEX, France
[2]EID Méditerranée, MONTPELLIER, France
[3]Universidade de São Paulo, SÃO PAULO, Brazil
[4]Faculté de Pharmacie - Université Montpellier I, MONTPELLIER, France
[5]IMEP, MARSEILLE, France

Chitobiase is involved in exoskeleton degradation and recycling during the moulting process in arthropods. In aquatic species, the moulting fluid is released into the aqueous environment, and chitobiase activity present therein can be used to follow the dynamics of arthropod populations. Here, chitobiase activity was used for monitoring the impact of mosquito candidate larvicides on *Daphnia pulex* and *Daphnia magna* under laboratory conditions. Both species were exposed to spinosad (2, 4, 8 µg $L^{-1}$) and diflubenzuron (0.2, 0.4, 0.8 µg $L^{-1}$) for 14 days. *Bacillus thuringiensis* var. *israelensis* (*Bti*; 0.25, 0.5, 1 µL $L^{-1}$) was used as the reference larvicide. Chitobiase activity, adult survival, individual growth, and fecundity, expressed as the number of neonates produced, were measured every two days.

In contrast to *Bti*, spinosad and diflubenzuron significantly affected both species in terms of adult survival, and production of neonates. As compared to *D. pulex*, *D. magna* was more severely affected by diflubenzuron, at low and medium concentrations, with reduced adult growth and much lower chitobiase activity. Chitobiase activity was positively correlated with the individual body length, number of neonates produced between two consecutive observation dates, and number of females and neonates. In addition, the significant positive correlations between chitobiase activity measured on the last sampling date before the first emission of neonates and the cumulative number of neonates produced during the whole observation period strongly support the potential of the activity of this chitinolytic enzyme as a proxy for assessing the dynamics of arthropod populations exposed to larvicides used for mosquito control.

### TU 193

**Do eastern mosquitofish male harass less when exposed to environmentally relevant levels of 17β-estradiol?**

M Saaristo[1], J Myers[2], M Allinson[2], BBM Wong[1]
[1]Monash University, MELBOURNE, Australia
[2]CAPIM, MELBOURNE, Australia

Behaviour is the outcome of many complex physiological and biochemical reactions. Animals adapt to changes in their environment through their behaviour and thus behaviour provides a sensitive early warning signal for the presence of human-induced compounds, such as endocrine disrupting chemicals (EDCs). Our study species, eastern mosquitofish, is widespread in Australia and found in sites heavily polluted by EDCs. Male mosquitofish use a modified fin known as a gonapodium during copulation to inseminate females, and previous research has found that females preferentially associate with males with longer gonapodiums. In this study, we exposed male mosquitofish to environmentally relevant concentrations of 17β-estradiol (E2) and examined how exposure affects the reproductive behaviour and gonapodium morphology of males. Specifically, we asked if E2 exposure decreases male copulation attempts and gonopodial display.

We set up a preference test, where female could first observe male behaviour (exposed and unexposed) and then mate with the prefered male. We measured the time and frequency of male behaviours: orientation, chasing, gonopodial display and copulation attempts, and the time female spent in close proximity with the preferred male. In addition, male mating success was assessed by calculating the number of live offspring and mating success tested against the morphology of the male's gonapodium. Results will be discussed within the context of male reproductive success, sexual selection and EDC exposure.

**TU 194**

**Toxicity of the sugar cane herbicides Diuron and Tebuthiuron in zebrafish (Danio rerio) early-life stages**

AM Moura[1], I Domingues[1], R Oliveira[1], CM Jonsson[2], AJA Nogueira[1]
[1]University of Aveiro, AVEIRO, Portugal
[2]Embrapa Meio Ambiente, JAGUARIÚNA, SP, Brazil

Herbicides are widely used in agriculture and are known as a diffuse source of pollution of surface water and groundwater. The impact of herbicides use on non-target organisms is little known although mutagenic and genotoxic effects in fish exposed to herbicides have already been observed. Sugarcane is the predominant crop cultivated in the state of São Paulo, Brazil, with an area comprising approximately five million hectares. In the present study, the toxicity of diuron and tebuthiuron, two herbicides widely used in sugarcane cultivation, was evaluated using the Fish Embryo toxicity Test (FET), with *Danio rerio*, a tropical cyprinid used in toxicological research. The endpoints monitored included pigmentation, otholith, yolk absorption, pericardial oedema, tail deformation, hatching, coagulation and death. Five concentrations of each chemical were tested, ranging from 0.001 to 0.08 g $L^{-1}$ of Diuron; and from 0.1 to 0.6 g $L^{-1}$ of Tebuthiuron. At concentrations over 0.02 g $L^{-1}$ of diuron and 0.24 g $L^{-1}$ of tebuthiuron, exposed embryos presented a general development delay, pericardial oedemas, tail deformities and a delay in yolk absorption. Despite the low acute toxicity of diuron and tebuthiuron ($LC_{50\text{-}96\,h}$ = 0.024 (0.022 - 0.026) g $L^{-1}$ and $LC_{50\text{-}96\,h}$ = 0.35 (0.17 - 0.53) g $L^{-1}$, respectively) observed for zebrafish early-life stages, deleterious effects at sublethal level could be observed. The endpoints used on this study allow a better understanding of the toxicity and mode of action of these two herbicides, suggesting that, chronic effects due to long term exposure to the herbicides can be very important, leading to significant alterations in the organisms and consequently disrupt the functioning of aquatic ecosystems. Thus, as these chemicals are widely used in the field, an evaluation of risk should be performed based on the monitoring of sublethal parameters in organisms belonging to several trophic levels.

**Biomarkers as a tool to study different scenarios of exposure to potassium dichromate in zebrafish early life stages**

D Costa, I Domingues, MS Monteiro, AMVM Soares
CESAM & University of Aveiro, AVEIRO, Portugal

Potassium dichromate (PD) was classified by the European Chemicals Agency as a "Substance of Very High Concern"due to the environmental and human health risk posed. PD enters the air, water and soil through natural processes and human activities such as chemical, leather and textile manufacturing and may be an indicator of environmental contamination. PD is genotoxic, carcinogenic, neurotoxic and interferes with cellular metabolic activity. The level of chromium in water is generally low (levels found in rivers are often around 1 ppb) and thus, a proper analysis of risk is best achieved by evaluating long term effects and different exposure scenarios able to take into account different exposure periods, age of the organisms and capacity of recovery after an episode of exposure. Moreover, sublethal parameters such as biochemical, behavioral and physiological must be used so that effects can be detected.

The aim of this work is to evaluate the effects of PD in zebrafish (Danio rerio) early life stages using different exposure scenarios. The test was based on the OECD guideline 210 (Fish, Early-life Stage Toxicity Test) and used newly fertilized eggs. In the first scenario (A), eggs were exposed to PD concentrations between 0,37 mg L-1 and 10 mg L-1 during 28 days. In the second scenario (B), organisms were subjected to a period of exposure (14 days) to the same PD concentrations followed by a period where organisms were transferred to clean medium (14 days) to assess the potential recovery. In the third scenario (C), organisms were first kept in clean medium for 14 days and then transferred to the above mentioned PD concentrations for 14 days to assess influence of age in the response to the chemical. A semi-static test design was used in every exposure scenario, with test medium renewal each two days.

At days 7, 14, 21 and 28 of all scenarios the biomarkers cholinesterase, glutathione S-transferase, lactate dehydrogenase and catalase were measured in order to contribute to the understanding of the dynamic of the toxic response and the influence of exposure time, age and recovery potential on that response. Moreover, biochemical responses were linked to behavioral, developmental (hatching and anomalies) and physiological (length and weight) parameters which are ecologically very relevant and indicators of the organism fitness.

**TU 196**

**The estrogen receptors in salmonid fish**

LES Nikoleris, MC Hansson
Lund University, LUND, Sweden

Estrogen receptors (ERs) and the genes that encode them are well conserved among vertebrates. They mediate physiological effects of hormones involved in growth, reproduction and development in both males and females. Compared to other vertebrates, salmonid fish species have twice as many ERs due to a unique and rather recent duplication event early in the salmonid lineage. Gene duplications are considered one of the major factors that enable species to rapidly adapt to various ecological challenges by providing novel sources for gene functions. The multiple ER genes could be expressed during either the fresh water phase or the marine part of their lives, helping adaptations to the different environmental conditions.

The activation of the ER is controlled by estrogen as well as their mimics. Endocrine disrupters, such as ethinyl estradiol in human contraceptives, interfere or bind directly to the ERs. Lately these compounds have become a major concern since they influence reproductive success. Affected species may develop a skewed gender distribution since genetic males could develop as intersex. As salmonids change life strategies repeatedly during their life cycle there could be an increase or decrease in sensitivity to xenobiotic exposure as the different hormone genes possibly play important roles in different environments.

We recently identified and quantified four different ERs in adult Atlantic salmon (Salmo salar). Our wild study populations originate from the Baltic Sea and the freshwater river Mörrum in Sweden. Our results confirm a complex system in transcription levels of the ERs diverging between locations, sex and tissues. We now investigate the ER gene complex in trout (Salmo trutta) in order to further clarify the distribution and thus the role of the different ERs in the salmonid life-cycle, migration phase and during embryonic development. The results will in the future help determine the impact of endocrine disrupters on the activity and functions of the ERs inside salmonid tissues, asking if it is an advantage or disadvantage to have several ERs?

**TU 197**

**The respiration rate at suborganismal and organismal level in the ground beetle along two metal pollution gradients**

J Bednarska, I Stachowicz
Institute of Environmental Sciences, Jagiellonian University, KRAKOW, Poland

Surviving in a polluted environment is usually connected with changes in metabolic processes. An increase in respiration rate may results from energetically costly processes of combating contaminant exposure (e.g. cellular repair mechanisms, elimination of contaminants) but a decrease due to damage in respiratory enzymes may be also observed.

While some species of carabids are able to maintain viable populations in areas highly contaminated with metals, they may still incur physiological costs associated with metal exposure. To address the question about costs of living in polluted areas, we measured biomarkers linked to metabolism in *Pterostichus oblongopunctatus* collected along two metal pollution gradients in the vicinity of two zinc and lead smelters: Olkusz and Miasteczko Slaskie, S. Poland. Because the response of an animal to stress is a complex reaction, which depends not only on the type of a chemical but also is influenced by many internal and external factors, studies on two or more gradients, each with a number of differently polluted sites, allow for more general conclusions and give better control over possible confounding factors.

The whole animal respiration rate was measured as oxygen consumption with Micro-Oxymax respirometer, and cellular energy consumption was measured as the electron transport activity (ETS), which is linked to cellular respiration rate. We found significant effects of body Cd concentration, body mass and collection date on the respiration rates at the individual level. Although regression analysis revealed a significant increase of respiration rate with increasing body Cd ($p<0.01$), the interaction between Cd concentration and body mass was also found ($p=0.01$). The interaction was caused by a rather unexpected opposite relationship: the respiration rate increased with Cd concentration in the largest beetles but decreased in the smallest. We did not find significant relationship for the respiration rate at the cellular level. The lack of relationship between body Cd concentration and ETS may indicate that ETS is either not sensitive enough or is prone to rapid temporal changes in conditions - as is the case for most biochemical biomarkers. The effects on whole-organism respiration rate would thus represent long-term effects of chronic exposure to Cd, while ETS - the instantaneous respiration rate in response to actual conditions at the time of sampling the cells.

**TU 198**

**Allometric slope to assess stress factors on biological communities**

JA Vonk, C Mulder
National Institute for Public Health and the Environment (RIVM), BILTHOVEN, The Netherlands

Biological food webs are strongly organized in hierarchical levels, as shown by their several multitrophic interactions. Studies focusing merely on single food chains are known to be difficult to extrapolate to higher hierarchical levels, like entire biological communities. Therefore, allometry (i.e. the relation between abundance and body mass of organisms in biological communities) provides unique tools to encompass single chains and to capture the energy flow and performance of entire food webs. Since the allometric slope of any food web is related to the relative distribution of differently sized species, it can be used as indicator for eco(toxico)logical disturbance.

By exploitation and management of soil systems, for instance, humans induce huge changes in the environmental conditions as a whole. Input of nutrients and toxicants alter the composition of soil food webs, as observed by the relative importance of bacterial vs. fungal pathways or smaller vs. larger invertebrates. These shifts in the abundance of organisms with different body size result in changes in the allometric slope of the soil food web. By comparing allometric slopes between affected soils and reference sites ("target"), the impact of the anthropogenic disturbance on the performance of food webs and the soil quality can be determined. Large deviations from normal operating range (NOR) indicate major disturbances in the soil food web.

In studies on soil systems in the Netherlands, we show that the elemental levels for phosphorus, copper, and zinc in the soil influence the allometric slope of food webs. The influence of increase in soil phosphorus concentrations on the functioning of soil communities can be explained by the change from fungal to bacterial pathways and the larger demand for phosphorus for fungivore invertebrates. However, comparable allometric changes under increasing soil copper and zinc content are recorded as well. A biological explanation for this last change is less clear, but chemical correlations between cations are plausible. Overall, we show that the allometric slope in soils reflects (1) the elemental conditions in the soil and (2) the functioning of food webs. Allometric slopes can therefore be used to assess the actual effects of stress factors on biological communities.

**Metallic pollution affects small mammal assemblages: evidence from a large smelter-impacted area**

CC Fritsch[1], FF Raoul[2], AA Vaniscotte[2], MM Coeurdassier[2], PP Giraudoux[2], AA de Vaufleury[2], RR Scheifler[2]
[1]CNRS, BESANÇON, France
[2]University of Franche-Comté, BESANÇON, France

Effects of pollutants on small mammals have mainly been studied at individual level while effects on populations and communities might be more relevant endpoints to assess long-term impacts of pollution on ecosystems. In field studies interested in impacts of pollutants on species assemblages, discriminating the influence of natural environmental variables (landscape, habitat) from the influence of pollution is an essential issue. In the present study, potential effects of metallic pollution on small mammal assemblages were studied over a large smelter-impacted area (40 km2, Northern France), where soils have been polluted for decades by Cd, Pb and Zn. Animals were trapped (8640 trap-nights) during autumn in woody habitats (copses, hedgerows, tree plantations, woods...) in 4 landscapes (agricultural lands, urban areas, shrublands and woodlands) each along a soil pollution gradient. Concentrations of metals were measured in soils where traplines were set. Metal concentrations were correlated, and here Pb was used to represent soil pollution. Lead concentrations in soils ranged from 73 mg.kg-1 to 42,000 mg.kg-1. A total of 1,338 individuals from 11 species were captured. The influence of landscape, habitat and Pb on assemblage structure parameters was analyzed using generalized additive models, placing the variables in this order and attributing a smoother to Pb. Results showed that total abundance differed between landscapes and between habitats, and in agricultural and urban landscapes, increased with pollution until ≈ 1000 mg.kg-1 of Pb in soil, and then decreased. Richness differed between landscapes, and, in urban landscape, increased until ≈ 1000 mg.kg-1 of Pb, and then decreased. Evenness varied only with soil pollution, showing a constant decrease. We found effects of pollution on assemblage structure independent from landscape and habitat, and hypothesise that pollution may affect small mammals by direct (toxic) and/or or indirect (suitability of habitats, availability of food) effects. Therefore, assemblage structure could vary because of the disappearance of species sensitive to metals and/or dominance of species poorly sensitive to habitat quality (opportunistic generalist species). Analyses of metallic pollution influence on assemblage composition are in progress, which may allow determining which species are mainly affected and which are the characteristics of small mammal assemblages in metal-polluted lands.

**Reproductive effects of ingestion of fungicide- and insecticide-coated seeds on red-legged partridge**

A López-Antia, ME Ortiz-Santaliestra, R Mateo
Instituto de Investigación en Recursos Cinegéticos CSIC-UCLM-JCCM, CIUDAD REAL, Spain

Birds from agricultural environments are susceptible to suffer lethal intoxications after ingestion of pesticides incorporated into plants or invertebrates, and so toxicity of agrochemicals has been proposed as a potential cause for avian declines in agricultural areas from Western Europe some sublethal effects, especially those related wit hreproduction, may also compromise population viability. Certain fungicides like vinclozolin, thiram or maneb have been reported as endocrine disruptors, and thus are likely to reduce reproductive success. Cereal seeds are usually coated with some of these pesticides before sowing, and these seeds constitute a main portion of the diet of some species during sowing seasons in autumn and late winter. The aim of this study was to analyse the effects of the ingestion of coated seeds by red-legged partridges (*Alectoris rufa*) on reproduction process and viability of their chickens. We tested three currently used chemicals, an insecticide (imidacloprid) and two fungicides (difenoconazole and thiram). Each experiment consisted in two groups of six couples of partridges each. One of the groups was given wheat seeds treated with the recommended dose for seed coating, whereas the other group was given seeds treated with a concentration twice as high as the recommended one. Treated seeds were administered for a 10-day period that concluded 20 days before the beginning of the reproduction. Cages were checked daily for egg-laying monitoring. Eggs were incubated and the following variables were retrieved: clutch size, egg length and width, shell thickness, fecundation and hatching rates, and chick survival and growth (i.e., mass and length) at days 0, 8, 16, 24 and 32 after hatching. Egg size was significantly reduced by difenoconazole ($F_{2,130}$=10.163; $p$<0.001) and imidacloprid ($F_{2,91}$=11.283; $p$<0.001), whereas thiram reduced eggshell thickness ($F_{2,66}$=6.224; $p$=0.003). None of the chemicals affected fecundation or hatching rates, but chicken survival was significantly reduced by the three compounds, with mortality rates >50% in all cases (*vs* <20% mortality of controls). Chicken growth rates were unaffected by the pesticides, although control chickens tended to show higher sizes when compared to other treatments. The last egg was laid 98 days after the end of the exposure. These observed lagged effects on chicken survival suggest a potential for reproduction disruption of coated seed ingestion

**TU 201**

**PCBs and ecotoxicological data. In silico analysis in relation with in vivo and in vitro data**

E Abbaszadeh Fard[1], MP Halm[2], S Rault[3], JF Ferrard[4], AM Veber[4], A Serpentini[5], JM Lebel[5], R Bureau[3]
[1]CERMN, UPRES EA-4258, FR CNRS INC3M, University of Caen Basse-Normandie, UFR, CAEN, France
[2]CERMN,University of Caen Basse-Normandie, CAEN, France
[3]CERMN, University of Caen Basse-Normandie, CAEN, France
[4]LIBE, University of Metz, METZ, France
[5]IFREMER, University of Caen Basse-Normandie, CAEN, France

Due to urbanization and agro-industrial growing, coastal ecosystems like Seine estuary, are increasingly exposed to the input of anthropogenic contaminants. Among the contaminants, Polychlorinated biphenyls (PCB) are industrial chemicals causing widespread persistent contamination in water and sediment. The toxicity of these compounds is well known on the vertebrates but few data exist about their ecotoxicity on aquatic (marine) species. In Seine estuary, some studies showed the presence of PCB in marketable and edible species (mussels for example). It is therefore essential to obtain new toxicity data for marine species with high economic potential for the Basse-Normandie region in France. In REACH, the use of in silico and in vitro methods is encouraged to minimize the cost of experimentation. Two main objectives of this study are: 1) application of in vitro and in vivo methods, in order to obtain new toxicological data of the PCBs on aquatic species; 2) definition of (Q)SAR models in order to predict the toxicity of the PCBs. Using in silico approach, a classification of the PCBs based on their structural characteristics and initial classifications (DL and NDL) has been firstly carried out. This classification leads to a selection of derivatives for in vivo and in vitro studies. In vivo acute toxicity (endpoints) of 18 PCBs on Daphnia magna and 14 PCBs on Selenestrum capricornutum was determined. In vitro studies were focused on the effects of three PCBs after 10 days of primary culture on enzyme activities and viability of a marine mollusk (Haliotis tuberculata) hemocytes: PCB153 (the most predominant PCB in environment), PCB 28 (PCB with the highest in vivo acute toxicity) and PCB77 (one of the most toxic PCB (DL) for the vertebrates). In vitro and in vivo results show that the different congeners of PCB have different toxicity profiles.

**TU 202**

**Development of q-PCR approaches to assess water quality: Effects of cadmium on gene expression of the diatom Eolimna minima.**

S Kim Tiam[1], A Feurtet-Mazel[2], F Delmas[1], N Mazzella[1], S Morin[1], G Daffe[2], P Gonzalez[2]
[1]Cemagref, CESTAS, France
[2]EPOC, ARCACHON, France

Aquatic ecosystems are nowadays highly impacted by anthropogenic activities and by the various resulting pollutions. Among these pollutions, heavy metal contaminations are of particular concern because of their acute toxicity and their potential accumulation and transfer along the food chain.

In this context, the development of tools for assessing water quality is a fundamental issue. The numerous qualities of periphytic freshwater diatoms communities as bio-indicators have already been shown and they are used in numerous indices for water quality evaluation as the Biological Diatoms Index (BDI, Coste *et al*. 2009) regularly applied in European territories.

Nevertheless theses indices have shown their limits in water quality assessment considering toxic pollutions. Therefore news approaches are called to emerge in the assessment of water quality, and investigations in the field of genetics could be very promising.

Therefore in our study, the impact of cadmium is evaluated at a genetic level by q-PCR on 8 genes of interest after exposure in laboratory conditions of *Eolimna minima*, diatom populations cultivated in suspension under controlled conditions by following their growth kinetics and their Cd bioaccumulation.

Population growth rates reveal a high impact of Cd at a concentration of 100µg Cd/L with a total inhibition of growth. These results are linked with the high bioaccumulation values calculated after 14 days of exposure, 57,0±6,3µg Cd/g dw and 734,1 ± 70µg Cd/g dw for exposures of respectively 10 and 100µg Cd/L .

Genetic responses reveal the impact of Cd on mitochondrial metabolism and chloroplasts photosystem of *E. minima* exposed to 10 and 100µg Cd/L with an induction of cox1, 12S, d1 and psaA after 7 days of exposure for the concentration of 100µg Cd/L and of nad5, d1 and psaA after 14 days of exposure for both conditions.

The first tests made on three different diatom species in suspension (*Eolimna minima*, *Achnanthidium minutissimum* and *Nitzschia palea*) with primers designed for *Eolimna minima* suggest high potential for their application to a larger range of diatoms species and prospects of application on natural biofilms.

Our study is a first attempt to the use of q-PCR for assessment of toxic pollution by genomic biomarkers on river benthic diatoms. The results obtained presage interesting perspectives, but the techniques developed need to be optimized before their use on natural biofilms for the development of new diagnosis tools of water quality.

**TU 203**

**Genotoxicity assessment in gonads, liver and gills of zebrafish (Danio rerio) by use of the comet assay and micronucleus test**

C Faßbender, T Braunbeck
University of Heidelberg, HEIDELBERG, Germany

Over the last decades, there has been a decline in fish populations in European and Northern American freshwater ecosystems. Anthropogenic chemical pollution is supposed to play a major role in this respect. Especially for the assessment of ecological risks of genotoxins in the aquatic environment, it is important to understand the relationship between genetic damage in endangered species and detrimental effects at the population level. For this end, it is necessary to be able to detect DNA fragmentation and micronucleus formation not only in somatic cells, but also in generative tissues of individual fish exposed to genotoxins. In toxicology, the comet assay or single cell gel electrophoresis has frequently been used with mammalian germ cells. In contrast, in ecotoxicology, the comet assay has almost exclusively been applied to cells from various somatic tissues. In the present study, adult zebrafish (Danio rerio) were therefore exposed in vivo under semistatic conditions to several concentrations of the known alkylating genotoxin methylmethanesulfonate (MMS) for two weeks. Genotoxic effects were investigated with the alkaline comet assay using primary cells from gonads, liver and gills. In addition, the micronucleus assay was used to identify stable chromosomal aberrations caused by genotoxicity in histological sections of the same organs. In primary hepatocytes, gill and gonad cells, MMS caused an increase of the tail moment. Likewise, the micronucleus frequency was elevated by MMS in gills and gonads, but not in liver. In conclusion, it could be demonstrated that the alkaline comet assay as well as the micronucleus test are appropriate for the detection of genotoxicity in primary gonad cells and histological sections of the gonads, respectively, of both sexes of the zebrafish. The investigation of population-relevant effects is underway.

**TU 204**

**Study of DNA lesions stability and detection of oxidative DNA damage by hOGG1-comet assay in Dreissena polymorpha**

CC Michel[1], Fr Vincent-Hubert[1], JD Lebrun[2]
[1]CEMAGREF, ANTONY, France
[2]Cemagref, ANTONY, France

Freshwater bivalve molluscs are considered as effective indicator of environmental pollution. The comet assay, allows the detection of DNA damage like the strand breaks and alkali-labile sites in different types of individual cells. The main oxidative lesion, 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodG), can be detected by the comet assay coupled with a human DNA repair enzyme hOGG1, involved in base excision repair. The aim of this study is to use the comet-hOGG1 assay in gill cells of *Dreissena polymorpha* to quantify 8-oxodG and to determine their stability. Mussels were exposed during 24h to BaP, MMS and Cd and DNA damage levels were measured during 3 days. This study shows that BaP induced DNA damage, with a dose/response relation, and 8-oxodG. The basal level of DNA damage is reached on day 3 indicating an effective DNA repair. The 8-oxodG level detected in MMS treated mussels is weak during the exposure. Cd induced 8-oxodG 6h after the beginning of the exposure. The level of 8-oxodG is higher with the higher Cd concentration but it was detected later. This study revealed that the comet-hogg1 assay is sensitive enough for the measurement of 8-oxodG in exposed mussels.

**TU 205**

**Characterization of growth, gene expression and behavioural effects of exposure to ozone-treated and untreated oil sands process water on Chironomus dilutus larvae**

JC Anderson[1], SB Wiseman[2], N Wang[3], L Perez[4], M Gamal El-Din[3], JW Martin[4], K Liber[5], JP Giesy[2]
[1]University of Saskatchewan, SASKATOON, SK, Canada
[2]Toxicology Centre, University of Saskatchewan, SASKATOON, SK, Canada
[3]Department of Civil and Environmental Engineering, University of Alberta, EDMONTON, AB, Canada
[4]Department of Laboratory Medicine and Pathology, University of Alberta, EDMONTON, AB, Canada
[5]School of Environment and Sustainability, University of Saskatchewan, SASKATOON, SK, Canada

Global energy demands continue to increase, driving a shift from conventional oil sources to further exploitation of alternative sources. Canada currently hosts the second largest proven oil reserves, with the majority located within the Athabasca oil sands of Alberta. Oil sands production has raised concern over greenhouse gas emissions, habitat loss and wildlife impacts. Water use is often overlooked, but is a key issue associated with oil sands development. To extract the petroleum pre-cursor from the oil sands, a process is used involving addition of hot water and caustic soda and results in oil sands process water (OSPW). This water is alkaline, saline and produced at a rate of approximately 3 m3 per 1 m3 of oil sands processed. Companies are held to a zero-discharge policy so over a billion m3 of OSPW are held in settling ponds and this will increase as production continues.

OSPW contains high concentrations of naphthenic acids (NAs). These are classified as carboxylic acids with the formula CnH2n+z O2 and have been implicated as the primary cause of the acute and chronic toxicity of OSPW observed across multiple taxa. To effectively treat OSPW for future release or reclamation, an approach is required that targets NAs. Ozonation can target NAs with greater molecular weights - those NAs that tend to be most persistent. To assess the effectiveness of ozonation to eliminate OSPW effects on relevant organisms, we initiated exposure studies with the benthic invertebrate Chironomus dilutus. OSPW was treated with either 30 or 80 mg/L of O3, and both ozonation levels were examined for effects on C. dilutus larvae following a 10-day exposure. Survival was not significantly impacted, but OSPW-exposed larvae were 64-77% smaller than their respective controls (p<0.05). Organisms exposed to 30 mg/L ozonated OSPW were no smaller than the controls (p=0.486). Larvae in 80 mg/L ozonated OSPW were only 40% smaller than the controls (p <0.001), so ozonation generally mitigated growth inhibition. In both assays, larvae exposed to untreated OSPW exhibited disordered case-building behaviours, but ozonation also eliminated these effects. The attenuation of behavioural anomolies and inhibited growth in the ozone-treated OSPW exposures suggests that NAs may be contributing to the effects observed. We are quantifying global gene expression in C. dilutus exposed to untreated and ozone-treated OSPW and aim to correlate molecular changes and whole-organism level effects.

**Ecological atlas of Azerbaijan**

S Mammadov[1], S Mammadova[2]
[1]State Land and Cartography Commitee of Azerbaijan Republic, BAKU, Azerbaijan
[2]Institе of Soilscience and Agrochemistry of Azerbaijan Nat. Acad. of Science, BAKU, Azerbaijan

"Ecological Atlas of Azerbaijan"represents uniform integral cartographical product at which drawing up under our management were used results of long-term researches of scientists of republic. Atlas represents the arch of the extensive information for research of ecological conditions in republic for the purpose of its optimisation, working out and realisation of a rational state ecological policy, ecological education, educate of various strata of society and as relevant endpoint increase of ecological culture. Value of the atlas for an assessment of ecological conditions in Azerbaijan within the limits of world environmental problems as a whole is great. The special thematic maintenance of the atlas is presented in 11 sections: atmosphere, hydrosphere, lithosphere, soils, biosphere, landscapes, plantar cover, fauna, natural accidents, society ecology, legal bases of ecology of Azerbaijan. The atlas contains more than 110 maps. For increase in information capacity of the atlas maps are accompanied by explanatories, tables, schedules and diagram's. Almost all maps of Azerbaijan are given in 1:1500000 scale, that considerably facilitates their comparison at the analysis of maps of the various maintenance. This scientific product represents an ecological relevant endpoint.

## ET09 - Laboratory and field measurements and alternative approaches in bioaccumulation

**Mercury bioaccumulation and biomagnification from diffuse sources in tropical estuaries (Ceara, Brazil)**

ACM Rodrigues[1], RMA Santos[1], DMS Sampaio[2], LM Buruaem[3], JR Gadelha[2], F Morgado[2], SN Abreu[2], LV Costa-Lotufo[3], AMV Soares[2]

[3]Labomar, Universidade Federal do Ceará, FORTALEZA, Brazil

Mercury (Hg) is a toxic metal of greater global toxicological concern. Imposed environmental legislation lead to a significant reduction in emissions from point sources, such as industry, and diffuse sources, such as the improper discharge of waste from these activities into the environment. However, prevailing environmental legislation is still insufficient to deal adequately with the Hg legacy mainly from diffuse source emissions.

Food consumption is known to be an important route of exposure and bioaccumulation for MeHg and trophic level is a very significant factor influencing Hg and MeHg concentrations in aquatic organisms, while increased temperatures speed up the methylation of Hg. Consequently, tropical ecosystems (such as rivers, estuaries and coastal regions) even receiving chronically low loads of Hg may experience biomagnification processes (driven by dissimilar uptake and depuration Hg rates) along the trophic chains, whereas bioaccumulation is expected to increase in response to the environment high temperatures. Therefore, the process of bioaccumulation of Hg in fish is expected to go faster and in shorter periods of time in tropical estuaries.

In this study, the fish *Ulaema lefroyi* (a benthic feeder that uses its highly protrusible mouth to forage for infaunal invertebrates, feeding primarily on bivalves, copepods, other crustaceans and polychaetes) was sampled and the content of Hg and MeHg was quantified in muscle tissue, liver and stomach content. Results are presented and discussed, indicating that Hg bioaccumulation and biomagnifications related mainly to remobilization processes results are expected to contribute to the knowledge of the biogeochemical processes that control the dynamic of mercury in the tropical environment.

**TU 211**

**Comparing mercury bioavailability and bioaccumulation in tropical and temperate ecosystems (Ceará, Brazil and Ria de Aveiro, Portugal)**

SN Abreu[1], RMAL Santos[1], ACM Rodrigues[1], DMS Sampaio[1], LM Buruaem[2], HMCS Vieira[1], JR Gadelha[1], F Morgado[1], LV Costa-Lotufo[2], AMVM Soares[1]

[2]Labomar, Universidade Federal do Ceará, FORTALEZA, Brazil

Mercury contamination is nowadays a worldwide problem in various ecosystems, presenting a high risk to biota over the world including human. A potential warming up climate scenario is expected to increase Hg methylation, therefore is extremely important to evaluate how different climate factors can affect mercury bioavailability. In this study, mercury bioavailability and bioaccumulation in tropical (Ceará river estuary, Brazil) and temperate (Ria de Aveiro estuarine lagoon, Portugal) ecosystems are compared using surface sediments, water and epibenthic fish, under dissimilar climate environments. Mercury was quantified by pyrolyse atomic absorption spectrometry in tissues, surface sediments and SPM filters. Certified reference materials TORT-2, Dorm-3 and Dolt-3) were also used for quality control. As reference site was used the non-contaminated Pacoti estuary (Fortaleza, Brazil). Results indicate different levels of bioavailability and bioaccumulation suggesting dissimilar mercury kinetics.

**TU 212**

**A novel approach for reporting concentrations of mercury in marine mammal muscle tissue**

JP Wintle, S Martin
Portland State University, PORTLAND, United States of America

When muscle tissue mercury values were normalized to 75% muscle water content, the mean, median and range values were drastically lowered. Although dry, wet, and fresh weight values are much higher than normalized values, reporting and running statistical analyses on these would give a false sense of THg accumulation. Using normalized THg values allows for a clearer indication of the amount of mercury the animal accumulated before stranding. A stranded animal whose bodily fluids are depleted will have a higher concentration of mercury than when healthy. Normalizing tissue weights for total mercury represents a universal method for clarifying results whether the tissue sample comes from a healthy or a decomposed animal.

**TU 213**

**Lifespan mercury bioaccumulation in Pomatoschistus microps: a field study in two temperate coastal ecosystems (Ria de Aveiro and Mondego estuary, Portugal)**

S Tavares[1], JP Coelho[2], M Dolbeth[1], UM Azeiteiro[1], ME Pereira[2], AC Duarte[2], MA Pardal[1]
[1]CFE (Centre for Functional Ecology), COIMBRA, Portugal
[2]CESAM (Centre for Environmental and Marine studies), AVEIRO, Portugal

Pomatoschistus microps (Kroyer, 1838) is one of the most abundant fish species in estuaries, lagoons and shores of Europe, being an important intermediate predator in the trophic webs. Regarding its importance and with the purpose of verifying its role in the mercury transfer along the estuarine food webs, lifespan mercury accumulation was assessed in this species in different contamination scenarios. Sampling was made in Ria de Aveiro, ecosystem that received mercury rich effluents continuously for five decades, what created a well-defined anthropogenic mercury gradient, and in Mondego estuary, assumed as a mercury free ecosystem. Mercury content of fish was in accordance with mercury contamination of the water and sediment, showing higher values near the contamination source. A mercury accumulation pattern along lifespan was denoted in all sampling sites, although showing different trends according to the environmental contamination. The differences between sampling sites are more evident in the mercury content of the youngest age classes, what suggests a rapid accumulation of the metal in these fishes. Organic mercury content was also assessed, following the same accumulation pattern than total mercury and representing over 90% of total mercury.

**TU 214**

**Percentage of trace elements and ultrastructural analysis before hatching on wild and captive avian eggshells from Thailand: evidence from scanning electron microscope**

M Areekijseree, K Sribuddhachart
Department of Biology, Faculty of Science, Silpakorn University, Sanamchan Palac, NAKORN PATHOM, Thailand

Fifty species from five orders (Passeriformes, Charadriiformes, Columbiformes, Ciconiiformes and Gruiformes) of before hatching avian eggshells were collected from Thailand. Results from EDX/SEI of SEM in all species of avian eggshells revealed the energy spectrum of the X-rays character emitted from the element of non metal (oxygen, O; carbon, C; silicon, Si; chlorine, Cl; phosphorus, P; sulfur, S), alkaline metal (sodium, Na), alkaline earth metals (magnesium, Mg; calcium, Ca), other metal (aluminum, Al), and transition metal (molybdenum, Mo). The percentage of all elements was found and has the following order: O (50.12-60.19 %)>Ca (17.48-29.48%)>C (16.67-28.33 %)>Al (0.08-0.75%) >Si (0.03-0.53%) >Mg (0.03-0.52%) >Na (0.08-0.40%) >P (0.03-0.22%) >S (0.02-0.19%)>Mo (0.03-0.11%) >Cl (0.04-0.09%). There was not a significant difference of elemental composition between 15 species of avian eggshells. We found high percentage of O, Ca, and C (97.39-99.62%), which the composition of calcium carbonate (CaCO3), and essential for avian embryonic development. Especially, Mg (0.52-0.07%), Na (0.13-0.40%), P (0.02-0.22%) were found in all avian eggshell species. These elements are major inorganic constituents of the avian eggshell which directly related to an increase in eggshell hardness. Interestingly, we also found Mo contamination in eggshell of Copsychus saularis and Nectarinia jugularis. SEI showed normal character on 3 layers of 15 eggshell species. The thickness of 3 layers was found and has the following order: a middle palisade layer > an inner mammillary layer> an outer cuticle layer. There are 2 types (ambiguous shape or knobbed shape) of mammillary layer. While, the morphology of palisade layer is spongy shape. It has porosities which connect from cuticle layer to mammillary layer. The total eggshell thickness of all species was ranging from 45.68+13.31 to 162.92+40.41 micrometer and correlated with Neoaves. This finding showed the utilization of SEM is a powerful and comfortable to analyze percentage of trace elements accumulation, metal contamination, and classified avian eggshells correlated with the avian evolution.

**Bioaccumulation of Molybdenum in the aquatic environment: literature and laboratory/field-generated data**

DG Heijerick[1], L Regoli[2], W Stubblefield[3], S Carey[2]
[1]ARCHE, GENT, Belgium
[2]IMOA, LONDON, United Kingdom
[3]Oregon State University, Department of Environmental and Molecular Toxicology, ALBANY, OR, United States of America

Information on the bioaccumulation of a substance in the aquatic environment can be used for different scientific and regulatory purposes (e.g., derivation of a $PNEC_{oral}$, setting water criteria based on the maximum tolerable daily intake of a substance through fish consumption). As part of the REACH requirements for >1000 tonnes substances, information on the bioaccumulation of molybdenum was collected from open literature and assessed on its relevance and reliability. Available data suggested homeostatic control of molybdenum in fish, i.e., decrease of bioaccumulation with increasing Mo-levels in the aquatic compartment. The overall robustness of the data-set, however, was rather poor with all exposure levels well below the $PNEC_{aquatic}$ for Mo. As a result, the aquatic $MTC_{hh,food}$ (Maximum Tolerable Concentration of a substance in the surface water that does not cause any harmful effects to human health via fish consumption) that was initially derived by Dutch authorities for Mo - using existing bioaccumulation data - was 2-3 orders of magnitude below the freshwater PNEC of 12.7 mg Mo/L as reported in the Chemical Safety Report of several Mo-substances. In an effort to expand the amount of reliable bioaccumulation data and to refine BAF-based water criteria, the International Molybdenum Association conducted two research studies in 2009-2010.

In the first study the internal Mo-content (total + organ-specific internal levels) was evaluated in various fish species (eel, stickleback, perch, carp bream, roach) that grew up in the discharge water collector tanks of a molybdenum trioxide/ferromolybdenum producing company, containing a mean Mo-level of 1.03 mg Mo/L. A second 120d-study under laboratory conditions exposed rainbow trout to two different Mo-levels (1 and 12.7 mg Mo/L), for a period of 60 days followed

by a depuration period of similar length.
Both studies generated bioconcentration factors well below 1 when muscle tissue was considered. Concentration levels in the muscle tissue of fish taken from both experiments remained below 0.2 mg/kg dry wt. Total concentration levels that were determined for rainbow trout during the exposure period were situated between <0.20 and 0.53 mg Mo/L. The outcome of these studies clearly support the inverse relationship between exposure concentration and bioaccumulation factor for molybdenum, and also demonstrate that molybdenum in fish is adequately regulated up to the $PNEC_{aquatic}$ of 12.7 mg Mo/L.

[4]Research group of Veterinary Public Health and Zoonoses, MERELBEKE, Belgium
A wide variety of micro pollutants might be present in surface waters. Some of these pollutants are only present in the environment for a small period of time, especially pesticides, which makes monitoring difficult. Moreover, little is known on the bioavailability and their related effects of accumulated micro pollutants. Therefore accumulated levels of a wide range of micro pollutants in field captured damselflies were measured and related to functional endpoints and biomarker responses.
We selected 7 ponds through Flanders (Belgium) based on expected differences in type and amount of pollution. From each pond around 40 individuals of damselfly larva species Ischnura elegans were captured. The collected organisms were placed in vivo for 24h, each in individual containers filled with water from there ponds. In each location the larvae-bodies were measurement on 15 different pesticides and 9 heavy metals.
To verify if the accumulated concentrations of the pollutants result in an ecological relevant effect, functional endpoints were measured. In fact general activity and feeding rate were scored over a fixed time period. The general activities were filmed and total distance, speed and amount of movements were counted. The feeding rate was assessed by scoring the number of juvenile waterfleas (Daphnia magma) ingested over a time period. As biomarker responses, Acetylcholinsterase (AChE), Glutathione S-transferase (GST) and energy budget (Ea) were measured in the head of individual damselfly larvae.
Five pesticides are accumulated in the larvae, Isoproturon, metalochlor, terbutylazine, linuron and dimethoate. The metal load is present in all samples with a great difference between de polluted and unpolluted sites. The GST activity and some energy budgets give a significant correlation to the accumulated metals and significant differences occur between the ponds for metal accumulation and biomarker responses.
Furthermore our results indicated that the accumulation of micropollutants can increase the induction of biomarkers and affect the general activity of the damselfly larvae Ischnura elegans.

**Antioxidant enzyme activities responses in freshwater biofilm in a metal polluted system**
B Bonet[1], N Corcoll[1], V Acuna[2], L Sigg[3], R Behra[3], H Guasch[1]
[1]Institute of Aquatic Ecology, GIRONA, Spain
[2]Catalan Institute for Water Research (ICRA), GIRONA, Spain
[3]Eawag. Swiss Federal Instiute of Aquatic Science and Technology, DÜBENDORF, Switzerland
Antioxidant enzyme activity (AEA) responses to metal toxicity have been studied in previous laboratory and microcosm experiments. Results indicated that AEA could be used as an "early warning system"and also AEA were proposed as biomarkers of metal adaptation. However, no field studies have so far assessed AEA in natural biofilms.
The main goal of this study was to assess seasonal patterns of metal exposure and toxicity in a metal polluted freshwater system based on biofilm AEA activities. We expected that AEA response in biofilms will be dependent on environmental variability, assuming metals to be the most important source of variability.
To reach this goal an annual monitoring study was carried out in the Osor River (NE Catalonia, Spain). It is located in a former mining area and receives elevated metals inputs (mainly Fe, Mn and Zn). Three sites were selected: Non-Impacted site (NI), before the mining source with a background Zn concentration, Site1 (S1) downstream the mining source causing an increase of Zn concentration, and Site2 (S2) farther downstream.
Physical and chemical parameters were analysed. Dissolved and bioaccumulated Zn, Mn and Fe were determined using ICP-MS analysis and free metal ions and labile species were calculated with the vMINTEQ. AEA analysed in biofilms included CAT, APX, GR, GST and SOD. The relative abundance of the groups of photosynthetic organisms was determined by means of a PhytoPAM fluorometer.
The free metal Zn concentrations and bioaccumulated Zn showed the same pattern over the monitoring period and were inversely related to the water discharge.
AEA in biofilms displayed different patterns over the year. In the NI, AEA did not follow the metal concentrations. In the S1, APX, GR, CAT and SOD decreased when free metals and bioaccumulation concentrations increased, suggesting an inhibition caused by accumulated metals. GST did not relate to metal exposure or accumulation. AEA dynamics might be explained also by other environmental factors such us light, as well as by spatial and temporal species compositional changes.
We can conclude that AEA responses in biofilms respond to metal accumulation. However, despite being very sensitive, AEA do not linearly correlate to the metal concentrations. Thus, the use of AEA measurements combined with other biomarkers in monitoring metal impacted sites can improve the predictive capabilities for ecological risk assessment.

**Mercury accumulation in laboratory-reared Chironomus riparius and in indegenous chironomids' assemblages**
A Pola[1], R Bettinetti[2], A Boggero[3], DAL Vignati[1]
[1]CNR-IRSA, BRUGHERIO, Italy
[2]Università dell'Insubria, COMO, Italy
[3]CNR-ISE, VERBANIA, Italy
Mercury is a priority pollutant characterized by a strong tendency to bioaccumulate in living organisms and biomagnify along trophic chains. These features follow from the transformation of inorganic mercury into the corresponding methylated form, mainly via bacterially-mediated mechanisms controlled by several environmental variables. From a risk-assessment point of view, mercury therefore requires an approach based on establishing its bioaccumulative potential in resident biota rather than the typical toxicity-based approach commonly used for other trace elements. In the case of small organisms (e.g., freshwater benthic invertebrates), collecting an adequate amount of biomass of resident biota for measuring Hg accumulation can become quite problematic. Resident organisms may also be absent due to e.g., strong pollution or cross-sites comparison hindered by the impossibility of collecting the same organisms at all monitoring points. Bioaccumulation experiments with laboratory-reared organisms therefore become attractive provided that they can accurately simulate Hg accumulation in indigenous biota.
We have exposed reared larvae of *Chironomus riparius* to sediments collected at various locations from an aquatic system impacted by Hg pollution. Assemblages of indigenous chironomids have also been collected and are currently being analyzed to validate laboratory results. In the laboratory experiments, adults of chironomids emerged after exposure to field-collected sediments have also been analyzed for Hg content. This type of measurement represents another useful tool of a combined laboratory-field approach to estimate the Hg load exported from contaminated aquatic systems to the surrounding terrestrial environments.

**TU 219**
**An evaluation of bioaccumulation data for Hexachlorobenze (HCB): can these data be used to convert biota standards into water based risk limits?**
CTA Moermond, EMJ Verbruggen
RIVM, BILTHOVEN, The Netherlands
For HCB, the EC has set quality standards in biota, but in the Netherlands a preference exists for quality standards based on water concentrations. To calculate these, reliable values for bioaccumulation are a must. Data on bioaccumulation, biomagnification and bioconcentration of HCB, both from the field and the laboratory, were assessed. To calculate biota standards into water standards, either bioaccumulation factors (BAFs) or the ratio of the bioconcentration factor and the biomagnification factor (BCF x BMF) can be used, where the BAF represents the quotient of the BCF and the BMF. Where BAFs are often determined in the field, BCFs are mostly determined in the laboratory. For the purpose of recalculating quality standards, only studies with water concentrations expressed as dissolved concentrations are considered valid.
The evaluation resulted in 19 valid values for laboratory BCFs, partly with water-based exposure and partly with dietary exposure, with a geomean of 12800 L/kg (5% lipid-normalised). Regarding biomagnification, 19 values for the biomagnification and 8 values for the trophic magnification factor were considered valid. From these data, an overall BMF of 3 can be deduced. In contrast, only 10 valid values for bioaccumulation factors were retreived from literature, with a geometric mean of 221000 L/kg (5% lipid-normalised). BAF measurements show a variation of more than one order of magnitude. Normally, BAFs correlate with trophic level or age of the fish, but for HCB this is not the case. An explanation for this deviation of what is expected from theory is lacking. Even at lower trophic levels (algae, small zooplankton), accumulation of HCBs already far exceeds what is expected through equilibrium partitioning. This affects BAFs at higher trophic levels as well. When comparing BCF values for fish multiplied by the BMF (12800 [GREEKX] 3 = 38400 L/kg) to the observed BAF values for fish (geomean 221000 L/kg), there appears to be a large gap between laboratory data and field data. While the confidence in the laboratory data is high, these data seem to be not relevant for the field situation.
Thus, from a scientific point of view, using biota standards could be preferred over recalculating them into water standards, because this involves the least uncertainties. Nevertheless, sampling of individual fish or fish species is accompanied with some additional uncertainty as well.

Since it was formed in 2005, the HESI Bioaccumulation Project Committee has successfully advanced the science of bioaccumulation ('B') in several areas: developing in vitro methods as part of weight of evidence approaches to 'B' assessment; publishing peer reviewed papers on the state of 'B' science; advancing models to better screen organic chemicals for 'B'; and funding research in basic fish physiology to better understand ADME processes. In addition, the HESI committee has collaborated with SETAC and others to sponsor workshops bringing together academia, industry and regulatory authorities to discuss and advance 'B' science.
A workshop was held in February 2011 to highlight recent and ongoing research efforts, to demonstrate progress that has been made in the field to identify key gaps in current 'B' knowledge, and to discuss how recent progress in 'B' science can be integrated into the regulatory environment. Topics included integration of modeled predictions with laboratory measurements, extrapolation from lab to field data, a review of ADME processes and determining method domain of applicability across chemicals and species, and abbreviated BCF studies. In addition the potential incorporation of these methods into regulatory 'B' assessments and what is needed to best communicate the scientific advancements to the risk assessment community was discussed. This poster summarizes the key discussions in the workshop. The ultimate output will provide guidance to the best path forward to further develop the research and continue to move the science of bioaccumulation forward.

**TU 221**
**Uptake and effects of particle-bound polycyclic aromatic hydrocarbons (PAH) from spiked sediment suspensions in rainbow trout (Oncorhynchus mykiss, Walbaum)**
M Brinkmann[1], C Cofalla[2], S Roger[2], H Schüttrumpf[2], H Hollert[1], S Hudjetz[1], J Kuckelkorn[1], U Kammann[3]
[1]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[2]Institute for Hydraulic Engineering and Water Resources Management, AACHEN, Germany
[3]Johann Heinrich von Thünen-Institut, Institut für Fischereiökologie, HAMBURG, Germany
In context of the ongoing scientific discussion about the potential ecotoxicological impacts of flood events, it is of vital importance to understand the detailed mechanisms of contaminant uptake from suspended particles and related effects in aquatic biota. As part of the interdisciplin-

ary project Floodsearch II, which was supported by the German Excellence Initiative, rainbow trout (*Oncorhynchus mykiss*) were exposed to suspensions of natural sediment from the River Rhine. Prior to suspension, the sediment was spiked with a mixture of the polycyclic aromatic hydrocarbons (PAH) pyrene, phenanthrene, chrysene, and benzo[*a*]pyrene at environmentally relevant concentrations. A control treatment without addition of PAHs was also included in the experimental design. The nominal concentration of suspended solids was 10 g $L^{-1}$ in both experiments. After 1, 2, 4, 6, 8 and 12 days of exposure, important physico-chemical parameters, concentrations of PAHs in water and suspended matter, as well as biomarkers of exposure to the analytes in rainbow trout ($n$=10; biliary metabolite concentrations, CYP1A protein content in liver tissue, as well as lipid peroxidation) were investigated. Instrumental chemical analyses revealed that analyte concentrations in suspended solids decreased over time, while the degradation rate was highest for phenanthrene, followed by pyrene and benzo[*a*]pyrene. This indicates that the loss was most probable due to microbial metabolization. Concentrations of biliary PAH metabolites in fish increased only slightly in the treatment without addition of PAHs, while mean levels increased to 166 µg $ml^{-1}$ for 1-hydroxypyrene (control value 4.6 µg $ml^{-1}$) and 17 µg $ml^{-1}$ for 1-hydroxyphenanthrene (control value 0.1 µg $ml^{-1}$) in the spiked treatment within two days, followed by a subsequent decrease over time. With a latency of two days, this peak of metabolism was followed by a peak of lipid peroxidation that indicates the oxidative stress caused by PAH metabolites. CYP1A protein levels are currently being evaluated using Western Immunoblotting. The results of this study clearly indicate the importance to account for the temporal variability of physiological markers and to support exposure experiments of aquatic biota to particle-bound pollutants with analytical data.

### TU 222

**Investigating variation in bioaccumulation potential of hydrophobic organic chemicals caused by lipid composition diversity**

A van der Heijden, MTO Jonker
Utrecht University, UTRECHT, The Netherlands

Bioconcentration factors (BCFs) reported in the literature are often highly variable for a single hydrophobic organic chemical (HOC). Though in some cases the variation may be caused by experimental artifacts (e.g. incomplete phase separation or nonequilibrium conditions), true mechanisms may affect bioaccumulation of HOCs in such a way that BCFs should perhaps be considered case-specific rather than generic parameters. Bioaccumulation is a product of equilibrium partitioning between an organism and its surrounding aqueous environment and is therefore determined by the characteristics of the interacting phases. For instance, temperature and pH of the aqueous medium and biotranformation capacity of the organism have been shown to affect bioaccumulation of HOCs. Another, less intensively studied factor is lipid composition. Fatty acid pools are known to be highly variable between species, but even intraspecies differences may occur due to a temperature-dependent mechanism regulating homeoviscosity of cellular membranes. In the present study, both inter and intraspecies variation in bioaccumulation were investigated by measuring sorption of PCBs to (1) biological homogenates generated from diverse aquatic organisms (i.e. snail, midge larva, water flea, blackworm, mussel, stickleback, eel, and carp), and (2) homogenates of blackworms and sticklebacks acclimatized to different environmentally-relevant temperatures (4 - 24 °C). Results indicated that lipid-normalized homogenate-water partition coefficients may differ for up to 0.86 log units between species. For both blackworms and sticklebacks, lipid-normalized partition coefficients for differently acclimatized batches were also significantly different, although differences were minor. However, there was no clear relation with acclimatization temperature. These results indicate that BCF values may not generally be applicable to any species for the purpose of risk assessment of HOCs, even when disregarding the interspecies variation in metabolic capacity. Studying homogenate-water partition coefficients provides clear advantages above using living organisms, as it enables measurements of sorption to biological material without the interference of complexing factors, such as biotransformation, kinetics, and growth dilution.

**Toxicokinetic and toxicodynamic modelling for Daphnia magna exposed to acetylcholinesterase inhibitors**

J Jeon[1], A Kretschmann[1], B Escher[2], J Hollender[1]
[1]EAWAG, DÜBENDORF, Switzerland
[2]University of Queensland, BRISBANE, Australia

Carbamates are well known as acetylcholinesterase (AChE) inhibitors, but, in general, less toxic than organophosphate pesticides (OPs) due to the relatively fast reactivation rate of AChE. In the presence study, we demonstrate a toxicokinetic (TK) and toxicodynamic (TD) model for carbaryl to describe the relationship between the internal concentration in test species, Daphnia magna, and the inhibition of AChE activity at several time points during the 48 h exposure. The internal concentration of carbaryl is measured as the estimate of inhibitor concentration at the target site, whereas the production of 1-naphthol is also monitored as a dominant transformation product (TP) of the parent compound. The TKTD parameters for carbaryl are determined by fitting data from in vivo and in vitro experiments. The results are compared to those for diazinon (Kretschmann et al., 2010), one of the representative OPs which exhibit irreversible AChE inhibition.

### TU 224

**Bioaccumulation, biotransformation and elimination kinetics of organic chemicals in Gammarus pulex**

R Ashauer[1], A Hintermeister[1], I O'Connor[1], M Elemelu[1], J Hollender[1], BI Escher[2]
[1]Eawag, DÜBENDORF, Switzerland
[2]The University of Queensland, Entox, BRISBANE, Australia

We investigate the bioaccumulation, biotransformation and elimination kinetics of 15 organic chemicals (Aldicarb, Carbofuran, Carbaryl, Malathion, Chlorpyrifos, 2,4-Dichloroaniline, 2,4-Dichlorophenol, 1,2,3-Trichlorobenzene, 4,6-Dinitro-o-cresol, 2,4,5-Trichlorophenol, Pentachlorophenol, Ethylacrylate, 4-Nitrobenzyl-chloride, Sea-nine and Imidacloprid) from diverse chemical classes and covering a wide range of physicochemical properties (log Kow from 0.33 to 4.96) in the freshwater amphipod Gammarus pulex. This study consists of metabolite screening and identification tests (24h exposure), biotransformation kinetics experiments with a 24h exposure followed by a depuration phase of variable length and toxicokinetic modeling. Further, a comparison of rate constants and bioaccumulation factors derived in this study (i.e. with biotransformation accounted for) with those from a previous study based on total 14C measurements (without consideration of biotransformation) was undertaken.
Known biotransformation products as well as the parent compound were identified by spiking unlabelled standard material of these to samples of control organisms and identification of these peaks via UV-detection. In case no reference standards were available or biotransformation products were unknown, extracts were analyzed after HPLC separation and electrospray ionization in either positive or negative mode with high resolution mass spectrometry using a LTQ-Orbitrap. Four compounds (1,2,3-Trichlorobenzene, Imidacloprid, 4,6-Dinitro-o-cresol and Ethylacrylate) were not biotransformed. For the other eleven parent compounds we detected 19 biotransformation products in total (up to three per parent) of which we identified nine.
Toxicokinetic models were fitted to the time-course of internal concentrations of parent and metabolite compounds. Comparison with bioaccumulation parameters based on total 14C-body residues from a previous study showed correlation of uptake rate constants within one order of magnitude around the 1 to 1 line, confirming that uptake rate constants are independent of biotransformation. Bioaccumulation factors are overestimated by the total 14C-study by a factor of six. Elimination rate constants for compounds which were biotransformed very fast were much smaller compared to those from the total 14C-based study because there the elimination rate reflects elimination of the biotransformation products.

### TU 225

**Sources and data quality of the existing data for bioconcentration**

A Lombardo[1], A Roncaglioni[1], MI Potoumenou[1], M Nendza[2], E Benfenati[1]
[1]Istituto di Ricerche Farmacologiche "Mario Negri", MILAN, Italy
[2]Analytisches Laboratorium, LUHNSTEDT, Germany

To protect environmental and human health, REACH legislation requires data, e.g.. for bioaccumulation the bioconcentration factor (BCF) in aquatic species, preferably fish. BCF is requested for all compounds produced or imported above 100 tonnes/y, and it is useful for compounds produced or imported above 10 tonnes/y to perform PBT (Persistent, Bioaccumulative, and Toxic) assessment and Chemical Safety Assessment. For PBT assessment two thresholds for BCF are set: 2000 and 5000 L/kg. Below 2000 L/kg a compound can be considered non bioaccumulative, above 5000L/kg it is very bioaccumulative and between 2000 and 5000 L/kg it is bioaccumulative.
In this work the experimental variability and data quality of five different public data sets and databases containing BCF data were analysed. One data set (Dimitrov et al., 2005) contains only single, reliable data, two contain mostly single data (Fu et al., 2009 and Footprint database) and two contain single or multiple data (CEFIC LRI and Arnot & Gobas, 2006 databases). In the CEFIC LRI database a Klimish reliability score is reported for some compounds. It should contain only reliable data. In the Arnot & Gobas database a global score is indicated, based on six different criteria. We analysed the experimental variability of a data set obtained combining the reliable data from the previous sources.
In general, in all databases/data sets with more than one value for each compound, the variability is greater than the difference between the two thresholds established by REACH. Moreover, for some compounds, the experimental variability is high, even more than three orders of magnitude (e.g. for DDT experimental variability is of 3.57 log units).

### TU 226

**Applicability and performance evaluation of QSAR models for bioconcentration in fish**

A Lombardo[1], A Roncaglioni[1], MI Potoumenou[1], M Nendza[2], AP Toropova[1], AA Toropov[1], R Kühne[3], A Franco[4], E Benfenati[1]
[1]Istituto di Ricerche Farmacologiche "Mario Negri", MILAN, Italy
[2]Analytisches Laboratorium, LUHNSTEDT, Germany
[3]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[4]Technical University of Denmark, LYNGBY, Denmark

Under the REACH legislation, human and environmental protection requires carefully assessing each compound produced or imported in EU. To reduce the number of animal tests (in particular tests involving vertebrates) and the cost, REACH promotes the use of all existing information and alternative methods (e.g. in-vitro, QSAR or read-across).
Goal of this work was to evaluate in which cases QSAR models can replace in-vivo tests. For this reason several QSAR models, developed within OSIRIS project (i.e. ChemPropTM and BCF regressions model for monovalent ionic compounds by Fu et al., 2009) or freely available (i.e. EPISuite, T.E.S.T., CAESAR, CORAL and logP-based equations) were tested. Performance and applicability of the models has been evaluated using a large dataset. The models were analysed both as regression models (in particular error distribution and correlation) and as classification models.
It is interesting to notice that the results of the different models do not always overlap. This offers the opportunity to identify strategies for the careful integration of different methods.
Besides the use of combination of the results on a purely statistical way, we will address the possibility to define a more reliable use of the model, referring to the applicability domain.
Financial support by the OSIRIS project (GOCE-CT-2007-037017) is gratefully acknowledged.

**Read-across model to estimate the BCF in fish from data for similar compounds**

R Kühne, RU Ebert, G Schüürmann
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

A validated BCF (fish) dataset for 473 compounds, collected within the former EU project CAESAR and made available by project partners within the EU integrated project OSIRIS, is exploited as the data base for an read-across approach. The model decomposes the training set and the test compound into atom-centred fragments (ACF) and selects the nearest neighbours of the test compound from the data base through the ACF similarity. The BCF data for these chemicals then are used to predict the result. With different levels of similarity, users of the model may switch between increased accuracy or a more general applicability. The performance of the model is shown via leave-one-out statistics. The implementation in the software system ChemProp provides the modelling results and details as well as the coverage of the applicability domain and an uncertainty estimation for the model result. Financial support from the EU Integrated Project OSIRIS (contract No. 037017) is acknowledged.

**Integrated testing strategies (ITS) for bioaccumulation: in vitro modules**

E Segner[1], L Lany[1], M Hawliczek[1], M Nendza[2], A Lombardo[3], A Roncaglioni[3], E Benfentai[3]
[1]University of Bern, BERN, Switzerland
[2]Analytsiches Laboratorium, LUHNSTEDT, Germany
[3]Pharmacological research Institute Mario Negri, MILANO, Italy

Under REACH, assessment of the bioconcentration potential is required for chemicals with a log Kow greater than 3 if it is produced or imported in quantities greater than 100 t/year. The

gold standard for the determination of the bioconcentration factor (BCF) is the OECD Test Guideline 305 with fish, which is demanding in terms of resources, costs and number of animals. Integrated? Testing Strategies (ITS) for bioaccumulation assessment take advantage of a variety of information sources in order to estimate whether a chemical is bioaccumulative (B, BCF > 2000) or very bioaccumulative (vB, BCF > 5000). Here, we discuss the potential contribution of in vitro methods to an ITS for fish BCF.
A major process influencing bioaccumulation of xenobiotics in fish is the endogenous metabolism or biotransformation, which will result in a lower BCF value than expected on the basis of the lipophilicity. In vitro methods provide information on the rates of biotransformation . Since the liver is the main site of xenobiotic metabolism in fish, in vitro assays to measure metabolic turnover of xenobiotics should be based on metabolically competent preparations from fish liver, either subcellular fractions such as S9 (supernatant 9000) and microsomes, or isolated liver cells. The metabolic clearance rates generated by such in vitro systems need to be scaled to the whole fish. To this end, physiologically based models can be used that convert the in vitro clearance rate of the liver preparations into the in vivo clearance rate, Km, of the fish. The Km can then be incorporated into existing BCF models to predict the in vivo BCF. Currently, in vitro-based BCF predictions are available only for a small number of chemicals, but these data look promising. In conclusion,the role of in vitro methods within a BCF-ITS would be to provide additional evidence for those cases when in silico-based predictions of the BCF lead to equivocal results.
Financial support by the OSIRIS project (GOCE-CT-2007-037017) is gratefully acknowledged.

## ET14 - Natural toxins in ecotoxicology

### TU 234

**Effects of botanical insecticides on the egg parasitoid trichogramma cacoeciae marchal (Hym. Trichogrammatidae)**

H Abdelgader
Agricultural Research Corporation, WAD MEDANI, Sudan

Parasitoids of the genus Trichogramma occure naturaly worldwide and play an important role as natural enemies of lepidopterous pests on a wide range of agricultural crops. Laboratory studies were carried to investigate the side effects on both the susceptible life stage (adults of parasites) and Less susceptible life stage (parasites within their hosts) of Trichogramma cacoeciae to two formulated products of each of two botanical insecticides: Azadirachtine (Neemazal T/S Blank and Celaflor) and Quassin (alcoholic or water extracts). The results showed that by exposing adults T. cacoeciae to residues of Neemazal formulations on glass plates, the tested preparations were either harmful (Neemazal-Blank) or moderately harmful (Celaflor). The two Quassin formulations tested were harmless. When treated host eggs were offered to adults T. cacoeciae, all tested chemicals were almost harmless. In a further test, host eggs parasitized at different time intervals (1-8 days), were sprayed at the same day. The results indicated that only Neemazal T/S-Blank formulation was slightly to moderately harmful reducing adult emergence. The results showed, in general, that both Azadirachtine and Quassin were relatively safe to the tested parasitoid and could therefore be used in combination with Trichogramma releases. The results of this study can be utilized in designing a less hazardous biopesticides control strategy to combat noxious insect pests with less negative impact on beneficial natural enemies as well as the surrounding environment.

### TU 235

**Evidences for genotoxicity of paralytic shellfish toxins produced by Gymnodinium catenatum in white seabream (Diplodus sargus)**

P Pereira[1], S Guilherme[2], M Barata[1], L Nicolau[1], MA Santos[2], M Pacheco[2], P Pousão-Ferreira[1], P Reis Costa[1]
[1]Instituto Nacional de Recursos Biológicos (INRB/IPIMAR), LISBOA, PORTUGAL, Portugal
[2]CESAM/Departamento de Biologia da Universidade de Aveiro, AVEIRO, Portugal

The re-emergence of the toxin-producing dinoflagellate *Gymnodinium catenatum* in 2005 after a ten years hiatus of absence in the Portuguese coast was the leitmotiv to the present investigation on the effects of paralytic shellfish toxins (PSTs) in fish. Although fish are frequently exposed to PSTs, the number of studies on its toxicity is low. In particular, reports on genotoxicity evaluation of PSTs are almost inexistent and the few available data are controversial. Thus, the aim of this study was to investigate the induction of cytogenetic damage, measured by the erythrocytic nuclear abnormalities (ENA) assay, in peripheral blood of white seabream (*Diplodus sargus*) exposed to a combination of PSTs produced by *G. catenatum*. *D. sargus* is a valuable species for Mediterranean aquaculture and abundant in littoral waters from Eastern Atlantic to Mediterranean Sea where blooms of G. catenatum occur and consequently toxin events. Toxins were extracted from a 15 L G. catenatum culture and their profile was determined by HPLC-FLD, showing the following compounds in decreased order of relative abundance (in a molar basis): C1+2 (34.3 %) > B1 (23.6 %) > C3+4 (17.1 %) > B2 (16.2 %) > dcSTX (4.1 %) > dcGTX2+3 (3.1 %) > dcNeo (1.5 %) > GTX2+3 (0.1 %). Fish (38 ± 2 g) were intracoelomically (IC) injected with a 0.5 mL single dose of PSTs (1.60 µg STXeq kg-1), using physiological saline solution (0.9 % w/v) as vehicle. A control group received only the vehicle solution. Fish were sacrificed at 2 and 6 days after IC injection, blood was collected from for ENA evaluation and liver was removed for the quantification of PSTs in composite samples.
PSTs concentration in fish liver after 2 days of exposure was 15.2 µg STXeq $kg^{-1}$. Following 6 days, a slight decrease to 12.2 µg STXeq $kg^{-1}$ was recorded. Although a combination of several PSTs were IC injected to fish, only dcSTX that initially constituted 4.1 % of the toxins was detected in fish, suggesting ability to metabolize PSTs and or to selectively sequester dcSTX. ENA frequency increased significantly both at 2 and 6 days after exposure in comparison with control fish. Current data demonstrated the genotoxic potential of PSTs in fish pointing to an ecological risk associated with the natural exposure of fish to *G. catenatum* blooms.

### TU 236

**Effects of microcystin-LR on the physiological performance of Daphnia magna and its offspring**

R Ortiz-Rodriguez[1], TS Dao[1], C Wiegand[2]
[1]IGB, BERLIN, Germany
[2]University of Southern Denmark, ODENSE, Denmark

Due to eutrophication and other factors, the frequency of cyanobacterial blooms has increased worldwide. Besides being a nuisance, they can produce toxins harmful to the ecosystem and human health. Some of the most common and potent cyanobacterial toxins are the microcystins MC, especially the variant MC-LR. As a consequence of blooms, the freshwater planktonic communities are affected, particularly the herbivores populations such as those from *Daphnia* spp. The cyanobacterial factors driving this effect are mechanical interference on feeding, nutritional inadequacy and toxicity. The physiological responses of *Daphnia* to MC have been widely studied; however a consensus on the tolerance and its transfer to the offspring has not been reached. Despite the importance of such interaction and the transfer of toxins to higher trophic levels, the effect of MC to *Daphnia* and its offspring is unclear.
Aim of our study is to address these questions, how are *Daphnia* and its offspring affected by MC-LR at the biochemical level? What are the consequences for the physiological performance? We analyzed the effect of MC-LR exposure on antioxidant and biotransformation enzymes and its relation with metabolic enzymes, comparing different age groups and offspring of treated *Daphnia*.
We exposed neonate and adult *D. magna* to MC-LR to determine the effect on enzymes catalase CAT, glutathione-S-transferase GST, pyruvate kinase PK, malate dehydrogenase MDH, lactate dehydrogenase LDH and the parameters thiobarbituric reactive substances TBARS and lactate. Additionally, we exposed *D. magna* to different schemes of exposure and collected its offspring for further exposure to compare their response with those from non exposed parents.
Results show MC-LR effects on CAT and GST. CAT activity increases in neonates exposed to the highest concentration but not in adults, GST has a concentration dependant response to MC-LR. TBARS indicated oxidative stress at high concentrations, pronounced in adults correlated to the lack of antioxidant enzyme activity increase. LDH is inhibited, impairing this metabolic pathway. Based on the ability to maintain enzyme activities and buffer oxidative stress, neonates may cope better with MC-LR than adults. The transgenerational effect of MC-LR depends on the scheme of exposure; there is a differential response of the offspring, particularly on CAT according to the exposure scheme of the parents.

**Comparison of the transcriptomic response of a Cd-sensitive and a Cd-tolerant Daphnia pulex isolate to cyanobacterial stress**

J Asselman[1], DIM de Coninck[1], SP Glaholt[2], JK Colbourne[2], CR Janssen[1], JR Shaw[2], KAC de Schamphelaere[1]
[1]Ghent University, GHENT, Belgium
[2]Indiana University, BLOOMINGTON, United States of America

We investigated gene expression of a Cd-tolerant and a Cd-sensitive *Daphnia pulex* isolate chronically exposed for 16 days to the toxic cyanobacteria *Microcystis aurigunosa*. Cyanobacterial blooms of this species, which are predicted to become increasingly prominent under climate change conditions, are known for its production of microcystin (a toxic cyclic hexapeptid). Life table tests revealed an increased tolerance of the Cd-adapted isolate to *M. aeruginosa*. The microarray experiment followed a 2x2 full-factorial design: Cd-tolerant isolate vs Cd-sensitive isolate. (control diet vs. 50% *M. aurigunosa* in diet). Microarray analysis of the gene expression patterns resulted in 4250 uniquely upregulated genes in the sensitive isolate exposed to *M. aeruginosa*. A subsequent metabolic pathway analysis revealed at least two significantly upregulated pathways in the Cd-sensitive isolate (but not in the Cd-tolerant isolate), i.e. biodegradation and energy metabolism. These results, in combination with microcystin accumulation data, suggest that the higher sensitivity to *M. aeruginosa* of the Cd-sensitive isolate may be due to a higher microcystin accumulation in this isolate, This research benefits from and contributes to the Daphnia Genomics Consortium.

**Effects of cyanobacterial extracts and cyanotoxins on the growth of microalgae**

CF Pinheiro[1], S Loureiro[2]
[1]University of Aveiro and CESAM, AVEIRO, Portugal
[2]CESAM & University of Aveiro, AVEIRO, Portugal

Toxin-producing cyanobacteria occur in aquatic ecosystems worldwide and their cyanotoxins may have adverse effects on aquatic organisms. However, not much is known about the potential effects of cyanotoxins on microalgae, an ecologically important group which plays an essential role at the base of aquatic food chains. The purpose of this work was to study the effects of Microcystis aeruginosa and Aphanizomenon ovalisporum cell extracts containing respectively the cyanotoxin microcystin-LR (MC-LR) and cylindrospermopsin (CYL) and pure MC-LR and CYL on the growth of three microalgae species, the freshwater algae Chlamydomonas sp. and Chlorella vulgaris and the marine alga Nannochloropsis sp. The effects of cyanobacterial extracts and pure toxins on microalgae growth were respectively investigated after 4 and 7 days of exposure in the concentration range 0.005-2.5 µg.ml-1 and 0.5-20 µg.ml-1 using microplate assays. Our results demonstrate different susceptibilities of microalgae to cyanotoxins. Pure MC-LR induced more pronounced effects on microalgae growth than M. aeruginosa cell extract. Pure MC-LR strongly inhibited the growth of microalgae species at concentrations higher or similar to 2.5 µg.ml-1 after 4 and 7 days of exposure, whereas the M. aeruginosa cell extract stimulated only the growth of microalgae species at the highest concentrations during the same exposure period. On the other hand, A. ovalisporum cell extract caused more pronounced effects on microalgae growth than pure CYL. The A. ovalisporum cell extract strongly affected the growth of microalgae at concentration of 2.5 µg.ml-1 after 4 and 7 days of exposure, while growth of C. vulgaris was only slightly inhibited by pure CYL at 10 and 20 µg.ml-1 after 4 days of exposure. Our results suggest microalgae growth response are species specific and dependent on the type of toxin. However, cyanotoxins are not likely to affect microalgae growth at environmentally occurring concentrations. This indicates that so-discussed allelophatic effects against microalgae are unlikely to occur, at least concerning microalgae growth.

### TU 239

**Transfer of the cyanobacterial toxin BMAA via irrigation from water to an agricultural plant (Triticum aestivum)**

V Contardo-Jara[1], A Poch[2], S Pflugmacher[3]
[1]Leibniz-Institute of Freshwater Ecology and Inland Fisheries, BERLIN, Germany
[2]Humboldt-Universität zu Berlin, Institute of Biology, BERLIN, Germany
[3]Institute of Technology, Dpt. of Ecological Impact Research and Ecotoxicology, BERLIN, Germany

BMAA (β-N-methylamino-L-alanine) is a neurotoxic non-protein amino acid produced by different species of cyanobacteria. It can occur as a free amino acid or protein-bound. It is discussed if BMAA is a possible cause of the "Amyotrophic Lateral Sclerosis/Parkinsonism Dementia Complex"(ALS/PDC), since protein-bound BMAA has been found in the brain tissue of ALS/PDC patients.
Triticum aestivum is one of the most important corns on the world market. If BMAA contami-

nated water is used for irrigation, BMAA may be absorbed by the plants. Hence, even a transfer of BMAA to animals and humans via the food chain is possible.
It was the aim to examine whether BMAA is absorbed from wheat plants when irrigated with BMAA containing water. (1) After irrigation of germinated wheat for 48 h with different concentrations of BMAA (0, 0.01, 1, 10 and 100 $mgL^{-1}$) sprouts and roots were analysed for free and protein-bound BMAA by LC-MS/MS. As rising oxidative stress is expected, activity of antioxidant enzymes peroxidase (POD) and catalase (CAT) were determined in both plant compartments at the same time point. (2) Sprouts and roots of plants irrigated with 100 $mgL^{-1}$ BMAA were additionally analysed for free and protein-bound BMAA, as well as for POD and CAT activity after 0.5, 1, 1.5, 2, 2.5, 3 and 3.5 h.
The exposure to 100 $mgL^{-1}$ BMAA showed that until 3.5 h there are higher amounts of free BMAA in roots than in sprouts. After 48 h this pattern is reversed with higher concentration of free BMAA in sprouts compared to roots. The results clearly evidence that BMAA in transported within the plant. The content of protein-bound BMAA was lower than that of free BMAA, thus rising with increasing concentrations of BMAA in the exposure medium. Furthermore, plants exposed to 10 and 100 $mgL^{-1}$ BMAA had two-fold higher amounts of protein-bound BMAA in sprouts compared to roots after 48 h.
POD activity was slightly increased in the sprouts of plants from all treatment groups, whereas only the highest concentration provoked a POD activity increase in roots. CAT activity increase was more pronounced. CAT activity was elevated after only 1.5 h in sprouts of plants irrigated with 100 $mgL^{-1}$ BMAA. Moreover, especially in sprouts there was a concentration dependent CAT activity increase yielding to the assumption that oxidative stress was generated due to the BMAA exposure.
In conclusion, irrigation is a potential way to transfer cyanobacterial toxins to the terrestrial environment.

**TU 240**

**Transfer of cyanobacterial toxins into edible plants via irrigation with lake water - a Chinese case study**

A Peuthert[1], L Kun[2], S Pflugmacher[1]
[1]Berlin Institute of Technology, BERLIN, Germany
[2]Anhui Environmental Protection Agency, HEFEI, China

The rising pollution of water bodies goes along with an increase of cyanobacteria in the microbiotic community. The ability of cyanobacteria to produce toxins is well known and many cases of poisoning of animals and humans have been described worldwide. Thereby the exposure routes were mainly via drinking water. Another possible risk is the irrigation of edible plants with cyanotoxin contaminated water, since plants are able to take up these toxins. This scenario takes place e.g. at the lake Chao (China). In this study the cyanotoxin content in vegetables (spring onion, pak choi and courgette) grown on the shore of lake Chao was investigated. Microcystins (MC) were measured in the cyanobacterial bloom containing lake. The continuous irrigation of the plants with lake water led to high accumulations of MCs in all vegetables. The MC concentrations in the vegetables were above the TDI ("tolerable daily intake") recommended by the WHO.

**TU 241**

**Harmful algae in the Venice Lagoon and in the Po River Delta (northern Adriatic Sea, Italy)**

D Bilanicova, C Facca, G Pojana, A Sfriso, A Marcomini
University of Venice, VENICE, Italy

An integrated approach for the structural identification and quantification of algal toxins, in Northern Adriatic Sea, specifically in the Po river delta and in the Venice lagoon, by applying a combination of analytical techniques such as optical and scanning microscopy (OM, SEM), and Liquid Chromatography coupled with High Resolution Time of Flight Mass Spectrometry (HPLC-HR-TOF-MS), is presented. The proposed approach has been preliminary applied to the investigation of harmful algae occurrence and distribution in the above mentioned coastal areas.
The performed sampling sessions showed that potentially harmful algae such as Dinophysis caudata, D. mitra and D. sacculus were present during summer period in most of areas directly influenced by seawater, such as the Venice port entrances and the Po river delta, but not in the inner Venice lagoon parts. Nevertheless, quantitative observations demonstrated that their abundance were always significantly below the conventional limit (~200 cells/L) for which poisoning events could occur. The presence of Pectenotoxin2 (PTX2) in phytoplankton cells extract was anyway confirmed by HPLC-HR-TOF-MS at Venice lagoon port entrance, so indicating the potential release of toxins in detectable amounts even at such low cell concentration levels.

**TU 242**

**Temporal variations of microcystins and anatoxin-a in San Roque reservoir (Córdoba-Argentina)**

DA Wunderlin[1], MV Amé[1], LN Galanti[1], M Ruiz[2], AL Ruibal[2], MI Rodriguez[2]
[1]Universidad Nacional de Córdoba, CÓRDOBA, Argentina
[2]Instituto Nacional del Agua-Centro de la Región Semiárida, CÓRDOBA, Argentina

The occurrence of cyanobacterial toxic bloom is well known worldwide. However, reports on the occurrence of cyanotoxins in South America are scarce. San Roque reservoir is an artificial lake, formed by a dam, which is the main source of drinking water for Córdoba city (1.5 million inhabitants). Fishing, swimming, and sailing are additional activities practiced in its waters. The main goal of this study was evaluating temporal variations of three common microcystins (MC-LR, -RR and -YR) and anatoxin-a in San Roque reservoir, looking to identify environmental factors that could promote the presence of these cyanotoxins in this water body. Cyanotoxins were quantified by HPLC-ESI-MS/MS in samples collected monthly from February, 2006 to March, 2007. MCs and anatoxin-a were detected in 71% and 38% out of analyzed samples, respectively. Highest levels of MCs were observed during summer, while anatoxin-a was mainly present during autumn. The occurrence of MC-RR and MC-LR was similar but MC-RR reached higher values than MC-LR. MC-YR was found in 4 samples, being the main cyanotoxin present in these samples. MCs levels showed positive correlation with Microcystis sp. and Pseudoanabaena sp. biovolume ($p<0.05$, $r=0.51$ and $r=0.55$ respectively), while anatoxin-a concentration showed positive correlation with Anabaena sp. and Oscillatoria sp. biovolume ($p<0.05$, $r=0.40$ and 0.48, respectively). Discriminat analysis showed that the presence of MCs in the reservoir could be favored at pH close to 8.0, in addition to low proportions of Chlorophyta and Crysophyceae in the phytoplankton. On the other hand, the dominance of anatoxin-a could be favored at higher levels of pH and chlorophyll-a, lower temperature and total phytoplankton biovolume, with total inorganic nitrogen close to 500 µg L-1. Low proportion of Criptophyta, Cyanophyta and Crysophyceae in the phytoplankton also favored the presence of antoxin-a. The co-occurrence of both toxins (MCs and anatoxin-a) was detected when the pH was over 7.6, with dissolved oxygen close to 9.2 mg L-1 and chlorophyll-a around 61 µg L-1. MCs levels exceed guidelines values recommended by WHO for either recreational or drinking water. This is the first report on the presence of anatoxin-a in Argentinean freshwaters, although anatoxin-a levels were below the guidelines established in other countries (i.e. New Zealand- 6 µg L-1). Further studies are necessary to fully assess environmental factors causing the observed temporal variation.

**TU 243**

**Rapid detection of Pacific-ciguatoxin-1 (P-CTX-1) in blood of coral reef fish, mice and humans using high-performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS)**

YL Mak[1], JJ Wu[1], MB Murphy[1], JCW Lam[2], WH Chan[1], LL Chan[2], PKS Lam[1]
[1]City University of Hong Kong, HONG KONG, Hongkong
[2]State Key Laboratory in Marine Pollution, City University of Hong Kong, HONG KONG, Hongkong

Ciguatera fish poisoning (CFP) is a kind of food intoxication caused by ingestion of coral reef fish contaminated by ciguatoxins (CTXs). Among the CTXs, Pacific-CTX-1 (P-CTX-1) is the major toxin in the muscle of carnivorous fishes from the Pacific Ocean, contributing to around 90% of the total lethality. Recently, cases of CFP have increased globally, probably due to greater international trade in and consumption of coral reef fish. To protect human health and minimize economic losses by the fisheries industry after CFP outbreaks, rapid screening of ciguateric coral reef fish is crucial. Analytical methods are currently available for the detection of P-CTX-1 in fish muscle. However, quantification of CTXs in blood has the advantages of being non-destructive and allows for repeated sampling for continuous monitoring, and blood CTX concentrations may serve as a surrogate for estimating levels in fish tissue. This study aims to develop a chemical method for quantifying P-CTX-1 in blood from coral reef fishes using sonication, together with high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS). Using the optimized conditions, matrix spike recoveries of P-CTX-1 in blood of nine coral reef fish species ranged from 76–98%. The variation among samples related to repeatability and reproducibility of the developed method was < 11%. Linear correlation coefficients for both solvent- and matrix-based calibration curves were above 0.997 and matrix effects in blood extracts were much lower than those in fish muscle extracts. The limit of quantification (LOQ) of P-CTX-1 in fish blood was determined to be 0.5 ppb; and it can be improved by the employment of a more sensitive HPLC-MS/MS. The whole analytical method required 12 hours for eight samples. The robustness of the present method was examined using blood from mice and humans so as to assess its potential for clinical diagnosis of CFP in animal models as well as humans and the matrix spike recoveries were found to be 77±7% and 71±10%, respectively. To validate the optimized method, blood will be collected from coral reef fish and mice that will be exposed to ciguateric fish extracts. This experiment will provide information about the absorption, distribution and elimination of P-CTX-1 in fish and mice.

**TU 244**

**Rapid, simple and efficient method of extraction of microcystins LR, RR and YR from fish tissues**

BL Aubry[1], P Juneau[1], PA Spear[1], S Haddad[2]
[1]Université du Québec à Montréal, MONTRÉAL (QC), Canada
[2]Université de Montréal, MONTRÉAL, Canada

Cyanobacteria are aquatic microorganisms which can be toxic to aquatic life and also to humans via food. In the recent years, the occurrence of cyanobacterial blooms has increased especially because of the eutrophication of lakes and rivers. Among the toxins they produce, there are the microcystins (MC). These are hepatotoxic cyanotoxins very stable and persistent in the environment. Microcystins can thus accumulate in flesh and organs of fishes and potentially transfer along the food chain.
The objectives of this study were to develop a rapid, simple and efficient method for microcystin extraction from fish tissues for MC-LR, -RR and -YR. In this study, we particularly focused on fish liver, muscles and blood. The liver is the target organ for microcystins, the muscles are usually the only part consumed by humans which makes them the principal vector of human exposure and blood allows the distribution of microcystins through the fish. We also verified whether it is adequate to lyophilisate the tissue before extraction or not.
In this study, samples of liver, muscles and blood were incubated in the presence of spiked standards of MC-LR, -RR and -YR. For samples of liver and muscles, one half of the samples was lyophilized and the other half was frozen pending extraction. We chose a solid-liquid extraction with methanol 100% and 80%. The detection method developed is a high performance liquid chromatography (HPLC) coupled to tandem mass spectrometry (MS/MS) using multiple reaction monitoring (MRM).
The extraction method developed allows a high recovery rate (min. 80%) for MC-LR, -RR and -YR extracted from non-freeze-dried liver and muscles and from the blood. For the extractions from freeze-dried tissues, the recovery was lower and varies between 26 and 67%. This method also allows a high and stable recovery rate for a large range of microcystin concentrations (15 - 240 ug.L-1) for each microcystine and each tissue.
The extraction and detection methods we have developed are simple, fast and efficient compared to other previously published methods which require either the preparation of a specific internal standard and protein precipitation, or extraction in acidic water at high temperature in a filtration system based on sand. After validation in vivo, this method of analysis will be used to study the accumulation of microcystins in tissues of trout and perch. This will ultimately improve estimates of human exposure to microcystins through fish consumption.

**TU 246**

**A model for emergency response and risk management of drinking water reservoirs affected by cyanobacteria blooms**

S Bogialli, L Lucentini, E Ferretti, F Nigro di Gregorio, M Ottaviani
Italian National Institute of Health, ROME, Italy

Hydrologic extreme events related to climate changes may contribute to the presence of blooms of toxic phytoplanktonand seriously impact the quality of surface water reservoirs used for drinking water supplies.
The occurrence of an extraordinary bloom of cyanobacterium Planktothrix rubescens, with maximum algal density exceeded 150 million cells/liter, was observed since the beginning of 2009 in the Occhito basin, (Apulia, Italy) most probably as the consequence of an flash cycle of drought and flooding. The event was used for a pilot study to evaluate a feasible model for risk management.
Emergency response related to the possible presence of harmful algae are mainly focused to mitigate the risk of toxins presence in distributed drinking water and to efficiently communicate risk information to the target population and authorities, according to the 'water safety plans' ap-

proach by World Health Organization.
Screening and confirmatory methods were evaluated in terms of reliability, practicability , response-time and cost-effectiveness in order to propose fit-for-purpose analytical tools for a multi-stage approach to control water basins affected by cyanobacterial blooms.
Response actions have included:
a) identification and quantification of cyanotoxins in raw, treated and distributed water;
b) specific evaluation of raw water treatments , combining granulated activate carbon (GAC) with conventional treatment practices, i.e. pre-oxidation, flocculation, sand filtration and post disinfection;
c) risk communication on different media channels, including press communicates and a dedicated web site within the Apulia Region Portal.
The above measures, as implemented through an intensive collaboration amongst the main stakeholders, were effective in successfully managing the health risk for the affected populations. Risk management plans for short-long term period were implemented involving specific investment for new flexible treatment system, investigation on environmental parameters inducing/affecting/regulating bloom formation in the basin related to seasonal changes, specific training activities for local environmental and health authorities.
Finally, general national criteria and procedures for a comprehensive risk assessment and risk management approach with reference to cyanotoxins in drinking water resources have been developed and validated.

**TU 247**

**Epigenetic toxicity of cyanobacterial extracts: effects of ozonation and chlorination**

I Sovadinova[1], P Babica[2], O Adamovsky[1], A Alpatova[3], B Marsalek[2], L Blaha[1], V Tarabara[3], B Upham[4]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Institute of Botany, Centre for Cyanobacteria and their Toxins, BRNO, Czech Republic
[3]Michigan State University, Civil and Environmental Engineering, EAST LANSING, Czech Republic
[4]Michigan State University, Pediatrics and Human Development, EAST LANSING, United States of America

Cyanobacteria and their toxins may present a hazard for drinking water safety. We examined *in vitro* potencies of *Microcystis* sp. water bloom to downregulate gap junctional intercellular communication (GJIC) and to activate mitogen-activated protein kinases (MAPK) in rat liver stem-like cells WB-F344. Both parameters are potentially associated with tumor promotion. The extract induced the acute inhibition of GJIC and activation of MAPKs ERK1/2 and p38 within 30 min of exposure at non-cytotoxic doses. Cytotoxicity was observed only at the highest doses after a 24-h exposure. A known tumor promoter, microcystin-LR, was detected in the extract by HPLC-DAD, but this cyanotoxin has been shown not to affect GJIC/MAPK in this *in vitro* model. Thus, the effects observed in our study were caused by not-yet-identified chemicals of the cyanobacterial origin. The inhibition of GJIC, activation of ERK1/2 and p38, as well as cytotoxic effects were completely eliminated when the extract was treated with ozone for 30-min. Chlorination with sodium hypochlorite had any significant effect neither on tumor promoting activity nor cytotoxicity, even when the extract was chlorinated for 24 hrs. Although chemical identity of the responsible agents remains to be elucidated, the information on the rapid elimination of the tumor promoting activity and cytotoxicity of cyanobacteria by ozone might have a particular importance for the selection of the best technology for drinking water treatment from cyanobacteria-contaminated reservoirs.

**TU 248**

**Identification of Protein Biomarker(s) Associated with Pacific Ciguatoxin (P-CTX-1) Exposure in Grouper (Epinephelus coioides)**

WH Chan[1], MB Murphy[1], TY Chen[2], LL Chan[3], PKS Lam[1]
[1]City University of Hong Kong, HONG KONG, Hongkong
[2]Institute of Biotechnology, National Cheng Kung University, TAINAN CITY, Taiwan
[3]State Key Laboratory in Marine Pollution, City University of Hong Kong, HONG KONG, Hongkong

Ciguatera is a form of food poisoning caused by consumption of reef fish contaminated with ciguatoxins (CTXs). Outbreaks of ciguatera have had both public health and socioeconomic impacts more than a century. CTXs are extremely potent"'the lethal potency of the most toxic CTX, P-CTX-1, is 100 times greater than that of tetrodotoxin. Ciguatera is not limited to tropical regions, but also occurs in non-endemic regions because of the expanding international trade in tropical fish species and the lack of practical and accurate testing methods for CTXs. Reliable biomarkers for ciguatera and/or CTX exposure in fish and humans have not been characterized to date. The identification of biomarker(s) related to CFP can support the development of more specific detection methods for the toxin, and greater understanding of resistance and biotransformation mechanisms in ciguateric fish. This study compared the effects of P-CTX-1 exposure on protein expression profiles in grouper (*Epinephelus coioides*) GL-a liver cells and in juvenile fish. Stable isotope labeling with amino acids in cell culture (SILAC) was used with a non-gel-based proteomic approach and liquid chromatography-tandem mass spectrometry (LC-MS/MS) for performing differential display analysis in the GL-a cells, while two-dimensional gel electrophoresis (2-DE) was used for analysis of the juvenile groupers. Heavy, [$^{13}C_6$ L-arginine ($R_6$) 4,4,5,5-$_2H_4$ L- Lysine ($K_4$) and $^{13}C_6{}^{15}N_4$ L-arginine ($R_{10}$) $^{13}C_6$ L-Lysine ($K_6$)] and light [normal L-arginine ($R_0$) and L-lysine ($K_0$)] amino acids were incorporated into the cells during culturing prior to experimental exposure. The juvenile groupers were fed with grouper larvae pre-injected with P-CTX-1. The proteins were extracted from the GL-a cells and juvenile groupers after exposure and digested for analysis by nano flow liquid chromatography quadrupole time-of-flight mass spectrometry (Nano-LC-QToF-MS) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-ToF-MS) respectively. Six proteins were identified with induction higher than two-fold in 0.3ng/g P-CTX-1 exposed cells. The mechanisms of these protein changes and their potential to be a biomarker(s) will be investigated.

**TU 249**

**Effects of combined mixture of microcystin-LR and cylindrospermopsin on the growth of Chlorella vulgaris**

CF Pinheiro[1], S Loureiro[2]
[1]University of Aveiro and CESAM, AVEIRO, Portugal
[2]CESAM & University of Aveiro, AVEIRO, Portugal

Cyanobacteria (blue-green algae) can simultaneously produce a variety of potent toxins in aquatic ecosystems including microcystin-LR (MC-LR) and cylindrospermopsin (CYL). The combined effects of these toxins, that can be found in water bodies, to aquatic communities are poorly understood and are of particular concern as a potential risk to human and animal health and to the environment. The purpose of this work was to study the joint effect of the cyclic peptide MC-LR with the alkaloid CYL on the growth of freshwater alga Chlorella vulgaris using a full factorial design. The two reference conceptual models for mixture evaluation based on the effect of individual compounds, concentration addition (CA) and independent action (IA), as well as the deviations to synergism/antagonism, dose-level and dose-ratio dependency were applied to the growth data. Experiment was carried out in 96-well polystyrene microplate and the effects of the binary mixture on growth of C. vulgaris were evaluated after 4 and 7 days of exposure in a concentration ranging from 0.5 to 20 µ.ml-1. The IC50 value for each toxin was compared to values calculated in the presence of the other toxin. In addition results obtained for the binary mixture were compared with those expected from the exposures to individual compounds and significant differences were observed. This work highlights the importance of this study on the effects of combined exposure to toxins and understanding their potential risks to aquatic communities.

**TU 250**

**Marine algal toxins and epigenetic effects: does okadaic acid induce alterations in DNA methylation in the mussel Mytilus edulis?**

B Vandegehuchte, CR Janssen
Ghent University (UGent), GENT, Belgium

Okadaic acid is a marine toxin, produced by different species of dinoflagellates such as *Prorocentrum lima* and *Dinophysis* sp. These species can proliferate to form a harmful algal bloom, resulting in filter-feeding shellfish accumulating these toxins. Human consumption of contaminated shellfish results in diarrheic shellfish poisoning. This is probably caused by the inhibiting effect of okadaic acid on protein phosphatases. Okadaic acid is also a known tumor promoter. It has been shown that this toxin affects DNA methylation in mammalian cells, with possible consequences for gene regulation and expression. In this study, the effects of okadaic acid on DNA methylation are tested in the mussel *Mytilus edulis*. This species is directly exposed to toxin producing algae and is known to accumulate okadaic acid. Global DNA methylation was measured by an LC-MS/MS method, which was previously successfully used to determine DNA methylation levels in the water flea *Daphnia magna*. Specific methylated sites were analyzed by an enzyme based method 'Amplification of intermethylated sites'. Results of this ongoing study will yield important insights in the toxic mechanism of okadaic acid in *Mytilus edulis*. Alterations in an epigenetic system such as DNA methylation may also give rise to transgenerational effects, which will be subject of further studies.

## LC03 - Increasing robustness of LCA methodology

**TU 254**

**How simple is it? - testing options for simplification on a LCA of mobile phone**

C Ambell[1], ÅU Moberg[2], C Borggren[2], G Finnveden[2]
[1]Division of Environmental Strategies Research, STOCKHOLM, Sweden
[2]Division of Environmental Strategies Research, KTH Royal Institute of Technology, STOCKHOLM, Sweden

The possibility to perform full-scale LCAs for new ICT products and upgraded models is very limited. Thus there is a need for simplification, but the methodological choices should be made with care and implications should be considered. The study presented here was performed to identify simplifications that could be made in the assessment of ICT products and different simplifications were tested on a previous LCA on a mobile phone.
From studying the results for the different impact categories and how they vary between different life cycle phases we learned that by only considering Global Warming Potential we can not make a satisfying environmental assessment of a mobile phone. To select a few impact categories only was neither an easy task based on the study results. Many of the impact categories varied to a too large extent. Furthermore, based on the current study we do not suggest the possibility of excluding any life cycle phases. However, some specific processes seem to be the major reasons for environmental impact of material acquisition and manufacturing. Thus, a possibility for simplification through focusing on some process within the life cycle may be feasible. Processes include gold production, electricity generation and chip production. Testing the possibility to use data for electronic components and all other processes from the Ecoinvent database, the results for global warming potential showed a high correspondence with the original figures which indicated that the use of generic data would give relevant results. However, for the other impact categories the results were not as promising as major differences were shown for most of them. Some first conclusions are at this stage that it is not enough to consider only global warming potential when ICT products are to be assessed from an environmental perspective. There are some processes in material production and manufacturing that seem to be of major importance. In line with earlier studies the electricity generation proves to be an important issue. However, the possibility to draw general conclusions on a set of process to focus assessments on need to be confirmed in further studies and through other case studies performed in the ICT field. Finally, as there is always the possibility that data gaps and uncertainties in current "full"LCAs will lead to the recommendation of simplifications which are invalid, more comprehensive LCAs always need to be made to complement the simplified assessments.

**TU 255**

**Investigation of LCA simplification approach: the wind power electricity case**

P Padey[1], I Blanc[2], D Le Boulch[3]
[1]EDF R&D / MINES ParisTech, MORET SUR LOING, France
[2]MINES ParisTech, SOPHIA ANTIPOLIS, France
[3]EDF R&D, MORET SUR LOING, France

Scientific publications related to the electricity generation systems from Life Cycle Assessment (LCA) show great variability in their results and conclusions. Thus it leads policy makers to consider LCA somehow as an inconclusive method. Moreover, LCA is usually considered in the industry sector as time and energy consuming.
This study concerns the onshore wind power electricity greenhouse gases (GHG) performances. It aims at developing a correlation facilitating access to these performances as a function of key parameters.
A thorough LCA literature survey and analysis of the ecoinvent 2.1 wind turbine (WT) LCAs have highlighted the importance of a limited numbers of parameters.
These, have been classified into 3 categories: technical (related to the intrinsic WTs characteristics such as weights or power curve), geographical (related to the wind conditions on the implantation site) and methodological (the lifetime defined arbitrarily).
A 17 WTs sample has been selected (from 800kW to 4.5MW) which is assumed to be representative of wind turbines installed since 2003, and forecasted for the near future. The WT are

characterized by their component weights, tower heights and their power curves. The WTs inventories have been built considering the main assumptions highlighted by the literature survey and the ecoinvent inventory assessment. For instance, we kept the same lifetime for both the moving and fixed part . We did not consider the end of life because this is too systems specific (regarding the possible scenarios).Then the electricity production for the WTs has been calculated according to their power curve and the mean wind speed.
The correlation relating GHG impacts per kWh produced by each turbine to the key parameters has then been defined across the whole sample. A confidence interval (based on the relative standard deviation) has been found out to vary according to wind speed. For a 20 years WT lifetime, the GHG performances vary from 6.8 g CO2 eq/kWh ± 10.6% (vwind= 9 m/s) to 38.3 g CO2 eq/kWh ± 14.8% (vwind=4m/s). For average wind condition in Europe (6 m/s) the correlation results (13g CO2eq/kWh ±12.2%) are in accordance with the literature average results (13.5 g CO2 eq/kWh). Moreover, varying the life time of WTs from 10 to 30 years have induced a high variability of GHG performances from 8.7 to 26.1 gCO2eq/kWh ± 12.2% (for vwind= 6 m/s), GHG performances of WTs are therefore found to be very sensitive to this methodological parameter.

**TU 256**

**Development of a life cycle assessment tool for construction, maintenance and use of civil works**

A López, A Alonso, A Bonilla
Tecnalia, DERIO, Spain

LCA assessments and experiences have become common practice in the building sector in the last years. However the number of studies carried out is still rather scarce in the linear infrastructures sector. A LCA tool for linear infrastructures has been developed within the CLEAM project framework, with the aim of making easier the application of LCA in the civil work sector and to provide a complete evaluation of the environmental impacts generated throughout the whole life cycle of an infrastructure.
The aim of the project is to simplify the assessment of environmental impacts in the sector of civil works and set the ground for evaluating constructive alternatives from the perspective of LCA thinking. With this in mind, the tool has been developed following two objectives: i.e. (i) simplifying data introduction and (ii) making the interpretation of results more user-friendly.
To fulfil the above objectives, the LCA tool for linear infrastructures is organized around a commercial budgetary database (Preoc 2009), upon which the LCA inventory has been developed. This inventory is the backbone of the developed tool. To assess environmental loads, the Ecoinvent Data v.2.0 has been used. As for the quantification of impacts, the ReCiPe midpoint and endpoint methods have been applied. Finally, as support for the evaluation process, the SimaPro software v.7.2 has been used.
The assessment has taken into consideration the manufacturing, construction, maintenance and use phases of the infrastructure's life cycle. In relation to the manufacturing phase, the manufacture of materials used in the infrastructure has been considered. For the construction phase, machinery, waste management and transport needs for the works have been evaluated. For the maintenance phase, material manufacturing as well as machinery have been considered. Finally, for the use phase, traffic emissions, lighting and traffic lights energy consumption have been considered.
The generated LCA tool allows assessing environmental impacts while considering the entire life cycle of the infrastructure. Furthermore, this easy to use and powerful evaluation tool allows comparing construction alternatives, as well as identifying critical materials or specific components and/or life cycle phases, even for the less experienced users. Hence, the twofold objective of this project is achieved.

**TU 257**

**The project BioEnergieDat: a German LCA data base for decision support on bioenergy**

L Schebek[1], A Ciroth[2], C Düpmeier[1], L Eltrop[3], S Simon[4], P Viebahn[5], HJ Wagner[6], T Zschunke[7], K Biemann[1]
[1]Karlsruhe Institute for Technology, EGGENSTEIN-LEOPOLDSHAFEN, Germany
[2]GreenDeltaTC GmbH, BERLIN, Germany
[3]Universität Stuttgart, IER, STUTTGART, Germany
[4]DLR German Aerospace Center, ITT, STUTTGART, Germany
[5]Wuppertal Institute for Climate, Environment and Energy, WUPPERTAL, Germany
[6]Ruhr-Universität Bochum, LEE, BOCHUM, Germany
[7]Hochschule Zittau/Görlitz, FB Maschinenwesen, ZITTAU, Germany

LCA studies on bioenergy are based on diverse methodological choices and factual specifications, resulting in discrepancies in data sets of identical technologies or products. Assessment of technologies for robust decision support fosters the need for further harmonization of methodological procedures, validation of input data and assumptions on specific processes. In the context of the German energy and climate policy, the need of an adequate database on bioenergy reflecting German framework conditions has been identified. A two-year's project for a database on energetic use of biomass for Germany has been launched by the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU) in September 2010. The project with the akronym BioEnergieDat is carried out by a consortium of seven scientific partners led by the Karlsruhe Institute of Technology (KIT). It is based on previous work and experiences of the German Netzwerk Lebenszyklusdaten and is aimed at a validated database for use within the German strategy on biomass, but due to a modular concept also for all applications of LCA and diverse related instruments like Carbon Footprint. It is intended to take over information from technology development as well as to provide methodological support for assessment of technology.
BioEnergieDat will generate harmonized and validated datasets for bioenergy based on the specific framework conditions of Germany, to be used as decision support for the assessment of technology as well as for environmental strategy development. The concept shall support methodological development as to specific questions of bioenergy like substitution effects or land use, it shall foster the evolvement of data quality procedures, and it shall provide novel IT solutions for efficient, reliable and fast exchange of data and information, supporting not only national but also international networking. First results of the project work will be presented as well as the embedding in the research programme on biomass energy use. The relationship of the project to the Sustainable Biomass Strategy in Germany will also be shown.

**TU 258**

**Enhancing the data basis for LCA through process simulation: the case of lignocellulosic ethanol production in Sweden**

C Liptow, AM Tillman
Chalmers University of Technology, GOTHENBURG, Sweden

One of the application areas of LCA is to assess the environmental impact of emerging technologies in order to support strategies and policies for technological development. However, in many cases this is restricted by a lack of robust data caused by the immaturity of these technologies.
A possible solution to this constraint is the use of process simulation, whose mass and energy calculations combined with LCA can be used to support strategic decision making for emerging technologies. For example, process simulation can generate data on the water consumption of a process as well as the level of pollution for the water leaving the process. Combining these data with additional data regarding water availability and quality and integrating both into an LCA can support strategic decisions i.e. the sustainability of industrial infrastructure intending to use the simulated process.
In our study we want to demonstrate the potential of using process simulation for the environmental assessment of emerging technologies, using the example of lignocellulosic ethanol production in Sweden. This is of particular relevance, since lignocellulosic ethanol production is currently not set up in an industrial scale in Sweden and therefore the study can deliver highly valuable information on how this technology could be further pursued and developed by the private and public sector in Sweden. In addition, our study uses the data generated for lignocellulosic ethanol to assess the environmental impact of producing bio-ethanol based polyethylene in Sweden from a local feedstock, which at a later time and under a wider scope could be used to support strategic decisions about where to build plants for the biomass based production of this widely used plastic.
In general, the use of process simulation in this case study is intended to further the use of process simulation for LCA purposes and consequently to make LCA more reliable and open the path to a wider set of application areas.

**TU 259**

**Considerations about using European LCA-database in a not European LCA-application: case study of waste destination in Brazil**

RA Nunes
TU DARMSTADT - COPPE - UFRJ, RIO DE JANEIRO, Brazil

In Rio de Janeiro Municipality 2,000 t of C&D (Construction and Demolition) waste are daily disposed at a MSW (Municipal Solid Waste Landfill). There is almost no recycling of C&D waste in the city. A LCA was carried out to investigate seven scenarios involving four alternatives for the C&D waste destination: (a) recycling at the source through small mills; (b) recycling at a stationary facility; (c) disposition in an inert landfill and; (d) disposition in a MSW. The results of the LCIA (Life Cycle Impact Assessment) have indicated that the scenario with less environmental impacts was the scenario with 20% recycling at the source and 80% disposition in an inert landfill. Nevertheless, it can be argued about the consistency of this result, because almost all data was secondary and from an European Database. In this work, having as case study the C&D waste destinations in the city of Rio de Janeiro, it will be discussed that in the absence of a national LCA Database (as in the case of Brazil) the use and the adjustment of data sets from an European Database can be a good option, considering however that the interpretation of the results must be based on different sensitivity and uncertainty analysis.

**TU 260**

**The use of Genetic Algorithms to solve the allocation problems in the Life Cycle Assessment**

M Cellura
Università di Palermo - Dipartimento di Ricerche Energetiche ed Ambientali, PALERMO, Italy

One of the most controversial issues in the development of Life Cycle Assessment (LCA) is the allocation procedure, that consists in the partition and distribution of economic flows and environmental burdens among to each of the products of a multi-output system.
Because of the use of the allocation represents a source of uncertainty in the LCA results, this paper presents a new approach based on Genetic Algorithms (GA) to solve the multi-output systems characterized by a rectangular (and thus non-invertible) coefficients matrix, without using computational expedients such as the allocation procedure.
The GA is a population-based stochastic global search technique inspired from the biological principles of natural selection and genetic recombination. Starting from a codified random set of possible solutions of a problem (population), the GA simulate the evolution of the population through genetic operator (as inheritance, selection, genetic mutation) up to obtain the optimal solution.
The evolution of a component of the population (single solution of the problem), its probability to procreate and to hand down its gene pool depend on its fitness: a solution is assessed as acceptable if it minimizes or maximizes a specific objective function.
The objective function is based on two principles: the respect of the bonds and the analysis of the performance of the solution. The genetic research represents a balance between "exploitation"(local research) of the optimal available solution and "exploration"(global research) of the space of the research.
The paper applies a GA to a multi-output productive process of essential oils, natural and concentrated juices from oranges and lemons.
The results obtained for the case study taken into consideration showed that the application of GA allows to respect the energy and mass balances for the examined system. Moreover, low differences between the inventory vectors obtained by using the GA and those obtained with the solutions based upon the traditional computational technique of the allocation have been observed. Since the real solution of the inventory vector is unknown, the authors are not able to compute a proper performance indicator for the implemented algorithms. However, considering that the differences of the obtained GA solutions from the traditional solution are not overwhelming, this methodology is worthy of further investigations.

**TU 261**

**Towards an integrated approach between Material Flow Analysis and Life Cycle Assessment**

L Ciacci, F Passarini, A Santini, I Vassura, L Morselli
Bologna University, BOLOGNA, Italy

The requirement of predictive methods has increased over the past decades in response to the environmental and socio-economical emergencies. Despite the huge amount of approaches and tools, it seems quite difficult to compare results obtained from different procedures. It is widely accepted that an integrated approach of disciplines and methodologies could help to cover all the complexities related to a problem in a life cycle thinking perspective.
In this work the potential of applying Material Flow Analysis (MFA) approach to Life Cycle Analysis (LCA) is discussed, aiming at proposing a systematic strategy of identifying Sustainable Practices. MFA is a systematic assessment of the flows and stocks of materials within a system defined in space and time. Emphasis is placed on linkage between sources, pathways an the intermediate and final sinks of a material (i.e. substances as well as elements). In these sense, MFA allows to identify the depletion or accumulation of substances early enough to take countermeasures towards more sustainable solutions. Furthermore, by means of MFA approach even small

changes, that imply difficulties in measuring effects in short time scales but that could lead to long term damage, may become evident.
MFA can be regarded as a method to establish the inventory for an LCA. This is especially true when LCA is applied to systems rather than to single goods. Indeed, the results of an MFA are quantities of flows and stocks of materials according to measurements, and the principle of mass conservation. In these sense, these are objective quantities (aside from analytical and numerical uncertanties). The interpretation and evaluation of MFA results, which may be conduct by means of LCA, is instead a subjective process, since it is based on social, moral, economical values.
Proposing an integrated approach between MFA and LCA will lead to overcome critical aspects that usually affect environmental studies. In particular, the impact assessment of LCA strives for assessing as many as possible substances and compounds to guarantee completeness while MFA is directed towards reducing the number of substances of study as much as possible to maintain trasparency and manageability.
Finding the best solution to fit results from MFA and LCA may lead to greater benefits in waste management, resource conservation and topics relating with Industrial Ecology issues.

### TU 262
**Hybrid IOLCA model to determine carbon footprint of products and services to estimate their true cost - A case study of pulp and paper sector in Spain**
ED Gemechu, I Butnar, M Llop, F Castells, MJ Amores Barrero
Universitat Rovira i Virgili, TARRAGONA, Spain
Nowadays, there is an increasing concern over the anthropogenic greenhouse gas (GHG) emissions more than ever. Different scientific researches reveal the fact that the way how products / services are produced and consumed is one of the major drivers of this accelerating pace of human related GHG emissions. Therefore, the need to change this unsustainable consumption and production patterns becomes increasingly urgent. One of the possible solutions to alter the current consumption and production patterns to sustainability is to account for the true costs of products / services, which reflect the actual social and environmental costs and benefits. Environmental tax which is proportional to products'/ services' carbon footprint reveals their true costs by internalizing all the external loads that are not included in the economy. This is then reflected in the actual prices and increases the prices of unsustainably made products. The traditional life cycle analysis (LCA) is the most product/service-specific; probably it is the best approach to calculate carbon footprint of products and services. However, the current methods of LCA suffer from problems of subjective system boundary selection, availability of data and time requirements.
An alternative approach to LCA is Environmental Input-output (EIO). It has some advantages over LCA as it takes into consideration all the upstream processes, but it still lacks strength to assess carbon footprint of products and services at a micro system level. Therefore, the best proxy would be given by a hybrid IOLCA which combines the best features of both LCA and EIO approaches. In this study we develop a Hybrid IOLCA model to estimate life cycle GHG intensity of products and services to determine their true costs. Paper production sector of the Spanish economy is analyzed by using hybrid IOLCA, which uses calculated LCA emissions of different paper products where LCA data is available and IO-calculated data for the rest. Results from the Hybrid IOLCA model are then compared with those obtained by pure LCA and EIO. Finally the carbon footprint of products and services are translated into environmental tax and the overall effects of tax introduction on the price of the products/services are then assessed.

### TU 263
**Life cycle analysis of advanced biofuels: accounting for coproducts and process residues impacts**
F Menten, A Prieur
IFP Energies nouvelles, RUEIL-MAILMAISON, France
Lignocellulosic materials and microalgae are promising sources for alternative fuels production in the transport sector. Expectations are that 2nd and 3rd generation biofuels have a more sustainable performance than the biofuels currently available, but significant uncertainty remains about how well they will perform.
Life Cycle Analysis (LCA) appears to be the appropriate tool to evaluate the environmental impacts of these developing technologies. Results of such environmental assessments may be applied to immature technologies in order to support sustainable process design and offer reliable results for policy making. However, the generic LCA methodology needs to be adapted to deal with specific issues related to advanced biofuels.
This work presents two case studies where these issues are treated:
- LCA of cellulosic ethanol from agricultural residues

The European Directive on the use of energy from renewable sources states that 'agricultural crop residues, including straw, bagasse, husks, cobs and nut shells (...) shall be considered to have zero life-cycle greenhouse gas emissions up to the process of collection of those materials.'. In this work, different possibilities to account for agricultural residues impacts are explored.
- LCA of microalgae biodiesel

Microalgae LCA is complicated by the fact that the carbon dioxide ($CO_2$) necessary for microalgae growth needs to be fed into the system (it is not captured directly from the atmosphere). When the $CO_2$ source is flue gas from a power plant, most of LCA practitioners consider it a process residue and no emissions are affected to it. As in the cellulosic ethanol case study, other possibilities are detailed.
The various possibilities to account for residues impacts explored in this work are: mass, energy and economic allocation; system expansion (substitution method recommended by ISO LCA Standards in the case of coproducts impacts accounting); consequential approach (comparison of life-cycle flows between conventional and alternative processes).

### TU 264
**Integrated design of a sustainable nursery school: energy and environmental evaluations with LCA**
N Villa, G Iannaccone, E de Angelis, L Zampori, G Dotelli
Politecnico di Milano, MILANO, Italy
The aim of the work was the design of a wooden nursery school in Italy, following sustainability guidelines. The choice of building materials, following a Life Cycle Assessment perspective, allowed the achievement of optimal energy efficiency and a consequent reduction of environmental impacts.
LCA analysis has been applied to a portion of the building and the energy demand for operation calculated considering an operation phase of 20-25 years, during which it is reasonable to discharge any extraordinary repairs; for the sake of brevity, in the operation phase scenario no ordinary maintenance has been considered as well. The energy efficiency and the environmental impacts have been studied focusing only on the construction and operation phases, while dismantling and demolition have been left out of this study. Energy use for building operation has been calculated with the CENED+ software, i.e. building primary energy requirements considering heating, domestic hot water and lighting. LCI analysis has been carried out exploiting ITACA database and alternatively ECOINVENT database. When using the latter database calculations were made using SimaPro software. However, the two approaches are correlated because ITACA database, which is an Italian database of building materials, heavily relies on ECOINVENT database. Fourteen impact categories are accounted for the materials listed in ITACA; instead, CML2 method has been used to perform LCIA with Simapro. Outcomes of the LCIA performed according to these two approaches enable a meaningful comparison only on seven impact categories; however, a critical analysis of impacts is required because conflicting results are found. For instance, both tools evaluate the positive contribution given by wood to the greenhouse effect, due to the $CO_2$ storage in it. However, discordant results come from the two approaches: with ITACA, wooden materials give a negligible positive contribution to the Climate Change, if compared to the total effect arising from the whole construction phase. On the contrary, using directly ECOINVENT with the support of Simapro software, the beneficial effect of wood products is much more evident. Being ITACA ultimately based on ECOINVENT, this discrepancy is difficult to explain if one does not consider the different geographical contexts; indeed, a consistent amount of ITACA data values, among which transports and country energy mix, are modified to take into account the Italian context.

### TU 265
**Importance of linkage between LCA methodology developments and their applications in practice**
A Laurent, SI Olsen, MZ Hauschild
Technical University of Denmark, KGS. LYNGBY, Denmark
Efforts are continually performed to improve the Life Cycle Assessment (LCA) methodology, with a strong focus on both the life cycle inventory (LCI) and the life cycle impact assessment (LCIA) phases. However, those methodological developments may not always be applied in practice, e.g. due to delays or improper implementation into LCA-software. In such situations, the consistency of the results obtained by the LCA practitioner may be threatened. The present study uses an update in the normalization references for the EDIP methodology to quantify, through two examples, the influence that such problems may pose in LCA practice. In the first instance, discrepancies observed when employing an old - but still in use - set of normalization references (emission year: 1994) and an updated one (emission year: 2004) are estimated for all commonly assessed impact categories. The second example analyses the modelling of pesticides in current LCI databases, which traditionally treat applied pesticides as emissions to agricultural soil whereas, the agricultural soil belonging to the technosphere, only the fraction of pesticides reaching the biosphere is to be considered in the impact assessment. Consequences from this inconsistent modelling approach on toxicity-related normalized impact scores are quantified using a European emission inventory. In both examples, it is demonstrated that an inadequate application of LCA may result in large shifts of focus in the environmental profile of the background load as expressed in the normalisation references, some specific impact categories being significantly overestimated while others underestimated. To ensure the validity of the results, upon which recommendations for decision-support processes are built, the use of frequent updates and checks on the proper application of the LCA methodology is therefore advocated.

### TU 266
**LCA applications in Turkey**
A Isler, Z Meydan, F Karaosmanoglu
Istanbul Technical University, ISTANBUL, Turkey
Life cycle assessment (LCA) quantifies the environmental impacts and energy requirements of products over their full life cycle. It is also called a cradle to grave approach, which compares the similar products with respect to the environmental burdens. Although LCA is not something new, the special interest has increased since 1990`s. LCA is increasingly being used as a decision support tool by governments, companies, and authorities in order to improve the environmental performance, pollution prevention strategies and environmental management systems. LCA studies include four phases (goal and scope definition; life cycle inventory analysis; life cycle impact assessment and interpretation) according the ISO 14040 series. LCA methods are improved in developed countries for new impact categories and characterization models using the international standards framework contained in the ISO standards. Developed countries widely recognize that environmental consequences of a product should be evaluated by considering the impact results for each of its life cycle. LCA is applied a wide range from production to service such as energy generation, waste management, bottle production etc. over the world. On the other hand developing countries like Turkey are in the inception phase with a rising awareness on LCA. Life cycle impact assessment phase cannot be conducted easily due to the lack of valuation and weighting data, but the number of the studies is increasing day by day. This study outlines the current situation of the LCA studies for different sectors (automotive industry, gasification technologies, mining, building technologies, packaging, moulding, iron and steel industry, biofuels and agricultural sector) in Turkey. The difficulties for the life cycle inventory analysis and life cycle impact assessment phases in the studies are outlined and the future of the studies and the developments are also presented for Turkey. The aim of this study is to be an example for the developing countries, which increase the use of the LCA in their countries.

### TU 267
**The EPD® approach as meeting point between robustness and communicability of LCA studies: the certification of an internal LCA process**
L Ruini[1], MM Marino[2]
[1]Barilla G. R. Fratelli SpA, PARMA, Italy
[2]Life Cycle Engineering, TORINO, Italy
As also suggested by the SETAC Meeting organisation, many LCA practitioners have proposed several approaches regarding "hot topics"such as allocation, cut off rules, biomass, etc... Often, researchers performing LCA aim to improve the methodology, while, on the other hand, applicants in the entity of industrial actors typically aim for strategy building or communications impact. This paper wants to describe the manner in which a large company currently integrates the life cycle approach into its policies and views while conserving both the robustness of the elaborations and the suitability for communication purposes.
BARILLA is currently one of the top Italian food groups. It produces more than 100 products in about 50 plants around the world. The company has been using the LCA since the beginning of 2000. Since 2008, life cycle thinking made its way into Top Management of the company, as an instrument to thoroughly study the production chain and localise the most substantial environmental impacts
In virtue of these issues, Barilla has placed LCA approach robustness and importance at the top of its priorities, also developing a specific strategy: in 2010 an internal LCA process was imple-

mented and certified in compliance with the International EPD® regulations. In this view, Barilla has decided to implement its EPD internal process, which is based on three principle elements:
- the LCA databases, in which all the most important raw materials, production plants, packaging materials and other useful information are studied;
- the Product system that represents the product group model calculation tool;
- the Product specific data, related to the production of a specific product.

The overall system is verified twice a year by an accredited Certification Body.
It is foremost that all adopted rules and hypotheses be established it utmost clarity in order to continuously increase the suitability and robustness of the LCA implemented by companies. Since databases are a key element, their availability and updating shall undergo constant improvement through a specific updating procedure. Furthermore, Barilla seeks to publish as much information as possible on the environmental impacts of the food production chain by employing tools such as the Double Pyramid paper, which studies the relationship between the nutritional and environmental features of food.

**TU 268**
**How potential carbon policies could effect producer grain cultivar selection: a LCA analysis of USA rice**
LL Nalley[1], BE Mcfadden[2], N Lyman[1]
[1]University Of Arkansas, FAYETTEVILLE, United States of America
[2]Oklahoma State University, STILLWATER, United States of America
Given the Obama administration's push to reduce carbon emissions, increasing consumer demand for environmentally friendly products, and industry pressure from companies like Wal-Mart to reduce net GHG emissions, the likelihood of implementing of some form of a carbon policy in the USA is increasing. Little research on how a potential government policy or increased consumer demand for lower GHG emissions in agricultural products could affect the varietal selection of crops. This study attempts to fill this apparent gap in the literature by addressing how a climate change policy/views that caused producers to internalize costs of GHG emissions would affect the cultivars producers choose.
Given the introduction of hybrid rice in the USA there could be large environmental benefits from its widespread adoption. Hybrid rice can yield 15-20% more than conventional cultivars with roughly the same input requirements. This study estimates a net carbon footprint for 14 of the most commonly sown rice cultivars in Arkansas in 6 locations throughout the state. The results should provide producers, millers, and buyers an idea of the relative difference in GHG emissions by cultivar so they can adapt to a potential carbon tax/offset policy or to changes in consumer demand. This research has global implications since roughly 50% of the world's population consumes rice daily.
Preliminary Results
To estimate GHG emission per acre, a range of input requirements were gathered for types of rice as well as cultivars for six counties in Arkansas. Monte Carlo simulation was used to model uncertainty in production. Using a LCA, carbon was estimated for both direct and indirect emissions. Carbon emissions were estimated per acre and per bu of rice. From a cap and trade standpoint, the ratio of CE/bu appears to be the driving factor in which cultivars will experience a loss/addition of acreage. From a carbon offset standpoint, the estimates generated in this study do not indicate, even under high carbon prices, that an offset market will change varietal selection by producers. Given that rice is the largest emitting row crop produced in the United States, it is likely that acreage would decrease given a cap and trade policy that includes agriculture. It would appear that consumer and industry demand for "greener"products and/or a cap and trade type policy that included agriculture, but not a carbon offset policy, could ultimately effect which rice varieties producers sow in the USA.

**TU 269**
**Accuracy vs. robustness: challenges of including LCA into legislations/standardization schemes for sustainable biofuels**
MC Faist Emmenegger
Empa, DÜBENDORF, Switzerland
The Swiss regulation on tax exemption for biofuels as well as the European renewable energy directive (RED) or the standardization scheme of the Roundtable on Sustainable Biofuels are based on LCA calcula-tions for the evaluation of the biofuels.
Detailed guidelines for the calculations are necessary to allow comparability of the results, to facilitate the applicability and to reduce the burden for the economic operators. To be complete, the guidelines should de-scribe the level of data collection, the rules for allocation to co-products and give guidelines for the calcula-tion of emissions in the agriculture. The legislations use different approaches regarding to the guidelines: whereas the Swiss legislation provides a questionnaire where the information has to be filled in by the opera-tor, the RED only provides general guidelines on the calculations, so that there are great efforts undergoing in the European Union to define them more precisely.
By defining very detailed guidelines and using standard factors to provide robust and comparable results, the legislations might fail to provide the right incentives, as environmentally sound practices, e.g. in agriculture, might not show in the calculations. On the other side, it has been shown that different assumptions in LCA studies might lead to very different results, so that a harmonization of the calculations is needed to obtain comparable results. A compromise between accurate results reflecting well the actual production pathway and robust results which can be compared with other pathways is therefore necessary.
A further difficulty in the assessment of biofuels is the fact that certain factors which can have a great influ-ence on the results like N2O-emissions or indirect effects are still burdened with a high uncertainty in calcula-tion or in the methodology. The main challenges for the implementation of LCA are i) to refine global models or define global valid approaches for emission modelling in agriculture, ii) to find the right level of detail with-out increasing excessively the data-collection burden for the economic operator and iii) to develop accepted approaches for dealing with indirect effects.

## LC05 - Life Cycle Management approaches for different industrial sectors (LCM)

**TU 274**
**Life cycle assessment applied to events: the case study of Gymnaestrada**
A Kounina, ET Tatti, SH Harbi, YL Loerincik, CC Coquerel, S Humbert
Quantis, LAUSANNE, Switzerland
Life cycle assessment was originally designed to evaluate environmental impacts of products. This methodology was extended to be applied to organizations. And lately, it has been adapted to be applied even to events.
The World Gymnaestrada, organized in Lausanne, Switzerland, in 2011, is the largest mass sport even in the world with more than 23'000 participants to be expected. However, this event will also generate increase of the city population of 20 %.
The organizing committee is interested to understand the environmental consequences of this event and would like to enroll in a sustainable development approach.
The evaluation of the overall environmental assessment of the event is part of the wide range of measures taken in order to implement these principles of sustainable development.
The goals of this project are to:
- Realize the environmental assessment of the World Gymnaestrada 2011
- Contribute to the establishment of a sustainable development mind for this event
- Value the impacts reduction measures towards the collaborators
- Create an evaluation tool that allows directing choices for the event
- Associate these elements to the communication of the event
- Contribute to create a life cycle assessment based tool for events

The results of the assessment, the tool and actions identified will be presented.

**TU 275**
**Allocation procedures effects on greenhouse gases emissions in energy systems industrial sector: a case study of hydrotreated vegetable oil**
D Garraín, I Herrera, C Lago, Y Lechón, R Sáez
CIEMAT, MADRID, Spain
The allocation procedure in a multi-input/output process is one of the most significant matters in Life Cycle Assessment methodology. This modus operandi allows the partition of the environmental burdens associated with a multi-output process into its product and co-products.
Oil hydrotreating units in refineries are aimed at reducing the sulphur content of mineral fuels in order to achieve compliance with standard specifications. Currently, this process is one of the best available technologies to obtain biofuels from vegetable oil. Several co-products are obtained in this hydro-reaction such as liquid petrol gases, methane, propane, butane or naphtha, so an allocation procedure must be carried out for sharing the environmental charges.
This study presents the greenhouse gases (GHG) emissions of a hydrotreated vegetable oil (HVO) from co-processing with mineral diesel in a hydrotreating facility of a Spanish oil refinery. Two different allocation procedures have been considered in order to compare the results in the hydrotreatment unit output: energy allocation and system expansion (or substitution).
Results show that GHG emissions are lower in the case of the substitution (around 3-4 g CO2 eq/MJ in its entire life cycle) if a hypothetical 100% HVO is considered. However, European Directive 2009/28/EC recommends an energy-based content allocation in the case of biofuel GHG emission balances.
Finally, it is worth remarking that both results highlight that this renewable diesel fuel could attain an excellent environmental performance in terms of GHG emissions savings (roughly 50-60%) in comparison with the above mentioned directive standards.

**TU 276**
**Life Cycle Assessment of daylight devices: the case of light pipes**
PK Sanchez Ramirez, PL Petti, AR Raggi
Università degli Studi "G. D'Annunzio", PESCARA, Italy
The benefits of the use of daylight devices for health are well known. Moreover, a better environmental performance than conventional lighting is expected; however, the increasing spread of these devices may lead to concerns about the actual environmental impact produced by them. In this context, this research deals with the environmental impact of one type of solar systems: light pipes. These systems are based on the principle of multiple reflections on specular surfaces: the system collects and transports daylight through a device, which is composed of three fundamental units: capture unit, conduct unit and diffusion unit. It is known that when they are used to produce light for a given area, there is no direct consumption of energy. However, this does not mean that they do not cause any impacts to the environment throughout their entire life cycle. As a methodological tool, LCA can evaluate, from an environmental viewpoint, the life cycle of a light pipe, so that more information about the potential impacts generated in the life cycle phases of a light pipe (including production, transport and end-of-life) can be obtained. This study was conducted with reference to a hypothetic light pipe of 80-cm length and 25-cm diameter. The data on materials and dimension of the components were extracted from specific literature. The environmental analysis reveals that the highest impact is potentially caused by the production phase of the light pipe; more precisely, one critical component is the aluminum tube. This means that if a light pipe manufacturer wants to improve the environmental performance of his/her product, it could be interesting to develop researches aiming at identifying a more environmentally-friendly tube material. This study has some remarkable limitations: the data collection was mainly based on scientific literature and commercial databases; moreover, some of the raw materials were replaced by similar ones because of the lack of data. Therefore this must be considered as a preliminary study. Further research with actual data and more accurate data collection is advised.

**TU 277**
**Life Cycle Management approach for the Sassuolo ceramic district**
D Corradini
University of Modena and Reggio Emilia, REGGIO EMILIA, Italy
The purpose of this study is to assess the environmental impacts of the different products and to evaluate possible actions to be taken to reduce them, including-market related considerations to verify their economic benefits.
The functional units chosen for this study is 1 m2 for each type of ceramic tiles representing the entire italian production. The LCA study has been performed using the SimaPro 7.1 software and four impact assessment methods: Eco-Indicator'99, IMPACT 2002+ and EPS 2000. The system boundaries for the analysis include the upstream phases, from raw material extraction, and arrive to the finished product packaging, thus obtaining "a cradle to the gate"overview. This choice has been forced by the lack of aggregated data regarding the use and disposal of ceramic tiles. LCI has been performed by using aggregated data regarding raw materials and energy consumption and emissions in air, water and ground. These data have been derived from a report regarding the ceramic district in the area of Sassuolo. Machineries and plants have not been considered in the present study.
The production step responsible for the main part of the damage is the firing phase, which is difficult to change because of technological reasons. The emissions related to the raw materials transport have a great influence on the overall environmental damage, though this is the aspect on which new suggestions have been advanced.
The proposal consists in replacing a part of raw materials using local minerals available. Before

assessing the new environmental impact, some experiments have been performed to verify how much of the original raw materials could be replaced without compromising the technological features of the product. Then a comparison has been made, resulting in a lower damage of about 15%.
To verify the economic benefit of such a change in raw materials composition, the Kraljic matrix has been applied. As a result of using local raw materials, a left shift has been obtained, from the 3rd (bottle-neck materials) to the 4th quarter (non critical materials).
This study shows how the environmental improvement strategies suggested by LCA have also economic benefits, and how LCA can be used within a LCM approach to support decision makers toward a more sustainable management of businesses.

**TU 278**

**Incorporating ecodesign into a SME: future ISO 14006**

MD Bovea[1], S Julio[1], M Jorge[1], B Ramiro[2]
[1]Universitat Jaume I, CASTELLÓN, Spain
[2]MACER SL, ALMAZORA, CASTELLÓN, Spain

The forthcoming ISO 14006, Guidelines for incorporating ecodesign into environmental management systems, is intended to provide how to guide companies to incorporate ecodesign into a management system. This standard will be partially based on the Spanish standard UNE 150301, developed in 2003. The main goals of this standard are among others: minimise the environmental impact of products/services, promote the life cycle approach, systematise the continuous improvement in the framework of ecodesign, help the market to become aware of the need for products/services incorporating the environmental requirement, and provide a label to those companies involved in ecodesign.
This article analyses the implementation of the UNE 150301 in MACER S.L., a Spanish small and medium enterprise (SME) in the metal mechanic sector. This company is specialised in design, manufacture and repairing/maintenance of moulds for presses in ceramic tile companies. The implementation of this standard has involved the following activities: the analysis of the manufacturing and repairing process of moulds; annual data collection of production, raw materials, energy consumption, waste generation, etc.; allocation of data to unit processes such as drilling, milling, turning, grinding, electrical-discharge machining (EDM), wire EDM, welding, rubberised, etc., by means of the electricity consumption measurement directly on machines; modelling the life cycle inventory for each raw material, auxiliary material and unit process; modelling the life cycle of a mould including all its components; obtaining environmental indicators; identification of significant aspects from the environmental point of view; setting environmental improvement targets and actions for achieving them; and preparation of the required documentation for certification according UNE 150301.

**TU 279**

**Review of simplified LCA approaches and tools: defining a streamlined tool for food LCAs addressed to SMEs**

I Arzoumanidis, A Raggi, L Petti
University "G. d'Annunzio", PESCARA, Italy

Life Cycle Assessment (LCA) is a tool which has been increasingly used in order to identify the environmental profile of goods and services. However, for a number of reasons, including its high resource-intensity, LCA has not adequately spread as a practical tool, especially over Small- and Medium-sized Enterprises (SMEs). Therefore, the need to identify simplified, even though reliable, methodologies within the LCA framework has increased. In the framework of a recently-started Italian nationally-funded inter-university research project on improving sustainability and competitiveness of the agri-food chain with innovative environmental management tools, specific objectives and tasks have been established concerning Streamlined LCA in food supply-chains. This paper aims at describing those objectives, as well as presenting some preliminary results.
One overall objective of this project is to identify and/or develop an appropriate simplified LCA tool or approach to be addressed to SMEs in the food sector. In order for this to be accomplished, the first step has been to perform a comprehensive scientific literature review of approaches and tools proposed so far in the framework of LCA for different products, seen from a broad perspective. Later on, after having obtained a thorough knowledge on the various approaches and tools available; this will be the starting point to develop a tool which can be best suited in the agri-food context.
This paper presents and discusses some preliminary results of the undergoing research.

**TU 280**

**Symbiotic exchanges and hazardous wastes in chemical industry. A 'path-dependent' case study**

R Taddeo, A Simboli, A Morgante
University G.d'Annunzio, PESCARA, Italy

The Eco-Industrial approach promotes the transition from traditional industrial clusters to Eco-Industrial Parks (EIP) [1-2], exploiting geographical proximity, existing synergies and peculiar socio-economic relation with the territory. This paper presents an hypothesis of symbiotic exchanges to redevelop a chemical industrial site located in Abruzzo Region: Bussi chemical site (BCS). It is one of the oldest Italian cluster and it involves five production units for a total of 220 employees. The sectors of activity are: basic chemicals, pesticides, micronized silica, production and distribution of electricity. This cluster reveals great opportunities in the re-use of by-products among two production chains: the reuse of the unreacted sand in the silicate sector and the sulfuric acid recovery for the detergency sector. The possible scenarios that could be implemented are: i) the exploitation of symbiotic internal exchanges; ii) the location of new industrial plant in the chemical site - this activity concerns the recovery of precious metals (as cobalt, vanadium, nickel, molybdenum) from used catalysts deriving from chemical and petrochemical industry; iii) the involvement of another regional cluster (Automotive industry) - in this case the exchanges could include: extraction of metals from electroplating sludges and used catalysts; exchange of product and by-products deriving from BCS, used as raw materials in the Automotive industry.
Preliminary results demonstrate great opportunities to improve economic and environmental performances of the cluster. An important reflection concerns the social acceptance that could represent a crucial limit in the transition process. Local community demonstrated a strong opposition to any proposal of redevelopment of the site related to the treatment of waste or by-products and to the establishment of new companies involved in these activities. This is due to the fact that, in the past, Bussi chemical site was protagonist of an environmental scandal for the presence of an illegal dump of toxic materials. The re-industrialization of the site following the EIP model met a distrust of local population used to conceive the production cycle as a linear cycle. Revolutionize this system, introducing a closed loop model, highlights the difficulty in conceiving wastes as a resource, not any more as cost to the company [3].

**TU 281**

**Environmental impact of striped catfish production in the Mekong Delta (Vietnam)**

J Potting, RH Bosma
Wageningen University, WAGENINGEN, The Netherlands

Intensive striped catfish production in the Mekong Delta has in the recent years raised many environmental concerns. To support policy making, we conducted a Life Cycle Assessment (LCA) to determine the environmental impact of producing striped catfish. The LCA was complemented with an assessment of biodiversity loss, water use, and flooding hazards. The goal and scope for the assessment, and the assessment results were discussed in a series of stakeholder workshops. The results Master Plan 2020.
The LCA covered all processes up to the exit-gate of the fish farm, and focused on global warming, acidification, eutrophication, human toxicity, and marine (MAET) and freshwater aquatic ecotoxicity (FWET). Except for eutrophication and FWET, the feed production, which largely took place outside Vietnam, dominated most of the impacts in the LCA. Among feed ingredients, rice bran dominated global warming and acidification, while wheat bran dominated eutrophication, mainly due to their quantities used. Fishmeal production, transport and energy processes dominated MAET. Grow-out farming in Vietnam dominated eutrophication and FWET. The water nutrient discharge was high in relative terms, but it hardly modified river water quality compared with that before sector expansion (0.01% increase while 0.0005% of river water passed through the ponds). Environmental impacts can be reduced by managing sludge, producing feed ingredients locally, processing feeds with lower Feed Conversion Ration and lower content of fishery products in the feed.

**TU 282**

**Environmental impact assessment of rapeseed and barley cultivation for fallow land in winter season using LCA**

SG Hong[1], JD Shin[1], WK Park[1], KH So[1], SI Kwon[1], DB Lee[1], YS Ok[2], SH Hyun[3], JG Kim[3]
[1]NAAS, RDA, SUWON, South-Korea
[2]Kangwon National University, CHUNCHEON, South-Korea
[3]Korea University, SEOUL, South-Korea

High input to the arable land contributed to increasing productivity, at the same time caused global environmental problems. In this context, rape cultivation has been asked to reassess its positive point such as utilization of winter fallow field. In this study, environmental impacts of rape cultivation in winter fallow after harvesting paddy rice were assessed and compared with barley cultivation as an competitor using LCA.
we collected raw data for input materials such as fertilizer and pesticide, and energy consumption rate by analyzing the type of agricultural machinery and working hours by 1 ton rape and barley as functional unit. Environmental impacts were evaluated by using Eco-indicator 95 method for 9 impact categories. Sensitivity analysis was conducted for crop responses to fertilization level and increasing productivity.
To produce 1 tonne of barley and rape, the potential of greenhouse effect in barley (1.85E+02 kg CO2-eq.) was higher than that in rape (2.16E+02 kg CO2-eq.). The environmental impacts of ozone depletion, acidification, heavy metals, carcinogens, summer smog and energy resources showed the higher potential in rape than barley. In case of eutrophication, impact of barley was higher than that of rape. For the sensitivity analysis, scenario 1 (crop responses to fertilization level) showed the environmental burden was not increased with the amount of fertilization only at the optimum crop responses to fertilization (N3). By increasing the productivity of rapeseed by 1 ton per ha, a quarter of greenhouse gas emission potential was reduced.
With these results, environmental load from rape cultivation in winter fallow land was higher than that from barley. However it is assessed that planting high productive cultivar and site-specific fertilization by recommendation might reduce the environmental burden by 30 %.

**TU 283**

**Finnish methodology for carbon and other footprints for food products**

R Hartikainen, JM Katajajuuri, H Pulkkinen, M Saarinen, F Silvenius, T Kauppinen
MTT Agrifood Finland, HELSINKI, Finland

The "Foodprint", Footprint of food -research programme started in late 2009 following the initiative of active Finnish food companies. The programme is planned to be completed in May 2012, and is funded by the Finnish Funding Agency for Technology and Innovation (Tekes) and participating companies.
The public Foodprint Tools project comprises of four phases. The first phase aims at describing a generic methodology and requirements for carbon (and other) footprint(s) of food products. Other work phases will be more detailed, concerning data collection, data quality requirements, actual tools to assess environmental burdens in agriculture etc. Some specific characteristics are described below.
a. Concerning attributional vs. consequential modelling approaches, the attributional approach is chosen to allow comparability of footprints and to create as concrete modelling backbone for companies as possible.
b. The impact categories considered in this initiative are climate change, eutrophication, acidification and primary energy.
Data quality is one of the main topics under investigation, and plain division of data to primary and secondary data is inadequate. In many situations it is impractical to collect primary data, and well-founded approximations are needed. In the methodology topics of adequate data sources, data to be collected directly from the supply chain and data to be collected from national statistics, databases etc. shall be handled in detail. The data which needs to be collected is planned to relate to data which primary producers already collect in Finland for other purposes.
Allocation is perceived as one of the main challenges in LCA studies, and therefore a special focus is given to it. Work is underway to develop general principles for choosing appropriate allocation methods and for avoiding allocation (e.g. through system expansion). Some examples of allocation situations are going to be further explored through the case studies.
Other issues to be further investigated are: different land-use impacts (carbon storage, sequestration, soil carbon change, land conversion) and the need to verify activity and emissions data. Also, one area of improvement and generation of defaults are emission factors for electricity production. It is proposed to use as specific emissions factors related to the actual electricity supplier. This means that when the production profile is known, defaults for different production types shall be used.

## NM01 - Detecting, quantifying and characterizing engineered nanomaterials in the environment and in biological systems

**TU 286**

**Nanoparticles in food: analytical methods for detection and characterisation**

RJB Peters, S Weigel, H Bouwmeester
RIKILT, WAGENINGEN, The Netherlands

Nanoparticles in Food
Analytical methods for detection and characterisation

Stefan Weigel, Ruud Peters, Hans Bouwmeester
RIKILT - Institute of Food Safety, Wageningen UR, Wageningen, The Netherlands
Email: stefan.weigel@wur.nl

"The Scientific Committee [of EFSA] makes a series of recommendations; in particular, actions should be taken to develop methods to detect and measure ENMs [engineered nanomaterials] in food/feed and biological tissues, to survey the use of ENMs in the food/feed area, to assess the exposure in consumers and livestock, and to generate information on the toxicity of different ENMs.". This citation illustrates the current situation with view to the analysis of engineered nanoparticles (ENP) in food. Nanotechnology applications for the food sector are intensively investigated and developed and nanomaterials are already in use as food additives or in food contact materials while at the same time very limited knowledge is available on the potential impact of ENP on consumers' health. Exposure of the consumer to ENP cannot be determined due to the lack of appropriate analytical methods.

This gap is addressed by the FP7 project NanoLyse. The NanoLyse project focuses on the development of validated methods and reference materials for the analysis of ENPs in food and beverages. The developed methods will cover relevant classes of ENPs, i.e. metal, metal oxide/silicate and encapsulate ENP. Rapid imaging and screening methods allow the distinction between samples which contain ENP and those that do not. These methods will be characterised by minimal sample preparation, cost-efficiency and high throughput. More sophisticated, hyphenated methods allow the unambiguous characterisation and quantification of ENP. These include elaborate sample preparation, separation by field flow fractionation and chromatographic techniques as well as mass spectrometric and electron microscopic characterisation techniques. The developed methods will be validated using the well characterised food matrix reference materials produced within the project. Interlaboratory method performance studies will demonstrate the applicability and soundness of the developed methods. The techniques and methods developed in this project for food could also be applicable to biological and environmental matrices (possibly after matrix tailored modifications).

**TU 287**

**Secondary characterization of TiO2 nanoparticles in biological media by Dynamic Light Scattering (DLS) and Transmission Electron Microscopy (TEM)**

D Bilanicova, G Pojana, D Cristofori, A Marcomini
University of Venice, VENICE, Italy

Advantages and limits of Dynamic Light Scattering (DLS) and Transmission Electron Microscopy (TEM) techniques for secondary size characterization of nanoparticles in biological media were addressed and discussed. Both techniques were employed to investigate size distribution of nano-TiO2 (Degussa-Evonik P25) in biological media commonly employed for in-vitro toxicological studies. Titanium dioxide nanoparticles were dispersed at physiological pH up to 5 mg/ml, stabilized with foetal bovine serum, a biologically compatible dispersant, according to specifically developed protocols, and their size distributions and stability vs. agglomeration were investigated in a wide set of biological media (DMEM, DMEM-HG, RPMI-1640 and DMEM-F12-HAM, with and without FBS). The influence of sonication step on the dispersion procedure has been also discussed. The obtained stock dispersions, when prepared according to the developed protocol, resulted to be stable at least 22 h despite the relatively high particle concentration level. Moreover, when diluted in all biological media tested, the obtained stock dispersions exhibited a very stable (at least 48 h) and similar size distribution, confirming the applicability of the proposed protocol for in vitro nanotoxicology testings.

**TU 288**

**Ecotoxicity of fluorescent silica nanoparticles in a battery of freshwater test species**

MP Casado, HJ Byrne, AL Macken, F Lyng
Dublin Institute of Technology, DUBLIN, Ireland

The anticipated increase in nanoparticle production makes exposure of the environment to these materials more and more likely. Assessing the benefits and risks of nanomaterials requires a better understanding of their chemistry, mobility, bioavailability, and ecotoxicity in the environment. Nanoparticles currently in use, or nearly so, in industry are studied as a priority. Amorphous silica nanoparticles are already used commercially in foods, have significant industrial relevance to Ireland via their use in the IT sector, and are thus likely to have an early appearance in the environment, making them a strategic starting point. By labelling these particles, representative biological and environmental fate as a function of size will be studied by tracking and imaging methods.

In this project, the ecotoxicitiy of well-characterized 50 nm and 100 nm plain and fluorescently labeled amorphous silica nanoparticles on a test battery of aquatic organisms representing four trophic levels are investigated. The tests used are validated and standardized short-term methods for estimating the acute and chronic toxicity of toxicants to bacteria, algae, invertebrates and fish. Preliminary results show no acute toxicity of concentrations up to 1000 ppm of the different types and sizes of silica nanoparticles to the different species and further testing is on-going to predict the chronic effects of silica nanoparticles on Daphnia magna reproduction.

**TU 289**

**Stabilisation of nanometric titanium dioxide in artificial seawater for in vivo ecotoxicity bioassays**

S Callegaro, G Pojana, A Marcomini
University Ca' Foscari of Venice, VENICE, Italy

Bioassays investigating nanometric titanium dioxide (n-$TiO_2$) ecotoxicity on marine organisms are often affected by a low reproducibility, which is mainly caused by the tendency of nanoparticles to agglomerate and rapidly sediment in artificial seawater (ASW) [1]. As a consequence, the organisms are exposed to time-dependent nanoparticle concentrations as well as to agglomerates with a variable size distribution [2]. In this work, the ability of alginate to stabilise n-$TiO_2$ dispersions in ASW at various nanoparticle concentration levels (1, 10, 100 mg/L) was investigated. Alginate is a polysaccharide naturally produced during the degradation of brown algae and, being not toxic, is widely used in the food industry as emulsifier and gelling agent [3]. Investigation by Dynamic Light Scattering (DLS) measurements showed that dispersions prepared in 0.5 g/L alginate-ASW solutions presented agglomerates with a constant (up to 72 h) and reproducible average hydrodynamic diameter of approximately 270 nm. The stability of dispersions at 100 mg/L was further examined with a stability analyser under centrifugal forces, giving a sedimentation rate of 0.14%/h. The sonication step was also investigated in order to obtain the smallest agglomerates. The employed ASW was characterised (salinity, conductivity, and total organic carbon content) prior to evaluating alginate harmful effects on the marine microalgae *Phaeodactylum tricornutum* and the anostracan crustacean *Artemia franciscana*.

**Natural and engineered metal oxy-hydroxides behavior in a wetland system receiving mining influenced waters and waste water from a treatment plant**

MR Pastorinho[1], BA Gartman[2], AJA Nogueira[1], JF Ranville[2]
[1]University of Aveiro, AVEIRO, Portugal
[2]Colorado School of Mines, GOLDEN, United States of America

Concern over environmental contamination by engineered nanoparticles (ENPs) has arisen due to the increase in the nanotechnology industry. Limitations on risk assessment are directly related to a lack of direct information on ENP stability. The absence of this information can be circumvented by studying natural NPs (NNPs) that can act as surrogates for examining the environmental behavior of ENPs. Mining influenced waters (MIWs) are excellent systems for study due to high concentrations of natural nanoparticulate hydrous iron oxides (HFO) precipitates. Constructed wetlands are engineered wastewater treatment systems, routinely used in remediation of these waters, being designed to encompass natural biological, chemical and physical processes (akin to the ones occurring in natural wetlands), thus enhancing water quality. One of these systems was installed in a sub-alpine stream (located in Jefferson County, Colorado, United States of America), receiving MIW from a number of mining sites together with effluent from a Wastewater Treatment Plant (WWTP). The effectiveness of the wetlands for removing NP-associated metals was investigated through natural and lab prepared iron oxides. Effect of the water composition on surface charge of NPs in sections of the system receiving MIW-only (the creek) and MIW mixed with wastewater effluent (constructed wetland) were investigated for the NNPs and compared to ENPs (NiO, Au, and CNTs). We observed temporal and spatial variations in the several MIWs, finding surface charges ranging from slightly positive, a rarely seen result, to slightly more negative. The considerable aggregation of HFO is consistent with these findings. Results suggest a variation of ENP stability over space and time.

**TU 291**

**Effects of organic carbon content and soil ageing on the fractionation of silver nanoparticles in soil**

C Coutris[1], EJ Joner[2], DH Oughton[1]
[1]Norwegian University of Life Sciences, AAS, Norway
[2]Bioforsk Soil and Environment, AAS, Norway

Due to sewage sludge application on soils, terrestrial ecosystems are very likely to be exposed to silver nanoparticles (AgNPs) and it is thus important to understand the behavior of Ag NPs once in contact with soil components. The aim of this work was to compare the behavior of silver under three forms, silver nitrate, citrate stabilized AgNPs (C-ANPs) and uncoated AgNPs (P-AgNPs), in two soils with contrasting organic matter content, and over time.

The physical and chemical properties of the studied soils as well as the nanoparticles size, shape, crystallographic structure and specific surface area were characterized. Soil samples were spiked with silver nitrate, C-AgNPs or P-AgNPs, and let for ageing 2 hours, 2 days, 5 weeks or 10 weeks before they were submitted to sequential extraction. The ionic silver solution and the two AgNPs types were radiolabeled so that we could detect and quantify silver by gamma spectrometry by measuring the 110mAg tracer in the different sequential extraction fractions. We thereby obtained for each silver form, soil type and time point a distribution of silver in the different fractions.

Silver was generally more mobile in the mineral soil, although the fractionation patterns were very different for the three silver types in both cases. Over 20% of the total C-AgNPs concentration were water soluble in both soils (<5% for AgNO3 and P-AgNPs) the first two days after spiking, but the fraction decreased to trace levels thereafter. This was compensated by an increase in the reducible fraction. Regarding P-AgNPs, 80% were not extractable at all, but contrary to AgNO3 and C-AgNPs, the water soluble and ion exchangeable fractions did not decrease over time in the mineral soil, and even increased in the organic soil.

**TU 292**

**Bioaccumulation of sediment-associated gold in different forms to the deposit feeder, Capitella teleta**

L Dai[1], T Banta[1], H Selck[1], D Gilliland[2], VE Forbes[1]
[1]Roskilde university, ROSKILDE, Denmark
[2]Joint Research Centre, ISPRA, Italy

There is much concern about the fate and effects of engineered nano-particles (ENPs) given their rapidly increasing applications in industrial and household products. Gold (Au) ENPs are used in a wide variety of personal care products and in materials science. Au and other metal ENPs, released into the environment, intentionally or accidently, may end up in the aquatic environment via sewage treatment plants, waste handling or aerial deposition. There are concerns that metal ENPs may have higher reactivity than other forms of metals due to their small sizes and high surface areas, leading to greater bioavailability and thus toxicity in aquatic organisms. However, studies of metal ENP bioavailability in the aquatic environment are limited.

We exposed the deposit feeding polychaete, Capitella teleta, to sediment-associated metal Au in different forms (particles and ions) to assess their relative toxicities. Au particles were tested at 4nm, 15nm, 40nm and 100-200nm sizes. After 2 weeks of exposure, almost all worms were alive and no significant difference in their growth rates was observed among Au treatments. Bioaccumulated Au concentrations in worm tissue will be presented and compared to relevant literature data.

## RA08 - PBT substances

**TU 295**

**Exposure to organochlorine compounds at the early stages of use of DDTs for indoor residual spraying(IRS) in domestic environments (Manhiça-Mozambique)**

MN Manaca, MN Manaca
IDAEA-CSIC, BARCELONA, Spain

Abstract

DDTs and their metabolites were determined in 88 breast-milk samples obtained before and during indoor Residual spraying-IRS with DDT (2002 vs 2006) and 91 straw and branches constituting the wall materials of dwellings collected during and a year after IRS (2006 vs 2007) in Manhica, Mozambique.

A significant increase in 4,4'-DDT and its main metabolite, 4,4'-DDE, was observed between

the 2002 breast milk (median values 2.4 and 0.9 ng/ml, respectively) and the 2006 (7.3 and 2.6 ng/ml, respectively, $p < 0.001$ and 0.019, respectively). However, the observed increases were not uniform and in some individuals high values (5100 ng/g lipid) were determined. Significant differences were found between the concentrations of DDT and related compounds in breast milk according to parity, with higher concentrations in primiparae than multiparae women.
Total DDT levels in straw from 2007 were significantly higher than from 2006.In the 2006 samples, the concentrations of total DDT ranged between 0.3 ng/g and 5600 ng/g. The predominant isomer was 4,4′-DDT (median = 47 ng/g). The straw sampled in 2007 were from sprayed dwellings except in two cases, the concentrations of total DDT ranged between 0.8 ng/g and 26000 ng/g. The predominant isomer was 4,4′-DDT (median=130 ng/g) followed by 4,4′-DDD (median=23 ng/g) and 4,4′-DDE (median= 20 ng/g).
Key words: DDT; IRS; Breast milk; Straw

**TU 296**

**Monitoring of polychlorinated biphenyls (PCBs) in human milk samples - comparative study within the seven years period**

MB Vojinovic Miloradov[1], MM Turk Sekulic[1], JR Radonic[1], IM Mihajlovic[1], TV Vukavic[2]
[1]Faculty of Technical Sciences, NOVI SAD, Serbia
[2]Institute of Child and Youth Health Care, Faculty of Medicine, University of Nov, NOVI SAD, Serbia

Polychlorinated biphenyls (PCBs), substances with great chemical stability, physical and chemical inertness, which fulfil PBT criteria (persistence, bioaccumulation potential and toxicity), are still present in our environment, even if their production was banned by Stockholm Convention. Human biomonitoring data represents the most reliable estimate of human exposure to POPs/PCBs resulting from recent and historical sources.
Aim of this study was to investigate concentrations of seven PCB congeners (PCB 28, PCB 52, PCB 101, PCB 118, PCB 138, PCB 153, PCB 180) in colostrums collected in 2009 from 22 healthy mothers living in and around the city of Novi Sad, Vojvodina. Results obtained in 2009 were compared with the results obtained in the same area in two previous sampling campaigns in 2003 and 2006 within seven years study.
Samples were taken from healthy mothers whose colostrums were stored into specially prepared glass containers. They were frozen at -20°C until analyzed. Deproteinisation of samples was performed with Carrez I and II solutions. Milk fats were extracted using acetone and n-hexane and cleaned by column chromatography using Al2O3. PCBs were eluted from the column using n-hexane and eluates were analyzed by GC-ECD (VARIAN CP-3380). PCB congeners (Ehrenstorfer, Germany) used as standards were min 99.9% purity. Quality control testing was further certified with reference material ERM-BB446 (ERM, Belgium). Recoveries of developed method were 80 - 102 %. Limit of detection (LOD) was 0.5 ng/g.
Congeners 28, 52 and 101 were below LOD in all 22 samples. Only one colostrum sample was not contaminated with any of seven examined PCB congeners. Mean values of PCB 118, 138, 153 and 180 were 1.0, 1.1, 1.3 and 0.8 ng/g whole milk, respectively. Measured concentration range was from 0.6 to 3.4 ng/g. Total PCBs value was calculated by assuming that the measured seven PCB congeners mean value (3 ng/g whole 3rd day milk) is 30% of total PCBs. Milk fat content was 1.6 - 5.3 %.
After a decreasing trend of assumed total PCBs between sampling campaigns in 2003 and 2006 (10.25 to 3.53 ng/g whole milk), increased value in 2009 (10 ng/g whole milk) indicates the continuous input of PCBs in human body through the food consumption and air breathing, from the environment probably contaminated by PCBs.

**TU 297**

**Crossing regulatory borders - the German concept of a harmonised assessment of PBT substances**

CA Rauert, A Böhnhardt, S Duquesne, U Jöhncke, A Kehrer, M Neumann, I Prutz, B Scholz-Starke, J Schönfeld, K Willhaus
Umweltbundesamt, DESSAU-ROßLAU, Germany

Substances which are persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) are subjected to very stringent regulation in the various EU substance regulations.
Any substance of anthropogenic origin that is likely to reach the environment and that resists degradation, accumulates in biota or within terrestrial or aquatic food webs and shows severe toxic effects, is expected to have a much higher impact on the environment than non-PBT substances. If a substance fulfills the PBT- or vPvB-criteria, many regulations aim to ban it from further use, to prevent exposure of the environment.
Across all regulations (industrial chemicals under REACH, Plant protection products under Regulation 1107/2009/EC, biocides on the basis of Directive 98/8/EC and human and veterinary pharmaceuticals by means of EMEA/CHMP/SWP/4447/00 (Medicinal Products for human use and CVMP/VICH/592/98 (veterinary pharmaceuticals), the actual trigger values for PBT assessment are identical, but data requirements as well as assessment "traditions"and regulatory consequences differ greatly. The latter vary from a complete ban or exposure minimisation to no consequences at all (e.g. human pharmaceuticals).
The German Federal Environment Agency - the UBA - aims at harmonising the PBT-assessment across the different substance regulations. The incentive is that the result of a PBT-assessment (i.e. the identification of a substance as PBT or non-PBT) should be consistent, if sufficient data is available, regardless of the individual regulation, as PBT-assessment is hazard-based - not risk-based - and various substances are registered under more than one regulation.
Even if at present the regulatory consequences of the identification of PBT-substances remain different across the various regulations, the procedure of PBT-assessment can - and should - be harmonised.

**TU 298**

**PBT Assessment using the revised Annex XIII of REACH - comparison with other EU frameworks**

CTA Moermond, MPM Janssen, JA de Knecht, MHMM Montforts, WJGM Peijnenburg, EMJ Verbruggen, PGPC Zweers, DTHM Sijm
RIVM, BILTHOVEN, The Netherlands

The European Regulation EC/1907/2006 (REACH) requires an assessment of PBT (Persistence, Bioaccumulative, Toxic) or vPvB (very Persistent, very Bioaccumulative) properties for all chemical substances produced or imported in amounts exceeding 10 tonnes per year, according to criteria in Annex XIII. However, not all substances on the EU market are screened against these criteria under REACH. For human and veterinary medicinal products, biocides, plant protection products, food and feed additives, etc., other EU legislation is in place regulating marketing and use. Besides this, compounds may also be screened for PBT properties within the OSPAR, Stockholm and IMO Ballast water Management conventions or the UNECE protocol on persistent organic pollutants (POPs), which all have their own suite of PBT or POP criteria. There is thus no uniform PBT/vPvB assessment in Europe, because various legislations use no, limited or dissimilar PBT assessments.
In this study, the PBT/vPvB assessment under REACH is compared to PBT or POP assessments within other frameworks. Attention is paid to how a substance is identified as a PBT/vPvB/POP substance, and what legislative steps, such as authorization or restriction, are taken following the PBT/vPvB/POP assignment. In addition to the different PBT or POP criteria of the various frameworks, there are also differences in the description of the criteria and if a weight of evidence approach is possible. Some EU frameworks still refer to the former Technical Guidance Documents (TGD), which preceded Annex XIII of REACH. Although differences between the TGD and REACH Annex XIII are small, this causes dissimilarities among the frameworks. The risk management follow-up of a PBT or vPvB identification, e.g. authorization or restriction, depends on the legal framework and specific conditions at which a substance is used, and whether a socio-economic analysis is included.
Irrespective of the framework in which a substance is used, individual European Member States may propose a substance for PBT or vPvB identification under REACH. However, only when a use of a substance is identified which is not covered by its regular framework, authorization of that use under REACH is possible. Differences among the EU-based legal frameworks create a challenge to harmonize the assessment of PBT/vPvB substances.

**TU 299**

**Predicting environmental behaviour of chloroxanthene and chlorothioxanthene congeners on the basis of quantitative structure - property relationships (QSPR)**

L Lubinski[1], AM Mostrag-Szlichtyng[1], MH Haranczyk[2], TP Puzyn[1]
[1]University of Gdansk, GDANSK, Poland
[2]Lawrence Berkeley National Laboratory, BERKELEY, United States of America

Xanthene is a heterocyclic chemical compound (containing oxygen heteroatom), widely utilized in the industrial production of fluorescent dyes. It is also used as a drug, inhibitor or contrast for cancer cells detection. Thioxanthene, a sulphur analogue of xanthene, is a component of several antipsychotic drugs (e.g. Chlorprothixene, Clopenthixol). Considering their broad application, significant amount of both compounds may occur in the natural environment and undergo chlorination processes leading to the formation of Cl- substituted congeners.
Analysing structural similarities of xanthene and thioxantene to other polycyclic molecules, they are situated in the same space as dibenzo-p-dioxin and anthracene, which are persistent, bioaccumulative and toxic (PBT) environmental pollutants of prior concern. Hence, xanthene and thioxanthene are prone to exhibit equally hazardous properties. Unfortunately, the availability of experimental data on the key physical-chemical parameters of chloroxanthene/chlorothioxanthene congeners is lacking. Therefore, little is known about an actual overall persistence (POV) and long-range transport potential (LRTP) of these compounds.
The presented research investigation aims at filling the gaps in existing scientific data as well as at estimating the environmental fate of 679 chloroxanthene and chlorothioxanthene congeners. We utilized previously developed QSPR MLR models to predict the values of log KOW (n-octanol/water) and log KOA (n-octanol/air) partition coefficients for all studied compounds. For each molecule, the relevant quantum mechanical descriptors were calculated at the level of the semi-empirical PM6 method. The half-lives in air, water, and soil for particular chloroxanthene/chlorothioxanthene congeners were predicted via the freely available US EPA tool 'The PBT Profiler'. Subsequently, we introduced these results into multimedia mass balance model 'The OECD POV and LRTP Screening Tool' for final POV and LRTP estimation.
The results were visualised as suggested by Klasmeier et al. (2006). Additionally, the differences between environmental fate of oxygen (xanthene) and sulphur (thioxanthene) analogues were investigated. Our study revealed that some of the investigated congeners show POP-like POV/LRTP or POV characteristics. As such, further studies that would verify the necessity to include studied molecules in the international lists of high-priority environmental pollutants are recommended.

**TU 300**

**Persistency assessment of poorly water-soluble substances**

S Fiebig, N Mendel, L Geisler, U Noack
Dr.U.Noack-Laboratorien, SARSTEDT, Germany

Under REACH a PBT/vPvB assessment is required for substances that are manufactured or imported in amounts of > 10 tons per year. The first step of persistency assessments is a screening like the tests on ready and inherent biodegradation provide. Often substances fail the criterion for ready biodegradability or an unequivocal assessment is not possible because the substance is not bioavailable for the degrading bacteria due to its low water solubility. Careful consideration of the physic-chemical properties of a substance is therefore necessary to choose the appropriate test design. As the biodegradation of a substance strongly depends on its mass transfer and the bioavailability for the degrading bacteria, there are several technical issues which need to be addressed while testing the biodegradability of poorly water soluble substances. Due to the historic background of the guidelines for testing ready biodegradability the test concentration is relatively high (2 - 100 mg/L) and not reflecting environmental concentrations. To improve the bioavailability of poorly water soluble substances in tests for ready biodegradability the pretreatment of the substance as well as the application technique and the agitation during testing needs therefore special consideration. Four techniques for the application of poorly water-soluble substances are commonly used and described in the ISO standard 10634 (1995) and recommended by the REACH guidance. These methods are direct addition, ultrasonic dispersion, adsorption onto an inert support material and the use of non-biodegradable emulsifying agents. So far no single method is recommended and routinely a combination of approaches is used for application. Based on the substance properties the application method has to be chosen carefully e.g. the use of the wrong inert support material can result in too strong adsorption and decreased bioavailability. Careful investigation of the application method prior to the test start can enhance the degradation distinctly. These investigations involve a relatively small extra effort and often more expensive simulation studies can be avoided. The influence of different application techniques on the bioavailability and biodegradation of poorly water-soluble substances was investigated and the results will be presented.

**Using Molecular Dimensions to evaluate bioaccumulation potential**

N Petry[1], P Adrian[2], C Durou[1]
[1]CEHTRA, SAINTE-EULALIE, France
[2]CEHTRA Europe, BRUSSELS, Belgium

In the REACH Regulation (but also under other directives/regulations), PBT and vPvB assessment is compulsory for all chemicals produced or imported above 10 t/year. Although the main regulatory criterion for B or vB attribution is the aquatic bioconcentration factor (BCF) (REACh Annex XIII), an evaluation of all available information is necessary and screening criteria, as log Kow, can be used. So, when direct comparison with criterion lay down in REACh Annex XIII is not possible, other indicators are to be considered in a weight of evidence approach. Among these, the molecular size and molecular weight (MW) may indicate a low bioaccumulation potential. Several descriptors can reflect molecular size but at present, the most reliable is the "average maximum diameter"(Dmax aver) developed by Mekenyan and Dimitrov . These authors showed that a chemical may be considered as not bioaccumulative if Dmax aver > 1.7 nm and MW > 1100 g/mol because very bulky molecules pass the cell membranes with difficulty . To calculate Dmax aver, conformational analysis is necessary and OASIS is the reference software to obtain energetically stable conformers representing conformational space of the molecules. The objective of this work was to find alternative or additional equivalent tools. We have based our work on the review of Brooke and Cronin , and we critically examined different modeling softwares related to molecular dimensions. By this way, we led to the combination of two softwares: Spartan was used for modeling calculations whereas the BBX descriptor from Mol2Mol gave a surrogate value for Dmax aver. This new procedure was tested on a set of 18 molecules reflecting a wide structural diversity and results were compared with data obtained with OASIS. In this communication we will present the results obtained and discuss the scope and limitation of our method in the context of PBT assessment.

**TU 302**

**Accounting for photo degradation in the PBT assessment of chemicals**

J Castro-Jiménez[1], D van de Meent[2], A Hollander[2]
[1]Ecole des Mines d'Alés, ALES, France
[2]Radboud University Nijmegen - Institute for Wetland and Water Research, NIJMEGEN, The Netherlands

In the current REACH guidelines substances are considered persistent if their half-life in marine water is greater than 60 days. Current estimations of half-lives in the aquatic environmental under REAH regulation are mainly done using recommended modeling tools (i.e. EUSES), in which photo degradation is not explicitly considered. REACH guidelines do not specify how "half-life in water"is to be deduced from laboratory measurements of direct photolysis according to official methods (e.g. OECD or EPA test guidelines). However, photolysis in surface waters has been identified as the main degradation pathway for some chemicals / pollutants, in particular those resistant to biotic degradation processes. The overall objective of this work was to investigate how direct photolysis of chemicals in the aquatic media can be accounted for in the current PBT assessment methodologies. In addition, an investigation on how to establish a generic procedure for extrapolating photolysis rates under laboratory conditions to field conditions was performed. The methodology followed was based on the revision of currently used laboratory test methods for direct photolysis, peer-reviewed scientific literature, and main modeling applications currently employed for the calculation of the persistency of a chemical in the aquatic environment. Data still under evaluation although a preliminary assessment point to light attenuation, pH of the water media (in particular for chemicals with acid-base properties) and dissolved organic matter (DOM) concentration being among the most important environmental variables affecting the direct photolysis rates. In addition, indirect photolysis has been shown to play an important role too. A standard procedure for extrapolating laboratory measurements of direct photolysis to half-lives in natural water is proposed. The developed extrapolation method has been incorporated into the multimedia fate model SimpleBox and the effect of incorporating photo degradation on the calculated persistence of some example chemicals in water has been analyzed.

**Analytical improvements: simultaneous pressurarized liquid extraction, silica gel, fluorosil, celite, alumina, and carbopack cleanup techniques for fish tissues analysis**

S Usenko, EM Robinson, B Subedi
Baylor university, WACO, United States of America

Pressurarized liquid extraction (PLE) was combined with multiple cleanup techniques including silica gel, fluorosil, celite, alumina, and carbopack into a single step. This simultaneous analytical extraction/cleanup technique was compared with a traditional packed column approach described by EPA method 1613. EPA method 1613 describes the analysis of polychlorinated dioxins and furans (PCDD/Fs) and polychlorobyphenyls (PCBs) in fish tissues involving multiple cleanup sorbents. Homogenized fish tissue (5 g) with anhydrous sodium sulfate was packed within an extraction cell directly over different combinations of commercially available adsorbents. Simultaneous pressurized liquid extraction and cleanup was performed with dichloromethane and hexane (1:1 v/v) using an Accelerated Solvent Extractor (ASE 350, Dionex). Analysis was performed with HRGC/ECNI-MS and HRGC/HRMS utilizing isotope dilution technique. Cleanup efficiencies for individual and combinations of sorbents within the extraction cell were compared to conventional packed column techniques and gel permeation chromatography. Different ratios of sorbents were also examined. Cleanup efficiencies were examined using target analytes percent recoveries, UV-absorbance and GC/EI-MS full scan spectra. This simultaneous PLE/cleanup technique reduces the intrinsic costs associated with sample preparation (time, labor and supplies) over conventional series approach by as much as 80% percent. The average recoveries of PCDD/F and PCBs in fish tissue (5 g) using PLE/silica gel/fluorosil/celite was 98 ± 8%. Combined cleanup technique allows the extraction of whole zebra fish of ~ 1g without any homogenization step. The recovery from in-fish spiking, on-fish spiking and over-fish spiking of analytes were 86 ± 7%, 83 ± 6%, and 77 ± 7%, respectively.

**TU 304**

**Implementation of alternative fuels in cement plants: a cost-benefit analysis between CO2 emissions and PBT risks**

J Rovira, M Mari, M Nadal, S Schuhmacher, JL Domingo
Universitat Rovira i Virgili, TARRAGONA, Spain

Cement industry is an industrial sector with very high-energy requirements. The use of alternative fuels such as sewage sludge or refuse-derived fuels (RDF) seems to be an important pathway to solve different problems. On one hand, the emission of greenhouse gasses (CO2) is reduced and a feasible solution is given to the waste management problem, while on the other hand, the partial substitution of traditional fuel may generate a change in the cement plant pollutant emissions and, consequently of the human health risks. Among the pollutants emitted by cement plants, PCDD/Fs and heavy metals cause especial concern because they are persistent, bioaccumulable and toxic (PBTs).

In recent years, many survey campaigns have been done around two different cement plants with different fuel consumption situations. The objective was to monitor the levels of PBT substances in different environmental compartments in order to evaluate the potential effect of the use of alternative fuels on the emissions. Levels of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs) and metal were determined in different environmental monitors (soil, vegetation and air) before and after the implementation of alternative fuels. The alternative fuels evaluated were sewage sludge and RDF, respectively. The results were used to perform a cost-benefit analysis. Economical benefit of reduction of CO2 emission was compared with the changes in human health risks due to exposure to metals and PCDD/Fs. In general, terms, the results of cost-benefit analysis in the two cement plants under study showed that the benefits of reduction of CO2 emission were greater than the cost of human health risk due to the exposure to metals and PCDD/Fs. This indicates that the exposure to PBT for residents around cement plants implementing alternative fuels does not pose significant risks for human health.

## RA09 - Risk assessment in the marine environment and regulation

**TU 310**

**Crude oil genotoxicity and cytotoxicity after short-term exposure of mussels**

JM Barsiene[1], L Andreikenaite[1], A Hjelle[2]
[1]Nature Research Center, VILNIUS, Lithuania
[2]International Reasearch Institute of Stavanger, STAVANGER, Norway

Significantly increased levels of micronuclei, nuclear buds and fragmented-apoptotic cells have been found in bivalves inhabiting the Būtingð- oil terminal area in the Baltic Sea, (Baršienð- et al., 2006a), zones close to the Russian oil platform D-6 (Baršienð- et al., 2008), in oysters and fish caged in Haven oil spill zones even 10 years after the oil spill (Bolognesi et al., 2006a). High levels of micronuclei and other nuclear abnormalities has been found in fish and mussels after 3-week exposure to crude oil processed from the Statfjord B platform in the North Sea (Baršienð- et al., 2006b; Bolognesi et al., 2006b; Baršienð- and Andreikð-naitð-, 2007). The study presents data on genotoxicity and cytotoxicity of the crude oil in gills of mussels Mytilus edulis, exposed to 0.5 ppm of the oil for 1-, 2-, 4- and 8-days. Induction of micronuclei (MN) and nuclear buds (NB) were assessed as the crude oil genotoxicity endpoints, induction of fragmented-apoptotic (FA) and bi-nucleated (BN) cells indicated cytotoxicity potential of the oil. Time-related elevation of MN incidences was detected in all experimental groups compared to control group of mussels. The elevation of MN frequency increased progressively with increasing duration of exposure, from 1.9 fold increase after 1 day exposure to 2.4 fold after 8 day exposure. There was no significant increase of nuclear buds in all experimental groups. Significant induction of fragmented-apoptotic cells (P=0.0115) was detected in mussel gills after 4-day exposure and bi-nucleated cells after 8-day treatment (P=0.0232). The data will be discussed in relation to long-term oil exposures, to genotoxicity and cytotoxicity responses after caging of mussels in oil platform zones, also will be pointed on genetic risk provoked by oil pollution in marine ecosystems.

**TU 311**

**Genotoxicity and cytotoxicity effects in mussels after short-term treatment with different concentrations of pyrene, fluoranthene and their mixtures with benzo(a)pyrene**

JM Barsiene[1], G Garnaga[2], J Syvokiene[1], K Lehtonen[3], L Andreikenaite[1], A Rybakovas[1], R Turja[3]
[1]Nature Research Center, VILNIUS, Lithuania
[2]Evironmental Protection Agency, KLAIPEDA, Lithuania
[3]Finish Environmental Institute, HELSINKI, Finland

Micronuclei (MN), nuclear buds (NB), fragmented-apoptotic (FA) and bi-nucleated (BN) cells were investigated in 16 experimental groups of mussels, which in the semi-static laboratory system were exposed for 48 hours to 4 µg/l, 12 µg/l, 36 µg/l of pyrene (Py), to 4 µg/l, 12 µg/l, 36 µg/l of fluoranthene (F), to 8 µg/l and 24 µg/l of Py and F mixtures and also to Py and F model mixtures with benzo(a)pyrene (BaP), as well as to 12 µg/l and 28 µg/l model mixtures of Py, F and B(a)P. 4 _g/l of BaP concentration was used in all model mixtures. Control group and control group with PAH solvent acetone of mussels maintained in filtered seawater. Pre-exposure group of mussels was dissected after 4-day acclimation of mussels in unfiltered seawater. Exceptionally high levels of MN (11.43"ð) and NB (14.14 "ð) were detected in mussels treated with mixture of fluoranthene and benzo(a)pyrene at 16 _g/l (F12+BaP4) and after exposure to fluoranthene 12 _g/l (MN - 10.57"ð; NB - 8.71"ð). The highest level of bi-nucleated cells (19.91"ð) was observed in Py4+BaP4 group, fragmented-apoptotic cells (9.50"ð) - in F4+Py4 mussel group. In nine of 16 studied groups, Mann-Whitney U-test revealed significant differences in frequency of bi-nucleated cells between control and exposed groups. Significant elevation of the other responses via control was observed in 4 or 5 groups. Positive relationships between induction of MN and NB, MN and BN, MN and FA, as well as between total genotoxicity (MN+NB) and cytotoxicity (FA+BN) were found by using the Pearson's correlation. Assessment of the BaP influence in model mixtures consisting of 4 _g/l and 12 _g/l of pyrene or fluoranthene and plus BaP of 4 _g/l disclosed significant effects of BaP in mussels treated with mixtures containing low (4 _g/l) concentration of fluoranthene or high (12 _g/l) concentration of pyrene. In the mixture of 12 _g/l of fluoranthene, any effects of BaP were defined (Unpaired T-test).

**Biochemical responses of mussels Mytillus galloprovincialis to petrochemical contamination along the North Iberian Peninsula Coast**

L Garmendia[1], LG Luis[2], I Marigómez[1], L Guilhermino[2]
[1]University of the Basque Country, LEIOA-BIZKAIA, Spain
[2]University of Porto, PORTO, Portugal

In order to assess the biochemical responses to petrochemical contamination, mussels, Mytilus galloprovincialis were collected in April, June and October 2010 in seven localities along the North Iberian Peninsula Coast (NIPC). Four localities were selected in the NW Coast of Portugal (Vila Chã, São Bartolomeu do Mar, Viana do Castelo and Carreço) and three localities in the Basque Coast (Arriluze, Gorliz, Mundaka). The sites were chosen according to the level and sources of petrochemical contamination. Three biochemical biomarkers were selected: acetylcholinesterase (AChE) activity was quantified in foot to assess mussels' neurotransmission levels, glutathione S-transferases (GST) activity and the levels of lipid peroxidation (LPO) were analyzed in gills as biomarkers of biotransformation and oxidative cell damage, respectively. All the biomarkers variations were studied in relation to abiotic factors variation using multivariate statistics. The levels of AChE activity were significantly higher in April than in June and October in all the studied localities, except in Arriluze where low activity values were found all along the study period. In mussels collected in the NW Coast of Portugal, no significant differences were found in the levels of GST activity among localities. In general, GST activity was higher in October than in April and June. In the Basque Coast, significant differences were recorded in the levels of GST activity both among localities and sampling times. The levels of LPO were significantly higher in June and October than in April in mussels collected from the NW Coast of Portugal, whereas in the Basque Coast, LPO values were significantly higher in April than in June and

October, except in Gorliz where significantly higher levels were recorded in October. Since the NIPC is a high risk area for marine oil and other chemical spills due to intense marine traphic, this is a most important baseline study allowing the assessment of impacts in future spills. This study was supported by the Portuguese Foundation for the Science and Technology and FEDER funds through the project RAMOCS (ERA-AMPERA/0001/2007; EU AMPERA ERA-NET, ERAC-CT2005-016165), and by the Government of the Basque Country through a post-doc grant to L. Garmendia (ref. BFI09.244) and K-EGOKITZEN project.

**Exposure assessment of active ingredients and byproducts in antifouling paints and ballast water treatment systems**

AGM van Hattum[1], J van Gils[2], A Baart[2], A Andreas[3], S Heise[3]
[1]Institute for Environmental Studies, VU University Amsterdam, AMSTERDAM, The Netherlands
[2]Deltares, DELFT, The Netherlands
[3]BIS - Consulting Centre for Integrated Sediment Management, HAMBURG, Germany

Antifouling paints and ballast water treatment installations may be sources of direct inputs of contaminants into the marine environment. Against the background of the requirements of the EU Biocidal Products Directive (BPD), the IMO Antifouling Convention of 2001, and the IMO Ballastwater Convention of 2004 there is a need for reliable modelling tools for the prediction of exposure and risks of new antifoulants and pollutants from ballast water treatment systems. In 1999 the first version of MAMPEC was released. The study was sponsored by the Antifouling Working Group of the European Paint Makers Association (CEPE/CEFIC) and the European Commission (DG XI) The model has since been improved with regular updates of the model. The latest release of MAMPEC version 3.0 is compatible with Windows Vista/ 7 and includes some important new features.

The model predicts concentrations of antifoulants in generalised 'typical' marine environments (open sea, shipping lane, estuary, commercial harbour, yachting marina, open harbour). The user can specify: emission factors (e.g., leaching rates, shipping intensities, residence times, ship hull underwater surface areas), compound-related properties and processes (e.g., $K_d$, $K_{ow}$, $K_{oc}$, volatilisation, speciation, hydrolysis, photolysis, biodegradation), and properties and hydrodynamics related to the specific environment (e.g. currents, tides, salinity, DOC, suspended matter load, port dimensions). MAMPEC includes options for advanced photolysis modelling, and incorporation of wind-driven hydrodynamic exchange and other non-tidal exchange processes important for areas without tidal action, or inland freshwater environments. Included are also the service-life emission scenarios developed by OECD and adopted by EU as the standard environmental emission scenarios, to be used for evaluation of the biocides under the Biocidal Products Directive. The model has been validated for a number of compounds and is today recognized by regulatory authorities in EU, USA, Japan, and other OECD countries. MAMPEC is currently also used in authorisations by GESAMP and IMO for the assessment of active ingredients in ballast water. The model is freely available from the software support site http://delftsoftware.wldelft.nl. The poster presentation will focus on available exposure models, areas of uncertainty, new developments, and research needs.

**Risk Assessment of copper in antifouling use**

KWJ Long, C Mackie
RCL, BILSTON GLEN, United Kingdom

In 1998, the Biocidal Products Directive (BPD) required the chemicals industry to initiate steps to address the risk assessment of chemicals in biocidal applications, including antifouling use. Described is the process of risk assessment of copper, the models used, the assumptions made, and preliminary conclusions of the industry assessment.

**TU 315**

**Individual and mixture toxicity of antifouling biocides using a novel multispecies slime assay**

Å Arrhenius[1], T Backhaus[1], HB Blanck[1], A Hilvarsson[1], K Langford[2], K Thomas[2], I Wendt[1], A Zgrundo[3]
[1]University of Gothenburg, GÖTEBORG, Sweden
[2]Norwegian Institute for Water Research (NIVA), OSLO, Norway
[3]University of Gdansk, GDANSK, Poland

Antifouling biocides are used in paints to prevent the growth of fouling organisms on submerged structures such as ship hulls. However, many of today's antifouling coatings fail to inhibit settling and growth of microalgal slime, a complex multispecies biofilm which is often dominated by diatoms. Here we present a simple, robust and highly realistic assay for evaluating the efficacy and ecotoxicological properties of antifouling biocides and formulated paints. To reflect the high diversity found in microbial fouling communities, we developed a settling and growth assay that uses microbial communities from natural biofilms as start material. In short, an inoculum is prepared from the biofilms using a scrape, shake, and sieve technique. Biofilms are then allowed to form during a phase of 72 hours of controlled exposure to a concentration-series of biocides. The established slime biofilms can then be analysed by various techniques, here we used biomass (estimated as chl a content). By this approach we include the whole multitude of indigenous, often non-cultivatable species that are the actual foulers. The assay hence integrates the different sensitivities of the various species as well as their ecological interactions during the settling phase. Eight common antifouling biocides were selected for initial testing. All were toxic to the settling of slime communities in a concentration-dependent manner, with EC50 values ranging from 0.6 nM to 4.4 µM. In addition, 2- to 6-component mixtures were tested with EC50 values falling into the span of individual toxicities, indicating the absence of strong synergisms. In fact, mixture toxicities were often concentration-additive, but antagonistic effects were also observed. Implications for risk assessment of antifouling biocides and paints will be discussed. The study is part of the Swedish Marine Paint research programme funded by MISTRA (www.marinepaint.se).

**Acute toxicity estimation of desalination byproducts at Chuja island desalination plant**

GS Park[1], SJ Yoon[1], SM Yoon[2], KS Park[2]
[1]Anyang university, INCHEON, South-Korea
[2]RIST, POHANG, South-Korea

Desalination of seawater has become an important and growing industry due to the present water shortage in the world. However, the desalination may result in environmental impacts, manly derived by the discharge into adjacent coastal waters of brine and additives produced during the desalination processes (e.g., biocides and membrane cleaning chemicals). To measurement of environmental impact by desalination, we approached environmental impact assessment (EIA) procedure proposed by Hoepner (1999) for the desalination plant of Chuja Island in South Korea. We conducted a series of marine bioassays using three phytoplankton, two zooplankton, and one fish species for source water, discharged brine waters and chemical additives. There was no significant toxicity on brine but high toxicity was found at the chemical additives as chlorine and membrane cleaning chemical. However, Chuja plant used little chemicals to treat source waters and produced freshwater. In terms of the habitat susceptibility it is located in relatively insensitive habitat, open rocky shore with gravel bottom. Based on these results, even the environmental impacts by Chuja desalination plant were not significant currently, monitoring strategies have to be established and conducted to estimate long-term effects from desalination in marine ecosystem. This study will be an example for EIA processes of desalination in Korea. This research was funded by Ministry of Land, Transport, and Maritime Affairs, Korea.

**TU 317**

**Disinfection by-product formation by ballast water management systems**

S Banerji, B Werschkun, Y Sommer
Federal Institute for Risk Assessment (BfR), BERLIN, Germany

Ship's ballast water is a vector for the spread of alien aquatic species, which have lead to substantial ecological and economical damage in the past. In an effort to resolve this problem the International Maritime Organization (IMO) passed a convention for the management of ship's ballast water in 2004, which is expected to come into force within the next two years. This convention requires ship's ballast water to be treated in order to eliminate alien aquatic species. Any ballast water management system using active substances needs IMO approval. Human health and environmental risk assessment is an important part of the approval procedure requiring identification of active substances and relevant chemicals and submission of specified datasets on their physical, chemical and toxicological properties. Identification of the active substances is straight forward since these are by definition the substances responsible for disinfection. The more critical point is to identify all relevant chemicals, predominantly disinfection by-products (DBPs), formed unintentionally and to assess their risk to human health and the environment. We analyzed the available data on systems submitted to IMO with regard to the formed chemicals focusing on three disinfection principles, namely electrolysis, ozone and UV. Our goal was to provide a basis for future risk assessments by identifying relationships between employed disinfection methods and predominantly detected DBPs as well as relationships between water quality or system performance parameters and DBP formation. We came to the conclusion that selection of DBPs for analysis is based on drinking water conditions and recommend selecting an extended set of DBPs using a system (i.e. treatment method) and hazard based approach.

**TU 318**

**The distribution of the salinity and biogenic elements in the surface microlayer of the Baltic Sea**

VJ Sukyte
Kaunas University of Technology, KAUNAS, Lithuania

Marine surface films are encountered at many places of the world's oceans, particularly in marginal seas and coastal regions. Since the late 1960s, much progress has been made in understanding the role of surface films on mechanisms and mass transfer across the ocean/atmosphere interface. The peculiarities of the distribution of the salinity and nutrients in the surface microlayer and the comparison of such with the distribution in the layers below in the region of deep-bottoms of the Baltic Sea (Landsort, Gotland, Bornholm, and Arkona) were investigated. The investigations were carried out during expedition in August 1982. Air -sea interaction experiments are then described. The sampling in the SML was performed by the trap method. It was shown that surface microlayer (SML) strongly concentrates biogenic substances: ions of inorganic nitrogen and phosphorous compounds. Their concentrations in SML were approximately tenfold higher than in the below surface layer's of the Baltic Sea. The salinity of SML in different parts of the Baltic Sea warred in the range of 0.043 - 0.646 "ð. The dynamics of the values of the salinity and nutrients ions, and their variability in distribution according their concentrations gradients in the different parts of the Baltic Sea has been also shown. The coefficients of enrichment of SML with investigated parameters have been evaluated quantitatively, and the selective range of the hydrochemical determinants has been established. On the basis of the presented data it may be stated that surface microlayer of the Baltic Sea seems to be a significant player in the atmosphere - sea interaction processes.

**New physiological biomarkers for express indication of aquatic ecosystems state on the base of adaptive capacities assessment of bivalves using standard test-stimuli**

SV Kholodkevich, T Kuznetsova
Scientific Research Center for Ecological Safety RAS, SANKT-PETERSBURG, Russian Federation

In the present work the results of the experimental study directed on working out of a new cardiac activity and valve movements biomarkers are obtained. A methodological basis of a given research is the estimation of adaptive capacities of test organisms by means of standard test stimuli in the range of species tolerance. Experimental rapid change of salinity of sea water on 50% was used as one of stimuli. On an example of mollusks Mytilus galloprovincialis Lam. of the Black Sea studies of organisms' adaptive capacity in normal state and after toxic influence of 500 mkg/l $Cu^{2+}$ were conducted on laboratory base of Karadag Natural Reserve of the National Academy of Sciences of Ukraine. Distinctive feature of the present study from our previous works performed on bivalves of the Baltic Sea was research of mussels' responses on hypo- and/or hypersalinity stimuli using noninvasive methods of monitoring not only of heart rate (HR), but valve gaping (VG) also. Thus, to study the peculiarities of mussel's responses to test stimuli from their physiological state we used acute dose of $Cu^{2+}$, which caused experimentally induced temporary decrease in adaptive capacities of tested mollusks.HR and VG were selected as integral parameters of mussel's health status. 14 mussels simultaneously were exposed to $Cu^{2+}$ and their HRs and VGs were investigated during long-term experiments. Effect of $Cu^{2+}$ on mussel's adaptive capacities was examined by test-stimulus after the toxic treatment and compared with cardiac and valve responses patterns before exposure. Analysis of studied parameters after exposure showed the significant differences in recovery time after standard salinity test followed by $Cu^{2+}$ exposure. Increase in discrepancies in individual responses after toxic treatment was also observed.

The results allowed us to propose the following new biomarkers:

- Evoked by standard test-stimuli value of ΔHR dispersion, in %;
- Time of organism recovery after test-stimuli, measured as restoration of individual background specific patterns in HR and in VG, in hrs.

The tendency for rapid recovery period for HR and VG to their initial values, during salinity tests can characterize better physiological status of tested organisms as having better adaptive capacities to restore their normal physiological state after test-treatments. The latter can give us an

opportunity to assess ecosystem health status for studied sites.
The work was supported by RFBR grant N 08-04-92424 BONUS_a.

**Embryotoxic and dioxin-like potential of Baltic Sea sediments and extracts as determined using the fish embryo test with Danio rerio and a RTL-W1 cell-based EROD induction assay**

J Lörks[1], TB Seiler[1], V Kloubert[1], W Ahlf[2], S Heise[3], K Schmidt[3], G Witt[3], H Hollert[1]
[1]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[2]Hamburg University of Technology, Department of Environmental Technology, HAMBURG, Germany
[3]Hamburg University of Applied Sciences, Department of Environmental Engineering, HAMBURG, Germany

The Baltic Sea, one of the largest brackish water regions in the world, is considered to be an especially sensitive and endangered marine ecosystem. The average residence time of Baltic Sea water ranges between 25 and 50 years, thus increasing the accumulation of pollutants.
For a deeper insight into the ecotoxicological effects of pollutants in sediments, both chemical and biological testing is important. The ecotoxicological risk assessment of native sediment samples using biological tests is affected by the bioavailability of persistent organic pollutants in the water phase. Direct sediment contact tests represent the bioavailability in ecosystems for different species, but extracts are essential for many biological tests and also for chemical analytics.
Baltic Sea sediments were investigated for their ecotoxicological impact on the development of zebrafish (*Danio rerio*) embryos. Preliminary tests adapted the whole-sediment toxicity test to samples with salinities above fresh water level. Using the fish embryo test system, whole sediment samples, ASE extracts and mild methanol/water extracts of all sampling sites were then assayed for deleterious effects. Further investigations of the extracts were conducted with the EROD induction assay using RTL-W1 cells for detection of dioxin-like activity. Target analytes were also determined analytically.
A no-effect salt concentration of 6.6 "ð in the testing medium (equals 28 "ð for the original sample) could be derived, and thus allowed to perform the whole-sediment fish embryo toxicity test with brackish Baltic Sea sediments. Results from the embryo toxicity test in 96 well plates with sediment extracts from ASE and shaking extractions with methanol/water were compared to data obtained testing native marine sediments. Findings revealed the bioavailable hazardous potential of sediments as well as the actual risk for fish embryo development. Finally, results on EROD inducing potential indicated putative dioxin-like activity at the investigated sampling sites. The data show an ecotoxicological burden for several Baltic Sea sediments, that is likely accessible for sediment-dwelling organisms.

**TU 321**

**Large and medium scale spatial variability in biomarker responses in herring (Clupea harengus membras), a commercially and ecologically important fish species in the Baltic Sea**

K Lehtonen[1], K Broeg[2], J Heinrich[3]
[1]Finnish Environment Institute, HELSINKI, Finland
[2]Alfred Wegener Institute for Polar and Marine Research, Germany
[3]Von Thünen-Institut/Institute of Fishery Ecology, Germany

The BEAST project ("Biological Effects of Anthropogenic Chemical Stress: Tools for the Assessment of Ecosystem Health", 2009-2011) is the most extensive international research project in the field of biological effects of pollutants carried out in the Baltic Sea region so far. As part of the sampling programme of BEAST, herring (Clupea harengus membras), a key species of the Baltic Sea ecosystem and one of the most important commercial species in the area, was collected from different sea areas (Gulf of Bothnia, G. of Finland, G. of Riga, G. of Gdansk, and Belt Sea) for the measurement of selected biomarkers (lysosomal membrane stability, acetylcholinesterase activity, glutathione S-transferase activity and catalase activity) as well as recording of histopathological changes. The results obtained showed marked between and within sea area variability, the former indicating differences in natural levels of certain parameters caused by the different abiotic regimes (mainly salinity and temperature conditions) in different parts of the Baltic Sea, while the latter being probably related to the prevailing local contaminant situations in each study area. The results imply that the causes of large and medium scale variability in biological effects needs to be carefully considered when interpreting and comparing the results attained from large and variable sea areas such as the Baltic Sea.

**TU 322**

**Assessment of ecosystem health in the Baltic Sea using the embryonic development of Monoporeia affinis as a bio-indicator**

M Reutgard, B Sundelin, AK Eriksson Wiklund
Stockholm University, STOCKHOLM, Sweden

The current work is a part of the Bonus project "BEAST"that targeted at developing integrated measures of chemical pollution and tools needed to detect and understand human-induced pressure on the Baltic Sea ecosystem. The project aims at establishing links between chemical pollution and biological effects within individuals, and higher organizational level. A possible candidate for evaluating chemical - biological effects at population level is analyzing the embryonic development of the Baltic key species amphipod Monoporeia affinis. The present work evaluates embryo malformations of Monoporeia affinis as a bio-indicator for regional assessments in the Baltic Sea. A total of 11 independent regional studies from polluted recipients are synthesized in a meta-analysis to provide quantitative and statistically defensible summary of the relationship across studies. Results show that embryo malformations meet several criteria for a pollution bio-indicator. It is shown that embryo malformations generally arise in the studied recipients, despite various types of emissions sources, suggesting that the variable works as a general indicator of pollutant effects in the Baltic Sea. Results show that the proportion of malformations increases with decreasing distance from point source, suggesting that there is a strong relationship between the studied emission sources and the malformation rate. The synthesis also indicates that embryo malformation is a sensitive variable that can detect pollution from point sources as far away as 20-31 km. It is concluded that the variable provides an unequivocal input which could facilitate decision-making and development of remedial action plans.

**TU 323**

**Is pollution changing the composition of estuarine zooplankton communities in the NW coast of Portugal?**

LR Vieira[1], F Morgado[2], L Guilhermino[1]
[1]University of Porto: ICBAS & CIIMAR, PORTO, Portugal
[2]University of Aveiro: CESAM & Departamento de Biologia, AVEIRO, Portugal

Zooplankton is considered critical for pelagic ecosystem functioning, since it connects producers to several fish species that depend all life or in the juvenile phase from this food source. Pollution can have negative effects on zooplankton communities (biodiversity, structure and/or functioning), with negative consequences for the functioning of the pelagic ecosystem. The aim of this study was to compare the effects of pollution on structure and dynamics of zooplankton communities taking advantage of two adjacent estuaries in the NW coast of Portugal with different levels of pollution (the estuaries of Minho and Lima Rivers). Zooplankton samples were collected monthly during the high tide for 1 year (2010-2011), using nets with different meshes (0.063-0.500 mm) equipped with a flow meter. Additionally, abiotic parameters were determined, indicative of water quality and primary production (chlorophyll *a*). The diversity of both estuarine communities was compared using diversity indices and analyzed in relation to variation of abiotic parameters using multivariate statistics. The preliminary results indicate significant differences in main taxonomic groups between the two estuaries and suggest a main role of pollution on these differences. This work was financially supported by the Portuguese Foundation for the Science and Technology (FCT), FEDER funds, European Social Fund and MCTES national funds through the project RAMOCS (ERA-AMPERA/0001/2007; EU AMPERA ERA-NET, ERAC-CT2005-016165) and a post-doctoral grant to Luis R. Vieira (FCT: SFRH/BPD/47407/2008).

**Implementing the tissue residue approach for a key Antarctic species - Antarctic krill (Euphausia superba)**

AH Poulsen[1], S Kawaguchi[2], CK King[2], M Leppänen[3], J Kukkonen[3], SM Bengtson Nash[4]
[1]The University of Queensland, BRISBANE, Australia
[2]Australian Antarctic Division (AAD), KINGSTON, TASMANIA, Australia
[3]University of Eastern Finland, JOENSUU CAMPUS, Finland
[4]Griffith University, BRISBANE, Australia

Persistent organic pollutants (POPs) are well known to accumulate in polar food webs; yet there is little ecotoxicological data available for environmental risk assessment of POPs in these extreme ecosystems. The premise of the tissue residue approach (TRA) is that xenobiotics cause toxic effects at similar tissue residues across species and geographical ranges, regardless of differences in external factors such as ambient temperature. Empirical data are however, fundamental for validation of the TRA for polar species. p,p'-DDE has been identified as a priority POP accumulating in Antarctic krill, which play a central role in the Southern Ocean ecosystem. This study evaluated the toxicological sensitivity of Antarctic krill to p,p'-DDE exposure on a body residue/effect basis. Baseline toxicity ('narcosis'), which is a commonly applied endpoint in the TRA, was used as indicator of sublethal toxicity. Several different exposure scenarios were tested: i) 96 h aqueous exposure of adult krill, ii) 1, 3 and 9 d aqueous exposure of larval krill and iii) 10 d dietary exposure of adult krill. For all exposure scenarios, krill immobility was induced at the low end of the body residue range (4 - 16 mmol/kg lipid weight (l.w.)) known to cause sublethal narcosis in temperate species (e.g. small fish, crustaceans). Internal effect concentrations (IECs) were relatively constant across tests (3.3 - 6.2 mmol/kg l.w.), although the degree of narcosis varied between tests. Adult krill reached partial immobility during 96 h aqueous exposure (IEC50partial immobility = 3.9 mmol/kg l.w.), whereas complete immobility and mortality were observed in the 10 d dietary exposure tests at similar internal concentrations (IEC50complete immobility = 3.3 mmol/kg l.w.). Complete immobilisation was observed in 20 % of larval krill after only 24 h exposure (IEC20complete immobility = 3.6 mmol/kg l.w.). The apparent variability in toxicological sensitivity between different life stages may be partly explained by differences in p,p'-DDE uptake rates. The observed differences in the narcotic response of adult krill between 4 and 10 d exposure indicate however, the possibility of delayed effects of p,p'-DDE exposure in Antarctic krill. Overall, the findings for Antarctic krill are in support of the TRA indicating that effective body residues for baseline toxicity in this polar species are comparable to those measured for temperate species.

## RA11 - Risk assessment of chemicals within REACH integrating alternative methods and non testing strategies

**TU 330**

**Opportunities and limitations of using alternative methods and non testing strategies in REACH registration dossiers**

G Deviller, V Burosse, C Dubourg, M Duchemin, C Durou, B Journel, A Sevestre, P Thomas
CEHTRA, VAULX-MILIEU, France

By 1 December 2010, substances manufactured or imported at or above 1000 Tonnes/Year (T/Y) as well as Carcinogenic Mutagenic or Reprotoxic substances category 1 and 2 manufactured or imported ≥ 1 T/Y, or substances classified as dangerous for the aquatic environment with R50/53 and manufactured or imported ≥ 100 T/Y had to be registered under REACH. The lack of data on the hazardous properties of chemicals was the driving force behind the development of a new chemicals policy in the EU nevertheless one of the objectives of REACH is to promote alternative methods for the assessment of hazards of substances both to reduce animal testing and to reduce the costs. The Consultancy for Environmental & Human Toxicology & Risk Assessment (CEHTRA) helped the industry sector to comply with their regulatory obligations providing input on more than one hundred REACH substance dossiers including several chemical classes such as organic, inorganic substances, mono and multi constituents.
The aims of this poster are to illustrate cases where non testing techniques have been used for filling data gaps to perform the environmental risk assessment for these substances in compliance with REACH. Both the tonnage and the objectives of information requirements have been taken into account. In this study, existing data coverage, reasoning for waiving tests, adequacy of possible alternative methods (QSAR modeling, in vitro and read-across), evaluation of existing data as part of a weight-of-evidence approach and experimental testing strategies are addressed. The final objective is to identify the most reliable approaches which have gained regulatory credibility and the limitations in using non-testing strategies under REACH, based on our experience, after the first registration dossier submission's deadline.

**TU 331**

**Lessons from ECETOC TRA based exposure scenarios**

J Kohli, JB Berlusconi, EB Beltran, LP Pontal, PT Thomas
CEHTRA, WATERLOO, Belgium

ECETOC TRA integrated tool has been the corner stone of exposure scenario modeling and risk characterisation in the first phase of REACH. The tool incorporates three principal methods to calculate Predicted Environmental Concentrations (PECs) and Risk Characterisation Ratios (RCR):
1- The Environmental Release Category (ERC) method developed for Tier I REACH scenarios,

and Specific ERCs (SpERCs)
2- In Tier 2; the OECD use models and the A&B tables from the Technical Guidance Document (2003).
3- Measured data approach in tier 3
Based on specific case studies, we discuss in this communication "work-arounds"which we used to provide a greater level of environmental relevance in our Chemical Safety Reports.
In the first part, we will share the statistical analysis of CEHTRA's REACH dossiers submitted in 2010 (proportion the different tiered levels of Environmental Risk Assessments, related time spend on them,[3DOTS]). In the second part, technical difficulties for a proper risk assessment will be summarized as well as the proposed solutions. Last, several technical adaptations of the existing tool will be presented.

**TU 332**
**A step change towards risk assessment in the 21st Century? Practical experiences with REACH.**
G Patlewicz, D Lander
DuPont, NEWARK, United States of America
Chemical Regulation and the means by which data is generated for the purposes of risk assessment is undergoing a tremendous shift. There is a strong impetus in Europe in particular to move towards non animal approaches to address data gaps for specific endpoints either in lieu of testing or as part of weight of evidence approach within Integrated Testing Strategies (ITS). An Exposure assessment considering workers and/or consumers is another pertinent factor to consider in the derivation of a robust risk assessment. The recent EU chemicals legislation REACH, in particular provides considerable flexibility in the application of non-testing approaches such as (Q)SARs, chemical categories and read-across for data gap filling.
There have been a number of efforts aimed at developing technical guidance, tools, and techniques for non-testing and tiered exposure approaches. Despite these efforts, there remains limited practical insight about how these approaches can be applied in the assessment of substances. Here, we provide an overview of the available approaches and how we have practically utilised them to address our REACH requirements.

**TU 333**
**The Klimisch Scoring System: a system in desperate need of modernization**
L Breton[1], B Journel[2], MB Duchemin[2], C Durou[2], P Adrain[2], PC Thomas[2]
[1]Intrinsik Environmental Sciences, Inc., OTTAWA, Canada
[2]CEHTRA, BORDEAUX, France
The evaluation of data quality under REACH and the HPV program is a key component for conducting robust hazard and risk assessments. The Klimisch scoring system is an approach used to assess the reliability of data, particularly toxicological and ecotoxicological data. The intention of the system is to harmonize data evaluation worldwide. However, recent studies have recognized the deficiencies in the Klimisch scoring system highlighting that interpretation of Klimisch criteria by evaluators is subjective, and semi-quantitative at best. Without data quality harmonization, an assessment can lead to different reliability codes which can affect the robustness of the risk assessment. In this presentation we describe a tool we have developed to provide a more consistent and logical evaluation framework to the Klimisch system while maintaining the same fundamental reliability codes. This tool has been tested and validated on a training set of studies by regulatory scientists. A second validation exercise further increased the accuracy and consistency of assigning reliability codes to studies compared to the original Klimisch approach. We pose some fundamental questions about the pertinence of the Klimisch system and whether a complete revision (while ultimately retaining the same 4 reliability codes) would be worthwhile.

**TU 334**
**Solvent abuse in ecotoxicology testing**
PC Thomas
CEHTRA, L'ISLE D'ABEAU, France
Attempts have been made to standardize aquatic ecotoxicity testing for the purposes of hazard assessment in norms and Guidelines (e.g. OECD 200 series). Generally, and with some exceptions, these documents describe methods applied to "ideal"substances without specific properties which lead to the need to modify the test design (e.g. adsorbing, volatile, reactive and poorly soluble chemicals). For these cases guidance is provided in supplementary documents such as OECD No. 23 Guidance document on aquatic toxicity testing of difficult substances and mixtures. In the specific case of poorly soluble substances (for the sake of argument defined here as <1 mg/L in the medium used), OECD No 23 has the following to say on the use of solvents: "because of the potential for interaction with the test substance resulting in an altered response in the test, their use should be restricted to situations where no other acceptable method of media preparation is available". Nevertheless, multiple testing facilities across the world are still performing flow-through studies using solvents as standard and because they usually manage to maintain the test concentrations throughout the study, they are generally being considered as "high end"valid studies for risk assessment purposes.
Alas, multiple cases have come to light which demonstrate that many of these studies are critically flawed. Notably, concentrations are maintained with high precision at levels in some cases greater than the measured water solubility limit of the test substance as measured in an OECD 105 solubility test (in pure water). Interesting, as OECD No 23 points out "It is unlikely that a solvent concentration of 100 mg/l will significantly alter the maximum dissolved concentration of the test substance which can be achieved in the medium". Yet, further investigation on several substances has revealed that the OECD 105 measured solubility may be one or more orders of magnitude greater than the actual solubility in the test medium used in aquatic toxicity test. Effectsfrom these flow-through tests with solvent have been observed above, at or close to the pure water solubility limit and these are systematically attributed to toxicity. In reality it would seem that the organisms are succumbing to a slow suffocation by undissolved droplets of test substance maintained in emulsion throughout the study, termed here "the vinaigrette effect". How then, to separate genuine toxicity from the vinaigrette effect?

**TU 335**
**A QSAR-based compound prioritization for lab-testing for chemical safety assessment**
U Sahlin[1], B Bhhatarai[2], E Papa[2], T Öberg[1], P Gramatica[2]
[1]Linneaus University, KALMAR, Sweden
[2]School of Sciences, University of Insubria, VARESE, Italy
The practical implementation of non-testing strategies such as Quantitative Structure-Activity Relationships (QSARs) is still an area of development. To this end, there is a need to solve issues on how to practically integrate QSARs model predictions in risk assessment with the long-term goal to increase the use of non-testing information for regulatory decisions while meeting the main challenges of quantifying and reducing uncertainty. We discuss to what extent different strategies of prioritization for testing chemical compounds result in various strengths of background information for chemical safety assessment under REACH. An application of a strategy, based on predicted data from QSAR models, to select a set of compounds on the ECHA preregistration list for further testing is provided and discussed. We propose to design a strategy of testing based on criteria related to the strength and spread of background information, the costs and the purpose of testing and with respect to the specific circumstances in the application which is given by the available background information.

**TU 336**
**Biotransformation of chemicals: linking octanol-water partitioning to Michaelis constants to search for general mechanisms**
A Pirovano, MAJ Huijbregts, IA O'Connor, AMJ Ragas, AJ Hendriks
Radboud University Nijmegen, NIJMEGEN, The Netherlands
The accumulation of xenobiotics in organisms is a key factor in the assessment of chemical risk and depends on transport and transformation processes. While rates of exchange with air, water, and food can be predicted fairly accurately from properties of chemical substances and biological species, biotransformation rates ($k_m$) are difficult to obtain. This is one of the main limiting factors in modeling accumulation, whose extent significantly depends on the degree to which biotransformation occurs.
As most enzymes follow first-order Michaelis Menten kinetics, biotransformation rates for many substances can be approximated as:
$k_m$ ($d^{-1}$) = $V_{max}$ ($\mu M \cdot d^{-1}$) / $K_m$ ($\mu M$)
where $K_m$ (Michaelis constant) indicates a measure of the affinity of the substrate for an enzyme and $V_{max}$ is the maximum reaction rate.
Though biotransformation rates apply to a specific combination of a chemical and a species, some general patterns are noted. For instance, accumulation of metabolisable compounds appears to be a factor of about 50 lower than that of persistent equivalents. This suggests that the underlying mechanisms may be (somewhat) more universal than usually thought. Perhaps, biotransformation potential of xenobiotic as well as biotic compounds has evolved according to similar principles. So far, such general mechanisms have hardly been investigated.
A preliminary approach to study the possible underlying mechanisms of xenobiotic and endobiotic metabolism can be the use of the Hansch relationship expressed in the following form:
$-\mathrm{Log}\, K_m = a \cdot \mathrm{Log}\, K_{ow} + b$
Here, $K_m$ and $K_{ow}$ represent the equilibrium constants for respectively the binding with an enzyme and the partitioning between octanol and water of the chemical. This linear relationship linking lipophilicity and metabolism was verified in studies on P450 drug metabolism.
In the present work, this equation was applied to enzymes involved in the metabolism (mainly in mammals) of endobiotics or xenobiotics, for example fatty acids, alcohols, and aldehydes. The Log $K_{ow}$-Log $K_m$ relationships were studied in order to understand the meaning of the regression coefficients obtained for various groups of compounds.
The final aim of this work is the prediction of $K_m$ for different chemicals, based on lipophilicity and other fundamental physicochemical parameters (e.g. molecular mass, charge, etc.), thus providing a possible tool to quantify $k_m$ for a better assessment of bioaccumulation.

**TU 337**
**Study on the toxicity of perfluorinated compounds to aquatic organisms**
JGM Peijnenburg[1], G Huiding[2]
[1]RIVM, BILTHOVEN, The Netherlands
[2]College of Environmental Science and Engineering, Dalian Maritime University, DALIAN, China
Because of their global distribution, environmental persistence and potential risk to human beings and ecosystems, poly- and perfluorinated compounds (PFCs) are of particular concern for research and regulatory communities. However, insufficient toxicity data are available to accurately assess their possible environmental hazard. Therefore, the toxicity of a number of structurally different PFCs for daphnids, algae, fish and lettuce was determined. It was found that the adverse effects of PFCs decreased with increasing fluorinated carbon chain length (nC).Smaller daphnid species tested were found to be more sensitive to these PFCs than larger daphnids. Toxicity patterns across species were found to be similar, offering possibilities for read across prediction of toxicity of either untested PFCs or untested aquatic organisms.

**TU 338**
**Predicting respiratory sensitization of chemicals by accounting for their soft-hard electrophilicity**
C Kuseva[1], OG Mekenyan[1], GP Patlewicz[2], GD Dimitrova[1], SS Stoeva[1]
[1]University Prof. Assen Zlatarov, BOURGAS, Bulgaria
[2]DuPont Haskell Global Centers for Health and Environmental Sciences, NEWARK, United States of America
In order for a chemical or its metabolite to induce respiratory sensitization, it must be able to bind covalently to proteins in a similar fashion to the formation of protein-hapten adducts that lead to skin sensitization. This hypothesis is supported by the high number of respiratory sensitizers that test positive in the local lymph node assay (LLNA) for skin. The main purpose of the present work is to discriminate the reactivity factors that result in skin and respiratory sensitization. Hard-soft electrophilicity of protein reactive sites in chemicals has been used as a means to categorize their interaction with nucleophiles of different hardnesses. Given the diversity of proteins in skin (Cys-, Lys-, and others), no specificity of electrophiles is anticipated with respect to skin sensitization. On the other hand, due to predominancy of Lys-nuclephiles in the lung, one would expect electrophiles with harder-electrophilic sites to cause respiratory sensitization. The reactivity module is combined with a simulator of lung metabolism. The specificity of lung metabolism as compared with liver/skin, such as upgrading oxidative reaction and downgrading reactions of reduction, alcohol/aldehyde dehydrogenases, etc. could modulate the effect of reactivity. The lung metabolism simulator produces metabolites of parent chemicals which are further filtered by the reactivity model. Development of an explicit nasal deposition is outside the scope of this work. Instead, we have focused on specific ranges of critical physicochemical parameters providing bioavailability information to the site of action. It is envisaged that the metabolism and reactivity components will be combined into an integrated model, using the OASIS software platform, to predict skin and/or respiratory sensitization.

**Hazard characterization and classification tool for complex inorganic materials**
AM Verdonck[1], V d'Havé[1], L Claeys[1], K Delbeke[2], K Lacasse[2], M Vangheluwe[1], P van Sprang[1], I Vercaigne[1], V Verougstraete[3], H Waeterschoot[3]

[1]Arche, GENT, Belgium
[2]ECI, BRUSSELS, Belgium
[3]Eurometaux, BRUSSELS, Belgium
Ores, concentrates, metal intermediates, slags and alloys are complex metal-bearing materials. These complex material streams from the metals sector are often characterized by a known but variable composition (variable depending on source and process). There is a need to reduce animal testing and to avoid costly standard laboratory tests on these material streams required by REACH and CLP while ensuring a science based hazard assessment. This poster presents MECLAS (www.meclas.eu), a hazard characterization and classification tool for complex inorganic materials. The ecotoxicological and toxicological hazards of such materials are estimated based on the hazard and the (if available, bio-available) concentration of the individual constituent species and/or minerals in the material. The background model is based on the CLP mixture rules and is estimating acute toxicity, skin corrosion/irritation, serious eye damage/irritation, respiratory or skin sensitization, germ cell mutagenicity, carcinogenicity, reproductive toxicity, specific target organ toxicity (for single and repeated exposure) and acute aquatic acute and long-term ecotoxicity. Knowledge on hazards of the various metal species ((self)classifications, (eco)toxicity reference values) were collected and stored in a background database. The tool's validity is based on an unambiguous conservative algorithm from EU CLP Guidance: summation/additivity formula to determine classification and, back-calculation to related hazard criteria. The applicability domain of the tool includes all complex inorganic containing materials. An example will finally demonstrate how elemental chemical analysis, mineralogical speciation analysis and bio-availability tests (transformation dissolution tests for environment, bio-elution tests for human health and surface correction) on source samples are inputted to the tool in a tiered way and how the hazard profile can be estimated for all endpoints mentioned above. In this way, it is demonstrated how complex inorganic materials can be assessed under CLP, animal testing can be reduced and costs can be saved.

**TU 340**

**INES-plugin for refined environmental risk assessment of chemicals under REACh Regulation: improvement of the ECETOC TRA tool**

E Beltran, L Pontal, M Darriet, J Kohli
CEHTRA, SAINTE EULALIE, France

For REACh registration purposes, various tools have been made available to assess the risk of chemical substances for the environment. Among these tools, ECETOC TRA (latest version released in June 2010) is based upon a Microsoft Excel® format, as a core of 9 linked spreadsheets. It allows Environmental Risk Assessments of chemicals to be performed making use of Exposure Scenarios, following the recommendations reported in Chapter R16 of the REACh guidance (Environmental Exposure Estimation, May 2010). Environmental Release Categories (ERCs) and Specific ERCs (spERCs) are implemented in the interface of ECETOC TRA. The current version of the tool can use up to 24 scenarios per substance; this means that regional concentrations for each environmental compartment are calculated considering the sum of 24 use scenarios as a maximum. As a comparison, EUSES allows a maximum of 20 scenarios following production. This represents a serious limitation in the use of the tool for certain classes of substances: for instance, substances which are used in a sizeable number of applications (e.g. as solvents and fragrance products), cannot be properly risk-assessed using the available tools. The worst-case assessment of the Environmental risks performed with conventional tools may be too conservative, and may thus lead to recommend too costly Risk Management Measures (RMMs). For such substances, a second round of assessment, including less strict RMMs may be performed. CEHTRA developed INES-plugin (Increase Number of Exposure Scenarios-plugin), an internal macro function to allow hundreds of scenarios be taken into consideration (i.e. far more than 24 scenarios). This upgrade allowed to model in a more appropriate way regional concentrations for such substances. In the current version, the full description of uses can be extended to a maximum of 1920 use descriptions, outperforming in terms of refinement all other environmental risk assessment tools.
CEHTRA had the chance to carry out numerous substance assessments in the perspective of the REACh registration using the upgraded tool. For a number of other assessments related to substances, the uses of which being poorly described by a limited number of use scenarios, might benefit from an increased finesse inherent in the sophistication of the tool used to perform them. The poster compares and contrasts assessments performed by the CEHTRA-modified tool with assessments performed using available tools.

**TU 341**

**Development of an ecotoxicological database on hazardous chemicals in accordance to REACH Regulation: the DESC example**

A Barra Caracciolo[1], AB Petrangeli[1], P Grenni[1], G de Donato[1], A Finizio[2]
[1]National Research Council - Water Research Institute, MONTEROTONDO ROMA, Italy
[2]University of Milan Bicocca, MILAN, Italy

A software system was designed and developed for managing information regarding chemicals produced and/or imported in the UE market, in accordance to a REACH (EC Regulation No 1907/2006) goal to organize the available information on substances chemicals and to make them easily accessible to the public. To achieve this objective three operative steps were performed: requirement analysis, conceptual analysis and logical project.
The requirement analysis consisted of drafting an initial document (requirement document) shared and commonly agreed with the stakeholder, represented by the Italian Ministry of Environment, in which the system goals were defined. The document describes what the software system should do and what are constraints in its implementation. Firstly it contains a description of needs of the system functions and the way to achieve the strategic objectives previously set. Secondly it defines a glossary describing all the ecotoxicological technical terms used in the system. Finally the document outlines the requirements and describes the services. The main function of the software was that to archive information related to hazardous chemicals, subdividing into five classes: 'General Information', 'Classifications', 'Overview', 'Chemical-physical properties ' and 'Ecotoxicological properties and environmental distribution". The software was equipped with a default set of features for consultation and data query that allows users to analyze the entire dataset of information.
The conceptual analysis consisted of the construction of conceptual models representing the system requirements and was implemented by means of the UML (Unified Modeling Language), a standardized general-purpose modeling language for software engineering: three different graphs were developed to take in account the data structure and functionality of the system and to model the dynamic aspects of system behaviour over time.
The conceptual analysis evidenced that the best solution to create a software able to manage huge a amount of data on chemicals was that to implement a database. For this purpose an Entity-Relationship Model (ER) was chosen. Finally the logical project was realized by developing a client/server system.
The database and the website were implemented by using respectively Microsoft SQL Server Express 2005 and ASP.NET 2.0 technology and are currently available on the internet at http://www.dsa.minambiente.it/SITODESC/.

**TU 342**

**MOPAC@home - an online database for small organic compounds**

S Brandmaier, V Srivastava, IV Tetko, R Körner, W Teetz, S Novotarskyi, AK Pandey, I Sushko
HelmholtzZentrum-Muenchen, NEUHERBERG, Germany

Molecular descriptors derived from 3D structures, in particular quantum chemistry descriptors, are frequently reported as a useful representation of chemical compounds, that can significantly improve the quality of QSAR or QSPR models to predict physico-chemical and biological properties, as well as toxicity of chemicals.
Unfortunately, the results of these studies are often not traceable and thereby not assessable, as the 3D structures of the molecules, that were used to derive the models, are not always accessible. Another obstacle, that makes it difficult to work with 3D structures is, that computing a global minimum energy conformation can be very time expensive, especially for large and therefore flexible molecules.
We introduce an online database http://www.cadaster.eu/mopac that optimizes molecular conformations with the semi-empirical AM1 algorithm from the MOPAC7 package. For each molecule in the database not only one structure is available, but a whole set of them, derived from different initial conformations.
The database supports stereochemistry and provides several ways to access the conformations. Molecules can be examined by an interactive on-line interface, a batch of molecules can be uploaded and a web service is available.
There are two main features for accessing the results of the AM1 optimization:
1) Users can search the database to determine conformations with global minimum energy
2) User can retrieve optimized local minimum energy conformation starting from a user provided conformation.
Furthermore users can upload and add molecules to our database as well as also their specific conformations. This mechanism allows updating the global minimum conformations, if better ones are uploaded.
To enable this service, we developed a robust pipeline that generates initial conformers, optimizes them with MOPAC7 and calculates for each conformer a set of quantum chemistry descriptors (HUMO-LUMO energies, partial charges, dipole momentum, etc.). The structural optimization is done by a BOINC server, which distributes the work units to volunteers supporting the project.
Both the structures and the provided quantum chemistry descriptors can be an important contribution to advance environmental toxicity prediction and drug discovery. Furthermore, the optimized conformations produced by this database could be used as a reference for QSAR/QSPR models, which depend on 3D descriptors.

**TU 343**

**ChemProp - chemical properties estimation software system**

R Kühne, RU Ebert, B Wagner, T Thalheim, A Richarz, G Schüürmann
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

The software system ChemProp comprises models to estimate compound properties and a database for chemical structures and properties, together with tools to manage compound sets.
The QSAR part addresses models for physico-chemical properties with particular remark to partitioning processes of environmental relevance and degradation, environmental fate, ecotoxicological endpoints, and human toxicology. It mainly employs models based on the topological matrix and thus does not require quantum chemistry. Particular remark is given to the applicability domain and model uncertainty.
The integrated database allows for structure and substructure searching, and addresses tautomerism and stereomerism. For effective data handling, it provides access to data in external resources in combination with the structure search facilities.
The software system is an essential part of the outcome from the EU Integrated Project OSIRIS (contract No. 037017), and is linked to the OSIRIS webtool. Respective financial support is acknowledged. In addition, it has been funded by the EU project 2-FUN (contract No. 036976)

**TU 344**

**Life Project ANTARES - Alternative Non-Testing methods Assessed for REACH Substances**

R Knauf
Federchimica, MILANO, Italy

The EU Regulation REACH which entered into force in 2007 in the EU represents today the most advanced system in the World to register, evaluate and authorize Chemical Substances. According to latest estimates some fourty or fifty thousand substances will be processed in 3 phases, starting with high production volumes ( from 1000 t) and the most concerning substances. The deadline of the 1. phase has been 30 11 2010.
To correctly evaluate the impact on the environment and human health Industry will pay a high cost (billions of euros), and millions of animals might be sacrified to produce the necessary toxicity data. To limit these problems, REACH legislation promotes the use of non-testing methods, including Read Across and quantitative structure-activity relationship (QSAR). Read Across bases the evaluation of the unknown compound on the values of similar chemicals, while QSAR uses some chemical descriptors to evaluate the toxicity. Experience on the validity, predictivity and feasibility of these tools is still under discussion. ANTARES wants to effectively address the problem to check how to use the non-testing methods, for which endpoints and in which way.
In Action 1 ANTARES foresees on overview on current common methods to evaluate their practical availability, costs, number of animals, etc. to identify higher requirements for the alternative methods. For this Federchimica took actions to provide an overview of laboratories which can provide the current tests.
Results: Numerous contacts were launched with public and private laboratory structures in Italy. Most of the collaborating companies offer phys-chem testing, 7 laboratories offer toxicological and/or ecotoxicological testing. 12 Italian laboratories have indicated GLP certification. A well-known GLP certified European laboratory also collaborates in the project.
5 Italian companies offer tests for at least 50 % of Reach tox endpoints, 4 of them can conduct equal/more than 50 % of Reach ecotox endpoint testing. Some laboratory indicated in vitro/alternative testing capability.The non-Italian laboratory covers more than 90 % of all requirements, one Italian laboratory has same capabilities.The monitoring of the Italian laboratory situation for Reach testing will continuo to update the situation for GLP certification on tox and ecotox

testing activities/capabilities. The next registration deadline 2013 will involve many substances which need new studies compared to the 2010 registered substances.

**TU 345**

**New developments in the OpenTox project**

A Karwath[1], R Benigni[2], B Hardy[3], C Helma[4], N Jeliazkova[5], S Kramer[6]
[1]Albert-Ludwigs-Universität Freiburg, FREIBURG, Germany
[2]Istituto Superiore di Sanita, ROME, Italy
[3]Douglas Connect, BASEL, Switzerland
[4]In-silico, BASEL, Switzerland
[5]Ideaconsult Ltd., SOFIA, Bulgaria
[6]Technical University Munich, MUNICH, Germany

The goal of the EC-funded FP7 project OpenTox (www.opentox.org) is to develop an open source-based predictive toxicology framework that provides a unified access to toxicological data and models. OpenTox provides tools for the integration of data, for the generation and validation of in silico models for toxic effects, libraries for the development and integration of modelling algorithms, and scientifically sound validation routines. OpenTox supports the development of applications for non-computational specialists in addition to interfaces for risk assessors, toxicological experts and model and algorithm developers.
OpenTox is relevant for the implementation of the REACH legislation as it allows risk assessors to access experimental data, (Quantitative) Structure-Activity Relationship ((Q)SAR) models and toxicological information from a unified interface that adheres to international regulatory requirements including OECD Guidelines for validation and reporting, and emerging guidelines from theEuropean Chemical Agency (EChA) and the European Joint Research Centre (JRC). The OpenTox framework is being populated initially with data and models for chronic, genotoxic and carcinogenic effects. These are the endpoints where computational methods promise the greatest initial potential reduction in animal testing required under REACH.
The OpenTox approach moves beyond existing attempts to solve individual research issues within this area, by providing a flexible, extensible, and user friendly framework that integrates existing solutions as well as providing easy access to new developments. For maximum transparency OpenTox is being organised as an open source community project. This allows a critical evaluation of the implemented algorithms, ensures a widespread dissemination and should attract external developers. Facilities for the inclusion of confidential in-house data and for accessing and integrating commercial prediction systems are also included.

**TU 346**

**QSAR and QSPR models for emerging pollutants: WP3 activities within the FP7 European Project CADASTER**

S Kovarich[1], E Papa[1], B Bhhatarai[1], M Rahmberg[2], S Nilsson[2], T Liu[3], T Öberg[3], N Jeliazkova[4], N Kochev[5], O Pukalov[5], W Teetz[6], S Brandmaier[6], IV Tetko[6], P Gramatica[1]
[1]University of Insubria, VARESE, Italy
[2]IVL Swedish Environmental Research Institute Ltd., STOCKHOLM, Sweden
[3]School of Pure and Applied Natural Sciences, Linnaeus University (LNU), KALMAR, Sweden
[4]Ideaconsult Ltd. (IDEA), SOFIA, Bulgaria
[5]Department of Analytical and Computer Chemistry, University of Plovdiv, PLOVDIV, Bulgaria
[6]Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum Muenchen, MUNICH, Germany

The EU-REACH regulation encourages the use of alternative in vitro and in silico methods in order to minimize animal testing, costs and time. Among these, quantitative structure-activity relationships (QSARs) represent a useful tool to predict unknown activities/properties for existing or even not yet synthesized chemicals. The development and validation of QSAR models for four classes of emerging pollutants (brominated flame retardants, fragrances, perfluorinated compounds and (benzo)triazoles is the central topic of Work Package 3 (WP3) within the FP7 European project CADASTER (CAse studies on the Development and Application of in-Silico Techniques for Environmental hazard and Risk assessment). The final goal of the project is to exemplify the integration of information, models and strategies for carrying out hazard and risk assessments for large numbers of substances, organized in the four representative chemical classes. The aim of this poster is to summarize the WP3 activities within CADASTER project and the QSAR/QSPR models developed so far for the four classes of compounds under investigation. This modeling activity involved different project partners in universities and research institutes across Europe (University of Insubria, Linnaeus University, IVL Swedish Environmental Research Institute, Ideaconsult Ltd. and Helmholtz Zentrum München), and was realized by different modeling approaches.
For each class, ad hoc QSARs were developed for all the available experimental data (i.e. physico-chemical properties, environmental and mammalian toxicity) in order to characterize environmental behavior and activity profile of the chemicals. In agreement with the OECD principles for the validation of QSARs for regulatory purposes, all the proposed models were checked for their robustness, external predictivity and applicability domain.
QSAR predictions, together with structural analysis (e.g. similarity analysis and multivariate ranking methods), were used for the identification of priority compounds (also among the ECHA pre-registration list) to optimize the experimental testing to be performed in WP2.

**TU 347**

**Physico-chemical property prediction of emerging pollutants: PFC and (B)TAZ for environmental distribution**

P Gramatica, B Bhhatarai
University of Insubria, VARESE, Italy

Perfluorinated compounds (PFCs) are a family of chemicals with a long carbon chain which is predominantly substituted by fluorine. They are used in different materials as non-adhesives, waterproof fabrics, fire-fighting foams, etc. (Benzo)triazoles (B/TAZs) are another class of chemicals with multi-nitrogenated aromatic ring system. They are widely used in industrial processes, deicing agents (1H-BTAZs), pharmaceuticals and pesticides. These chemicals are considered as "emerging pollutants"as they are broadly distributed in the environment because of their extensive use and are considered to be hazardous as they cause adverse effects to humans and other non-target species. Their high concern as pollutants, lack of data and crucial Authorisation under REACH legislation urges for a need to maximize the information inherited in the existing data. Internally robust and externally validated QSPR models were developed for the endpoints, as also recommended under the REACH regulation, to predict large set of unknown properties for existing or not yet synthesized chemicals.
For PFCs, three QSPR models each on Water Solubility (WS), Vapor pressure (VP) and Critical Micelle Concentration (CMC) were developed and structural applicability domain (AD) study was verified. 174 (78.7%) compounds were found within the AD of all three models. The multivariate analysis by Principal Component Analysis (PCA) was performed for the prediction of these chemicals. In addition, Bioconcentration Factors (BCF) values were collected for most common PFCs and the relationship between the end-points was studied. The increasing trend of BCFs is in opposite direction to that of WS and CMC and the trend is found different for carboxylates and sulfonates.
For B/TAZs, four QSPR models each on WS, VP, KOW (Octanol/Water partition) and Melting Point (MP) were developed. 351 compounds were studied for structural AD study and out of which 66 are found within the AD of all four models for which at least one experimental data was available. These compounds were studied using PCA in a multivariate plot to understand their leaching and volatility behavior. Comparison with soil sorption partition coefficient (KOC) was performed by using predictions from earlier published models. More soluble, more volatile and more sorbed chemicals are highlighted. The 1H-B/TAZs were found to be among the more soluble and less sorbed compounds.

**TU 348**

**QSAR prediction of aquatic and mammalian toxicity of triazoles and benzo-triazoles**

E Papa[1], S Cassani[1], E d'Onofrio[1], S Kovarich[1], M Rahmberg[2], S Nilsson[2], P Gramatica[1]
[1]University of Insubria, VARESE, Italy
[2]IVL Swedish Environmental Research Institute Ltd., STOCKHOLM, Sweden

Triazoles and benzo-triazoles (TAZ/BTAZ) are potentially hazardous chemicals that adversely affect humans and other non-target species, and are on the list of substances of very high concern (SVHC) in the European regulation of chemicals REACH.
TAZ/BTAZ are synthetic molecules used in various industrial processes (to obtain pharmaceuticals and agricultural products), and have a wide application as anti-corrosives, cleansing agents for textiles, flame retardants, photographic emulsions, etc[3DOTS]Furthermore they are abundantly used as components of liquid deicing agents for aircraft and airport runways. Because of their wide use they have been found distributed throughout the environment, mainly in water compartments. The amount of experimental data available for these molecules is insufficient for a comprehensive characterization of their environmental and toxicological profile and they have been included among the four classes of chemicals studied in the European FP7 Project CADASTER (CAse studies on the Development and Application of in Silico Techniques for Environmental hazard and Risk assessment).
In this study we investigated and modeled by QSAR different endpoints of interest to define the potential aquatic toxicological profile of hundreds of TAZ/BTAZ, and the possible correlations among their aquatic and mammalian toxicity. The studied end-points were: $LC_{50}$ in *Onchorhynchus Mykiss*, $EC_{50}$ in *Daphnia Magna*, and $EC_{50}$ in algae. Data for mammalian acute toxicity in rat ($LD_{50}$ oral exposure) were also investigated and modeled. Different theoretical molecular descriptors were calculated by different proprietary and freely available online software (DRAGON, Hyperchem, and the CADASTER online platform for the calculation of molecular descriptors - www.cadaster.eu). The endpoints of interest were modeled by multiple linear regression (MLR), and the Genetic Algorithm was used to select the relevant molecular descriptors by the MLR-Ordinary Least Squares (OLS) method. The best models were validated for their predictive performance using leave-one-out, bootstrap and the scrambling of the responses. External validation was also performed depending on the dimension of the studied experimental datasets. The reliability of the predictions was always evaluated in order to verify the chemical applicability domain of the models.

**TU 349**

**Prediction of uptake and elimination rates for polar organic compounds in aquatic species**

IA O`Connor, MAJ Huijbregts, A Pirovano, AMJ Ragas, AJ Hendriks
Radboud University, Nijmegen, NIJMEGEN, The Netherlands

Ecotoxicological models are important tools to conduct environmental risk assessment. Ideally, the model should be based on mechanistic understanding of the processes, and parameters should be obtained by properties of the compound and species. Only this allows extrapolation to other species and chemicals.
Uptake and elimination are fundamental processes in most compartmental models. Uptake and elimination rates are commonly considered to be a function of organism mass, water/air flow through gills/lungs, and diffusion through water and lipid layers. The diffusion of organic chemicals through the lipophilic membrane depends mainly on the octanol water partition coefficient (Kow).
However, for more polar compounds (logKow<3) octanol is not a sufficient surrogate of the membrane, because other characteristics such as e.g. hydrogen bonds become more important. Descriptors accounting for polar characteristics have been included in many QSAR approaches predicting the absorption of pharmaceuticals. These QSARs focus on absorption through membrane layers, hence absorption through mammalian intestine, blood brain barrier and skin by passive diffusion.
In addition to passive diffusion, carrier mediated transport can become relevant, if the xenobiotics can use transport systems of endobiotic compounds. Uptake of pharmaceuticals is often a mixture of passive diffusion and carrier mediated transport.
The objective of this study is to improve the prediction of uptake and elimination rates of polar compounds on organism level with a focus on aquatic organisms. The approach consists of improving the prediction of 1) passive diffusion and 2) carrier mediated transport. Prediction of passive diffusion may be improved by incorporating descriptors accounting for polar characteristics and molecular volume. The influence of carrier mediated transport will be examined by investigating kinetics and affinities of selected biotics and their transport proteins and extrapolating the findings to structural similar xenobiotics of relevant environmental concern. The estimation of rates for passive diffusion and carrier mediated transport will be based on datasets of compounds with a logKow < 3, i.e. uptake of selected pesticides and industrial chemicals into aquatic organisms, and absorption of pharmaceuticals through mammalian cell lines.

**TU 350**

**How useful are QSARs within a regulatory framework? Validation and applicability domain assessment of QSARs related to PBT endpoints.**

F Van Nederkassel[1], K Vandersteen[2], M Eliat[1], F Verdonck[1], K van Malderen[2], M Vangheluwe[1]
[1]ARCHE, LEUVEN, Belgium
[2]Federal Public Service Health, Food Chain Safety and Environment, BRUSSELS, Belgium
The regulatory use of Quantitative Structure Activity Relationship (QSAR) models is expected to increase under chemical management systems such as REACH. In silico model predictions are a time & cost-effective alternative for animal testing and benefit animal welfare. In 2004 the OECD responded to the need for guidance on QSAR application by developing acceptance criteria for the validation and regulatory use of QSARs, which were also adopted in the REACH guidance. Of particular interest are the criteria about the external validation to determine the true predictive power of a model and about the applicability domain (AD) since predictions are most reliable if they fit the model's AD. Six models predicting PBT (Persistency, Bioaccumulation, Toxicity) endpoints were selected for external validation and AD assessment. The evaluated P models were BIOWIN and MultiCase; the B models were BCFWIN and CAESAR; and the T models were ECOSAR and MultiCase. Validation set chemicals (79 substances) data were selected from Risk Assessment Reports of the European Chemicals Bureau and others. The AD assessment of the models was done using structure similarity methods of Ambit Discovery. In the validation of P models, a combination of BIOWIN 3 and 5 models performed the best: precision ranged between 80-92%, predictive value between 67-96%, false negative and positive ratios were 8% and 20%, respectively. Highest values for precision (92%) and predictive value (96%) were obtained for not ready biodegradable chemicals. In the validation of the B models, it was concluded that both CAESAR as BCFWIN did not pass the criteria for regulatory use (false negative ratios >50%). The validation of the T models showed that the chronic ECOSAR model for fish can serve as first screening tool in risk assessments. The acute ECOSAR and MultiCase models did not pass the regulatory criteria. With respect to the AD assessment, The used structural similarity methods were not capable to completely capture the mechanistic basis of the models. These findings indicate the need to develop a global similarity test to determine whether the structural features in a validation chemical are covered in the training set of a QSAR. Wider application and acceptance of QSARs for regulatory use will require further model development and more thorough validation and AD assessment. The large amount of high quality experimental data that becomes available within REACH can be used to achieve these requirements.

**TU 351**
**Comparison of approaches to define Applicability Domain for the application of QSAR models**
FA Sahigara, K Mansouri, D Ballabio, V Consonni, R Todeschini
Milano Chemometrics and QSAR Research Group, MILANO, Italy
QSAR validation is a critical phase to analyse performance of the models and interpret their mechanistic relevance. One of the five OECD principles for QSAR validation requires implementing a defined domain of applicability for a given QSAR model. This allows a better understanding of how reliable the model predictions are within a given chemical space. In other words, the predictions that fall within the model domain of applicability are reliable and the ones outside refer to extrapolations.
There are several approaches already developed till date to define applicability domain for QSAR models, based on structural aspects or mechanistic understanding, however most of them offer several advantages accompanied with some major limitations. Moreover these approaches cannot make any decisions on their own unless an expert judgement is involved. The idea of this poster presentation is to provide a brief overview of such commonly used approaches to define the applicability domain, addressing their basis of interpretation, algorithm implemented and the reliability they offer in terms of their approach. We made an effort to compare the features of these approaches on simulated and real QSAR datasets to provide a better scenario of existing situation and to address the current drawbacks that need to be considered in the future.

**TU 352**
**The use of (Q)SARs as part of a larger registration strategy for REACH**
LS Rockett
WRc plc, SWINDON, United Kingdom
The European Union REACH regulations require the submission of detailed information on the physico-chemical, toxicological and ecotoxicological endpoints of chemicals. For the last few years, WRc has been heavily involved in REACH, aiding companies and consortia to develop registration strategies, commission laboratory testing, collate and evaluate data, fill data gaps and prepare dossiers for registration.
One of the methods employed to fill such data gaps is (Quantitative) Structural Activity Relationship ((Q)SAR) modelling. (Q)SAR modelling requires the identification of chemicals of structural similarity to the chemical of interest. Data on the toxicity of these structurally similar chemicals is then used to predict the likely toxicity of the chemical of interest. These results can then be used for a number of purposes:
- To guide experimental testing strategies;
- To provide mechanistic data to support chemical grouping;
- To improve the evaluation of existing data as part of a weight of evidence approach; and
- To potentially provide a full replacement for toxicity testing.
However, it is not simply enough to generate a prediction using (Q)SAR models. Consideration must be given to the robustness, reliability and appropriateness of these predictions. To this end, the Organization for Economic Cooperation (OECD) has derived guidance on the use of (Q)SARs, which state that (Q)SARs must include the following characteristics:
- A defined endpoint, i.e. the endpoint should be something that can be measured experimentally such as an LC50 or an EC50.
- An unambiguous algorithm, this is to ensure transparency in the description of the model algorithm. However, the OECD has acknowledged that this may not be possible in commercially-developed models.
- A defined domain of applicability, i.e. the limitations of the model should be clear.
- Appropriate measures of goodness-of-fit, robustness and predictivity.
- If possible, a mechanistic interpretation.
This poster presentation will demonstrate several examples where (Q)SARs have been employed as part of a larger strategy to aid clients with REACH registration. It will include examples where we have considered the application of these predictions to be appropriate, and examples where the use of (Q)SARs were not considered to be appropriate for the chemical and/or endpoint of interest, and the reasoning behind such opinions. In the interests of client confidentiality, specific chemical names will not be included.

**TU 353**
**Exposure assessment under REACH: the backward approach**
F Vermeulen[1], NM Deleebeeck[1], P Anthonio[2]
[1]ARCADIS Belgium nv, BERCHEM, Belgium
[2]ARCADIS The Netherlands bv, 'S-HERTOGENBOSCH, The Netherlands
Chemical safety assessments under REACH require the lead registrants to gather detailed information on the uses in their supply chain in order to demonstrate safe use for the environment and human health. This has shown to be a rather difficult and elaborate procedure which often results in little options for refinement. In order for the lead registrant to be compliant with the REACH requirements, a practical solution is to apply a backward approach for the environmental exposure calculations.
The backward approach aims at defining the maximum allowable daily discharge to the environment and is partly an iterative procedure. The steps determining the iteration involve the selection of the most sensitive environmental compartment, the application of risk management measures (RMM), and an assumption regarding the regional exposure estimate. Due to the lack of refinement data, many exposure scenarios require the application of a number of generic RMMs to guard safe use, and these measures not only influence the calculations but also affect the legal obligations for downstream users. Practical experience has shown that this backward method in many cases offers a good solution to move forward when communication in the supply chain ceases or a generic approach is more appropriate (e.g. when numerous members take part in a SIEF or consortium).

**TU 354**
**Development of methodologies for risk trade-off analysis toward optimum chemical substance management**
W Naito, K Tsunemi, K Yoshida
National Institute of Advanced Industrial Science and Technology, TSUKUBA, Japan
Chemical substance management in Japan is shifting from regulation and management based on the degree of harmful effects toward management based on risk assessment. Management based on risk assessment involves seeking low-risk alternative substances and making maximum use of the benefits of chemical substances, as well as seeking to keep risks within an acceptable range. However, if appropriate risk management does not take place, risks other than the initial ones faced when selecting an alternative substance could emerge, thereby countering the risk reduction effect (i.e. a risk trade-off emerges). Nevertheless, with regard to current risk assessment technology, the exposure information required to evaluate many chemical substances is inadequate, and quantitative comparison of risks among different chemical substances is currently difficult. Given the above, this project aims to develop risk trade-off analysis techniques that businesses can utilize for highly precise quantitative analysis of chemical substance risks. The new techniques will also enable businesses to compare and consider the various common indicators of each risk as well as select appropriate alternative substances. In this presentation, we will introduce the conceptual framework of the project along with a case study on brominated flame retardants (BFRs).

## RA13 - The future of ecotoxicological risk assessment - biological traits, ecological vulnerability, improved SSDs, indirect ecological effects

**TU 358**
**Time-dependent SSDs**
E Billoir[1], DR Fox[2]
[1]Pôle de Recherche ROVALTAIN en Toxicologie Environnementale et Ecotoxicologie, VALENCE CEDEX 9, France
[2]Australian Centre for Environmetrics, University of Melbourne, MELBOURNE, VICTORIA, Australia
In ecotoxicology, endpoints are generally estimated at the end of some pre-determined exposure period (eg. 4-day fish survival, 21-day Daphnia magna reproduction, etc). The analyses focus solely on the response as a function of concentration. However the response is generally a function of both time and concentration and ignoring the time dependency can lead to severe bias in environmental risk assessment (Baas et al., 2010, Heckmann et al., 2010). For aquatic organisms, it is usually possible to test its response at intermediate points in time. For effects on mortality or reproduction, it is part of the standard protocol, however these data are usually not used in subsequent data analyses.
The species sensitivity distributions (SSDs) has become a key instrument in water quality guidelines. While the technique is regarded by most as a significant improvement on the use of safety factor, it is not without its problems and limitations. One of the most severe shortcomings is its reliance on the largely discredited NOEC. As an alternative to the conventional NOEC-based analyses, Fox (2010) has recently described a model-based Bayesian method for the estimation of no effect concentrations (NEC) and hazardous concentrations (HC). We extend this approach by adding the time dimension into the models. Using time-series data sets, we investigate the changes in NEC over time, and their impact on the HC value and uncertainty.
Baas J, Jager T, Kooijman B. 2010. Understanding toxicity as processes in time. Science of the Total Environment 408: 3735-3739.
Heckmann L-H, Baas J, Jager T. 2010. Time is of the essence. Environmental Toxicology and chemistry 29: 1396-1398.

**TU 359**
**One SSD model, three HCp estimators: but which is better?**
GL Hickey, PS Craig
Durham University, DURHAM, United Kingdom
The species sensitivity distribution (SSD) model is firmly embedded in the regulatory arena as a method to derive the so-called 'predicted no-effect concentration' for a defined species assemblage exposed to a toxic stressor.
The REACH technical guidance document (TGD) (ECHA, Guidance on Information Requirements and Chemical Safety Assessment), states that the log-normal SSD "is a pragmatic choice", an assumption that has become commonplace in the ecotoxicological risk assessment community. The best way to fit a log-normal SSD for purposes of hazard assessment, on the other hand, is confusing. The sought-after quantity which intermediate ('Level 2' within the REACH TGD) risk assessments are based upon is the hazardous concentration to 5% of the defined species assemblage (the HC5).
A standard approach is to estimate a median of the HC5 from the sampling distribution. This estimator has well understood statistical properties by construction. However, two alternative estimators - also based on a log-normal SSD - frequent the risk assessment literature. These estimators are constructed by least squares estimation of the ordered logarithmically transformed

toxicity data modelled onto the corresponding plotting positions (cf. quantile plots). Standard hypothesis testing and diagnostics of the linear regression are inappropriate without further constraints (cf. generalized least squares).
We consider evaluating which estimator, subject to the log-normality assumption, exhibits the best performance. The problem reduces to a fundamental problem of how to measure the performance of an estimator. This can be done by (1) 'discrepancy' between the estimator and 'true' value, or (2) 'discrepancy' between the true potentially affected fraction of species and the intended level.
Evaluation of different 'standard' criteria (variance, bias, etc.) under the perspective of (1) indicates that the median estimator performs better for all reasonable samples sizes. For (2), the results concur on important scales of discrepancy. However, this performance is highly sensitive to the chosen criterion/scale and sample size. We conclude that the median estimator is preferable and that controversy could be overcome by a risk assessor reporting probabilistic distributions for risk managers in a Bayesian framework in addition to summary statistics; the median estimator is known to be a special case of this.

### TU 360
**Acute toxicity of organic chemicals to Gammarus pulex correlates with sensitivity of Daphnia magna across most modes of action**
R Ashauer[1], A Hintermeister[1], E Potthoff[1], BI Escher[2]
[1]Eawag, DÜBENDORF, Switzerland
[2]The University of Queensland, Entox, BRISBANE, Australia
We investigate the sensitivity of the freshwater crustacean amphipod Gammarus pulex towards organic xenobiotic compounds in comparison to the sensitivity of the crustacean cladoceran Daphnia magna. Also we studied the influence of the chemical's mode of action on the relationship between the sensitivity of G. pulex and that of D. magna. We tested the acute toxicity of twelve compounds (Malathion, Aldicarb, Carbofuran, 2,4-Dichloroaniline, 2,4-Dichlorophenol, 1,2,3-Trichlorobenzene, 4,6-Dinitro-o-cresol, 2,4,5-Trichlorophenol, Ethylacrylate, 4-Nitrobenzyl-chloride, Sea-nine, Imidacloprid) with different modes of action and physicochemical properties towards the freshwater amphipod G. pulex in laboratory experiments. Additional toxicity data was was collected from literature and databases (data pairs for 44 chemicals in total). The chemicals were assigned to seven mode of action groups. The relationship between the sensitivity of G. pulex (48h-LC50s and 96h-LC50s) and that of D. magna (48h-EC50s) was investigated using regression analysis and correlation plots.
G. pulex is two to three orders of magnitude more sensitive towards neonicotinoids than D. magna. For organophosphates we find that D. magna is more sensitive than G. pulex by approximately a factor of six. None of the other mode of action groups exhibited a significant difference between the sensitivity of D. magna and that of G. pulex, however chemicals with the same mode of action grouped together in the same area of the correlation plot.
For the whole dataset, with the neonicotinoids included, 68% and 93% of all G. pulex toxicity data are within one and two orders of magnitude of the D. magna data, respectively. Without the neonicotinoids 75% of all G. pulex toxicity data are within one order of magnitude of the D. magna data and 100% within two orders of magnitude.
The regressions with all data and with all data minus neonicotinoids were both significant linear relationships with slopes around one. When neonicotinoids are excluded the regression resembles the 1:1 line very closely. As the slope is around one and the intercept around zero we conclude that G. pulex is generally equally sensitive towards organic xenobiotics as D. magna. Such a simple prediction rule would predict sensitivity of G. pulex based on that of D. magna within one order of magnitude for 75% of all compounds and within two orders of magnitude for 100% of the compounds in our dataset, if neonicotinoids are excluded.

### TU 361
**Trait-based sensitivity assessment of specific toxicants: getting deeper into specific traits**
A Ippolito, R Todeschini, M Vighi
University of Milano-Bicocca, MILANO, Italy
Assessing the sensitivity of different species to chemicals is one of the key point to predict the effects of toxic compounds in the environment. Trait-based predicting methods proved to be extremely efficient in order to assess the sensitivity of macroinvertebrates toward compounds with non specific toxicity (narcotics). Nevertheless predicting the sensitivity of organisms toward compounds with specific toxicity is much more complex, since it depends on the mode of action of the chemical.
We tried to predict the sensitivity of several freshwater macroinvertebrates toward two classes of plant protection products: organophosphates and pyrethroids. We built two databases: one comprehend sensitivity data (retrieved, evaluated and selected from the EPA ECOTOX database) and another one which collects biological traits. Aside from the "traditional"traits usually considered in ecological analysis (i.e. body size, respiration technique, feeding habits, etc.), we use multivariate analysis to relate the sensitivity of organisms to some characteristic (physiological, biochemical, etc.) which may be involved in the process of intoxication. We investigated for example whether the complexity of nervous system is relevant to assess the effects provoked by neurotoxicants like organophosphates and pyrethroids.
Results show that biological traits could be used to predict sensitivity to toxic substances, although more studies are needed to provide sound predictive methods. One key point to achieve a complete mechanistic understanding of the process is the choice of traits, whose role in the discrimination of sensitivity should be clearly interpretable, and not only statistically significant. A relevant drawback is the lack of information on the traits with the necessary taxonomic detail.

### TU 362
**Main factors driving population dynamics of a pollution indicator species**
A Palmqvist, VE Forbes
Roskilde University, ROSKILDE, Denmark
The marine deposit-feeding polychaete *Capitella capitata* is a classical re-colonizing species frequently used as an indicator of habitat disturbance (natural and anthropogenic). It is now recognized that *Capitella Capitata* is in fact a complex of sibling species of which some species are very opportunistic whereas others are both less mobile and less tolerant to disturbance. Some of these sibling species have been extensively used for both laboratory experiments and field surveys, though in the field different sibling species are indistinguishable based on morphological characteristics alone. With a combination of various types of laboratory experiments and model simulations the present study aims to pinpoint the most important factors driving the dynamics of field populations of *Capitella* spp., in order to focus further research, monitoring and management of disturbed areas. The importance of larval dispersal ability and settling behaviour was explored through both a matrix metapopulation study and targeted settling experiments. With increased focus on incorporating more ecological relevance into ecotoxicological studies, we designed experiments to mimic and explore the boom-bust dynamics of *Capitella teleta*. Our results emphasize the influence of dispersal ability and settling behaviour on the population dynamics of classical re-colonizing polychaetes and highlight the importance of understanding the principal factors driving re-colonization of disturbed sediments. Not surprisingly, food availability seems to be the main driver for both larval dispersal and settling behaviour as well as the main determinant of density dependence in *Capitella* spp., and is more important for settling in organically contaminated areas than is the presence of sediment associated contaminants at ecologically relevant concentrations. The take home message from this study is that in order to extrapolate to field populations for risk assessment and management purposes, it is necessary to choose representative model species for which we understand and can incorporate key aspects of their ecology and biology. Such knowledge can help to focus testing and research on endpoints that are more relevant for effects on populations.

### TU 363
**Ecotoxicological research in terms of sensitivity distinctions of lotic insect larvae with Imidacloprid**
D Becker[1], S Classen[2], K Liedtjens[1], TG Preuss[1], HT Ratte[1]
[1]RWTH Aachen/ Institute for Environmental Research, AACHEN, Germany
[2]Research Institute for Ecosystem Analysis and Assessment e. V. - gaiac, AACHEN, Germany
Abstract
The contamination of running or stagnant waters with harmful substances, in particular insecticides, can be very dangerous for macroinvertebrates. Despite the fact that aquatic insects represent the most important and vulnerable group of organisms inhabiting streams and rivers, there are only a few species that have been used routinely in bioassay studies. Against this background the sensitivity of lotic Ephemeroptera, Trichoptera and Plecoptera larvae was examined. Due to the fact that the neonicotinoid Imidacloprid is one of the most used insecticides worldwide it was selected as the test substance.
The acute toxicity of Imidacloprid was determined on different larvae species and larval stages. The test period was 96 h in M4 medium. The test was conducted with 5 different concentrations with 5 replicates each and 10 replicates for the control. After acclimatisation of the larvae in M4 medium, they were transferred to 100 ml beakers. Depending on their size, 1-5 larvae were inserted in each beaker. Each beaker was aerated to ensure the oxygen saturation of the medium. The first results show a high sensitivity of the larvae towards Imidacloprid. The EC50 after 96 h for Epeorus assimlis is 5,06 µg/l, Habrophlebia lauta 31,18 µg/l, Cloeon dipterum 43,33 µg/l, Baetis rhodani 5,21 µg/l and Hydropsyche spec. 23,07 µg/l. This indicates that the various species differ in their sensitivity towards Imidacloprid. The different larval stages within on species seem to react distinct towards Imidacloprid.
All the tested species are more sensitive compared to Daphnia magna (239,07 mg/l after 48 h). Chironomus tentans shows an EC50 of 5,75 µg/l (Stoughton et al. 2008) and C. riparius 12,94 µg/l after 96 h (Pestana et al. 2009). Nevertheless Chironomus spec. are sediment dwellers and therefore are well suited organisms for sediment bioassays but less suited for other types of assays. These first outcomes show the importance of using not standard organisms for a better assessment of the situation in the field. It is expected that limnic macroinvertebrates, present in the water at the time of application, will react more sensitive to pesticides than standard organisms in the laboratory do. For example Imidacloprid can be found at concentrations of 1-14 µg/l in surface water (Jemec et al. 2007). Compared to Chironomus, the larvae of Ephemeroptera, Trichoptera and Plecoptera are better suited to reflect the stream and river ecosystem.

### TU 364
**Resistance to chemical contamination in Daphnia longispina: consequences on the phenotypic response to predation risk.**
LT Pestana, N Rodrigues, AMVM Soares, I Lopes
Universidade de Aveiro, AVEIRO, Portugal
Natural populations historically exposed to low levels of chemical contamination may evolve resistance to that particular contamination. Theories on adaptive changes predict that the acquisition of such resistance may involve fitness costs, which can be considered in terms of energetic and resource allocation.
On the other hand, aquatic species rely on plastic traits to defend themselves against natural stressors like predators. The induction of these antipredator defences is mediated by water-borne chemical cues. These induced defences also have associated costs which can include decreased tolerance to future environmental change such as contamination
Because both acquisition of resistance to contaminants and phenotypic plasticity can involve fitness costs , the present work intended to study if an increased resistance to copper on the cladoceran Daphnia longispina O.F. Müller is associated with loss of plasticity in terms of the response to fish predation rik . To attain this objective, four cloned lineages of D. longispina, exhibiting different sensitivities to lethal levels of copper, were exposed to three levels of predator-release kairomones from Gambusia affinis: 0.25, 0.5, and 1 fish/l, plus a control (solely ASTM). Life cycle parameters (time to release and number of neonates at first brood, total number of neonates per female, growth, and intrinsic growth rate), feeding inhibition, and respiratory rate, were monitored for each cloned lineage. A similar pattern of response, for all the measured endpoints, was observed for the two lineages most sensitive to copper. And, this pattern of response was different from that of the two resistant lineages. However, though differences in the monitored endpoints were observed between the sensitive and resistant D. longispina lineages, a significant association between responses to kairomones and resistance to lethal levels of copper was not observed.

### TU 365
**Trait-based approaches for the assessment of agricultural impact on invertebrate communities of Swedish streams**
QQ Goedkoop
Swedish University of Agricultural Sciences, UPPSALA, Sweden
We used a data set of benthic invertebrates from 200 streams in south Sweden to test the use of trait-based approaches for the assessment of multiple stressors originating from agricultural practices in the catchment (and assumed pesticide impact). Agricultural land use for the streams varied from 4-95% of the catchment, thus providing a data set reflecting a gradient from largely unimpacted, forested catchments to those with an almost exclusively agricultural land use. Moreover, field-level information on crops and expected use of pesticides were used to estimate pesticide impact on these streams. Multivariate methods were used to identify gradients in community composition and to test for correlations of observed community changes with proxies for the impact of agricultural land use on stream integrity. Traits that corresponded with these environmental gradients will be discussed. We test the power of a suite of biological metrics, including the trait-based SPEAR and taxonomy-based EPT and pollution metrics, to quantify the integrated

impact of agricultural activities on stream invertebrates. An attempt is made to distinguish the impact of pesticides from those caused by habitat degradation, using a suite of habitat descriptors extracted from field protocols. Lastly, we identify important landscape elements (from GIS) that contribute to the vulnerability of streams.

**TU 366**
**Susceptibility of different life stages of Folsomia candida (Collembola) to hydrophobic organic compounds**
D Giesen
Vrije Universiteit Amsterdam, AMSTERDAM, The Netherlands
Hydrophobic organic compounds (HOCs) represent important component of soil contamination and poses a great threat to ecosystem function and human health. Since soil ecosystems are often exposed to organic pollutants, it becomes important to evaluate the risk of these chemicals to soil organisms and populations. For that purpose, several standard toxicity tests with soil organisms are already established. The collembolan Folsomia candida is a common soil invertebrate, used in standard ISO (11267) and OECD (232) toxicity test guidelines. Prevalently chosen endpoints in these tests are the EC50 concentrations for reproduction (50 % reduction in reproduction) for 10-12 day old animals. Subsequent analysle like microarray gen expression profiles are often based on these calculated EC50. However it remains unclear which life stage is the most sensitive. In the development of soil invertebrates the physiology and the morphology changes rapidly. Standard test can't reveal if the toxic effects applies to eggs, young hatchlings or adults. In this study 2-5 day old eggs and two different age classes (2-5 days and 26-28 days) of Folsomia candida were exposed to three different hydrophobic organic compounds (phenanthrene, 1,2,4,5-tetrachlorobenzene and 2,3,5,6-tetrachloroaniline). In earlier standard tests these compounds showed different effective concentrations based on their logKow. Phenanthrene and 1,2,4,5-tetrachlorobenzene both showed baseline toxicity whereas for 2,3,5,6-Tetrachloroaniline evidence grows to have an uncoupling effect. Natural standard LUFA 2.2 soil was used as substrate. Survival, reproduction and hatching success were evaluated after 28 or 35 days, respectively. The endpoint concentrations were calculated with a log-logistic model. Over test period total soil concentration were extracted from subsamples and were measured by HPLC. The obtained results showed high differences among life stages and among compounds when compared within the test and with results from standard toxicity tests We conclude that for future ecological risk assessment the life stage analysis should be taken into account.

**TU 367**
**Selected biological traits reveal soil invertebrate exposition to trace metal contamination**
CR Hedde[1], I Lamy[2], F van Oort[2]
[1]INRA, VERSAILLES, France
[2]INRA UR251, PESSAC, VERSAILLES, France
For decades, human pressures have threatened the ecological integrity of soils. The draft Soil Framework Directive (COM(2006) 232) has listed the main eight soil degradation processes to which soils in the EU are confronted, of which soil biodiversity loss and contamination. These two aspects have been successfully monitored in stream ecosystems using invertebrate biological traits. In this context, we aimed at developing a similar approach for soil monitoring.
In the present work, we aimed at elucidating soil macro-invertebrate response to trace metal (TM) contamination, in term of composition and functional role. Soil macro-invertebrates can be exposed to trace metal either by ingestion or by contact; they can also avoid to be exposed by escaping. We proposed to evaluate these three ways using a trait-based approach. We assumed that the type of exoskeleton, the diet of invertebrates and the wing morphology are related to the way invertebrates are exposed to pollutants. So we hypothesized that the proportion of (i) soft-body, (ii) geophageous and (iii) wingless invertebrates decrease as trace metal concentration increase in soil. Geophageous invertebrates are also key in terms of soil aggregation and organic matter turn over. We selected five plots located in the 1500-ha-wide agricultural plain ( Pierrelaye-Bessancourt, France). This plain has been contaminated by irrigation with raw wastewater of Paris city for 100 years. As a result, the contaminated soils display strong and heterogeneous accumulation of organic matter, metal pollutants and dissolved salts in surface horizons. In this agricultural plain, high values of soil metal contents have been recorded, e.g. up to 1500 or 15 mg kg-1 dw soil for Zn or Cd, respectively
The present work demonstrate that functional trait approach allow to discriminate three different responses at soil contamination increase. The negative linear relationship of soft-body invertebrates to TM concentration reveals an additive effect of contamination. This functional trait is very sensitive since difference was observed between communites in uncontaminated and weakly contaminated plots. The response of geophageous or wingless invertebrates reveals a threshold effect, but at different soil contamination level. The lack of geophageous invertebrates can imply drastic losses in soil functioning, ie soil aggregation, porosity or organic matter turn over.

**TU 368**
**Potential application of traits-based bioassessment approaches for use in the study of multiple stressor impacts on freshwater ecosystems in the Athabasca oil sands region (Canada)**
G Armanini[1], JM Culp[2], DJ Baird[2]
[1]Prothea, MILAN, Italy
[2]Environment Canada @ Canadian Rivers Institute, University of New Brunswick, FREDERICTON, Canada
The Mackenzie River Basin headwaters (Canada), including the Athabasca and Peace River watersheds, is currently facing significant environmental challenges from a range of human activities, including, but not limited to: bitumen mining of surface and subsurface oil sands deposits, currently operating and future hydro-electric schemes, agriculture and small-scale urbanization. The major stressors to freshwater communities in the area are thus hydro-carbon concentrations, changes in pH values, and reducing water availability. As commonly observed at the global scale, the co-occurrence of these major stressors is common in the area and it constitutes a great management challenge. Biological monitoring systems has not been widely implemented in the oil sands region (with the exception of the Regional Aquatics Monitoring Program), although there is a desire to expand their use within the region. One potential future application of biomonitoring data collection is their use in the development of specific diagnostic indicators of environmental stress. The single stressors diagnostic development is particularly needed where, as in the oil sands region, co-occurring, and potentially co-acting stressors, have to be ranked in terms of their ecological importance with the goal of identifying drivers of any observed ecological change. It has been recently recognized that the linkage of trait responses to stressor gradients can enhance causal assessment and thus support the development of new generation diagnostic tools. A review of available traits-based approaches for developing single stressors diagnostic was undertaken and it gave useful indication on potential pathways to develop comparable indicator of oil sands related stressors i.e. hydro-carbon contamination. The review has been focused on identifying: 1) available biomonitoring data in the region; 2) natural sources of variability and major anthropogenic stressors affecting biological communities; 3) available trait information and 4) traits-based approach for bioassessment with focus on oil sands region. Based on this review, final consideration on potential to develop traits-based diagnostics to tease apart multiple stressors affecting the biological communities in the Mackenzie River Basin headwaters were drawn.

**TU 369**
**Effects of tebuconazole on the structure and metabolism of stream microbial communities**
J Artigas[1], N Pascault[2], M Marechal[1], J Chastain[3], G Voyard[3], A ter Halle[3], S Pesce[1]
[1]Cemagref Lyon, LYON, France
[2]INRA, UMR CARTELL, THONON LES BAINS, France
[3]Clermont Universite, Universite Blaise Pascal, CLERMONT-FERRAND, France
Streams are often subjected to diffuse pollution, especially in extensive vineyard areas where the use of plaguicides is frequent. The main objective of this study was to determine the effects of Tebuconazole (fungicide, TBZ) in the structure and metabolism of algal and bacterial communities forming biofilms. Biofilms colonized in reference (Saint Joseph, SJO) and polluted (Saint Ennemond, SEN) stream sites from la Morcille stream (Beaujolais region, Eastern France) were exposed to two different TBZ dosages (2 microgTBZ/L; 20 microgTBZ/L plus controls). Biofilm structural (algal and bacterial abundances and community composition) and functional descriptors (primary production, respiration, metabolic diversity) were surveyed during a 22-days experiment by using artificial stream channels. We observed a decrease in the proportion of live/dead bacteria in biofilms from the two study sites (SJO and SEN). However, decreases in bacterial respiration and photosynthetic efficiency were only consistent in biofilms from the reference site (SJO), but not in those from the polluted site (SEN). The Biolog EcoPlates analysis determined that moderate dosages of TBZ (2mg/L) may homogenize the metabolic diversity between reference and polluted communities. TBZ inputs in streams may have consequences in ecosystem processes, such as the organic matter decomposition, since it decreases bacterial activity. But also, TBZ decreases the photosynthetic efficiency, and therefore, the potential primary production in the stream environment. Our results confirm that the TBZ (fungicide) has indirect effects on algal and bacterial communities, especially in those communities that has not been previously exposed to this toxicant.

**TU 370**
**A new ecotoxicological module for water quality assessment and monitoring**
AE Gerhardt
LimCo International, IBBENBÜREN, Germany
The European Waterframework Directive (2000/60/EC) aims at achieving a good ecological and chemical status of water bodies in Europe until 2015. Whereas the ecological status assessment builds on different moduls, such as hydromorphology, macroinvertebrates, aquatic macrophytes/algae and fish community assessment, the chemical status is defined as compliance to environmental quality standards set up for selected priority and dangerous substances, which are being reviewed regularly. We propose a new ecotoxicological module bridging between the biological and the chemical approach. Based on exisiting data for macroinvertebrates for the biological module, the SPEAR-index (SPecies At Risk) provides an initial screening tool. In case the SPEAR-Index indicates problematic values at a site, a thorough ecotoxicological assessment should be performed in a second step. In this step we propose GamTox, the new multi-metric and multi-level ecotoxicity test for application both in the laboratory and in situ. GamTox can be performed as short-term acute test, as long-term chronic test and in continuous online biomonitoring with the automated Multispecies Freshwater Biomonitor®. Different parameters can be recorded in the animals, such as survival, behaviour (locomotion, ventilation, feeding, precopula), reproduction and mode-of-action related biomarkers, such as MTs (metals) and AChE (neurotoxins). The international Gammarus working group is currently validating and standardizing GamTox.

**TU 371**
**Ecological vulnerability and degradation of chernozems in Republic of Moldova**
TG Leah
Institute of Pedology, Agrochemistry and Soil Protection "N.Dimo", CHISINAU, Moldova
Moldova is characterized by very complex of soil cover. Main soils are chernozems, 70% of the land surface. Land reform in Moldova has not created conditions for increasing soil fertility, sustainable land use, increasing agricultural production, exerting therefore negatively impact the country's economy. In this context Moldova risks to lose the greatest wealth of country - chernozems fertility. Soil quality and vulnerability of most agricultural land is poor and a part of land - critical. The most serious forms of soil degradation are erosion, dehumification, and impoverishment of nutritive elements, salinisation, secondary compacting, and active land sliding. These forms and processes decrease soil production or destroy completely the soil cover. The ecological damages are also significant: depletion of agricultural fields, biological degradation, surface water pollution with nutrients and organic substances. Erosion is the main factor of soil degradation. According to soil surveys, soil eroded area has increased during 40 years from 594 000 ha in1965 to 878 000 ha in present, increasing annually by 7100 ha. Depending on the degree of erosion eroded soil fertility decreases in the following: weakly eroded - by 20%, moderately eroded - 20-40%, strongly eroded - 40-60%, very strongly eroded - 60-80%. The greater the degree of soil erosion, the greater is their vulnerability to this factor. During the 100 years of exploitation of soil in agriculture the humus content decreased by 35-45%. Losses depend on the speed of humus mineralization (dehumification) and erosion processes. Soil humus balance is negative - minus 0.7 t / ha. The total annual agricultural land lost 2.4 million tons of humus. Natural conditions in Moldova ranks among the primary tasks of irrigation, especially for the South, which is the most vulnerable to climate conditions, where the immersion factor is 0.5 to 0.6, and droughts are repeated at a frequency of three years. Currently, irrigation of agricultural land is carried out primarily by local sources of water (inland rivers, lakes, ponds) that is characterized by high degree of mineralization, alkaline and chemically adverse reaction. As a result, there is secondary soil salinisation and solonețizarea, which contributes to increased ecological vulnerability. The existing land use has led to compaction of the arable layer. Recently plowed chernozem layer of structure is characterized by massive structural elements strongly compacted.

**TU 372**
**Do pesticides affect trends in microarthropod communities according to food preferences as indirect effect?**
C Vaj[1], CAM van Gestel[2], M Vighi[1]
[1]University of Milano - Bicocca, MILANO, Italy
[2]VU University, AMSTERDAM, The Netherlands
In agroecosystems the use of plant protection products is common practice. During the applica-

tion a fraction of these products reaches the soil, making the soil community exposed to different pesticides. These products have been developed to kill the target organisms (fungi, plants or insects), but may give adverse effects also on non-target species. The effects can be direct on the species, or indirect, due to the effect of the pesticide on another organism (e.g. prey or predator). An example is the effect of a fungicide on fungi eaten by fungivorous animals.
These possible indirect effects were studied in the field, by investigating a microarthropod community exposed to plant protection products in a vineyard in Northern Italy. Three sampling points were chosen, in a gradient of contamination: one inside the field, and two 4 m and 10 m away from the last plant row. The community was sampled in a sampling scheme drawn according to the insecticide applications. In particular, to evaluate indirect effects, three samples were examined: two after the application of herbicides and fungicides but before application of the insecticide chlorpyirifos, and the third after chlorpyrifos application. All the information about the active ingredients used was obtained and the exposure of the community was assessed with traditional ecotoxicological tools. The sampled organisms were identified at least to the order level, but for some taxa to the family level, or a division into major groups was made. Information on the diet was obtained from the literature to divide the different taxa into groups according to their food preferences. Results were related to the control 10 m away from the field. The hypothesis was that before the use of chlorpyrifos, there could be indirect effects on the abundance of organisms due to the elimination of food sources, while after chlorpyrifos application the direct effect of the insecticide should become visible.
Different trends were observed in the community, according to the food preferences of the taxa: bacteriophages, for example, showed a decrease between the two dates before chlorpyrifos application, while the numbers of fungivorous, phytophagous and detritivorous organisms were almost constant. Coprophagous, necrophagous and secondary consumers showed a constant decrease during the entire productive season. The ratio between indirect and direct effects was highlighted, demonstrating that direct effects overshadow the indirect ones.

**TU 373**

**SPEAR application on a small-scale scenario**

A Ippolito[1], M Liess[2], E Varolo[3], M Vighi[1]
[1]University of Milano-Bicocca, MILANO, Italy
[2]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[3]E. Mach Foundation, Innovation and Research Centre IASMA, S. MICHELE ALL'ADIGE (TN), Italy

Despite numerous studies have dealt with the topic, the real extent of the effect caused by pesticides loads in freshwater communities is still largely unknown.
One of the main problem is to distinguish between natural and anthropogenic environmental factors, as well as between different anthropogenic factors. Species at risk (SPEARpesticides) index uses biological traits of organisms to determine whether organisms are vulnerable or not to pesticides exposure. The SPEARpesticides index have already been successfully validated over large-scale areas in different biogeographical regions of Europe using both species-level or family-level data on stream invertebrates.
Here we propose a different application of the index on a smaller, detailed scale, in order to verify the reliability of the SPEARpesticides index in site-specific risk assessment.
We consider two different mountain streams in Trentino-Alto Adige region, northern Italy. They are located only a few kilometres apart and present similar characteristics (i.e. hydrology, hydrochemistry, etc). However, one of them is considerably prone to pesticide exposure, due to intensive apple orchard cultivation in the watershed, while the other presents almost no human impact, and could be used as reference site. The exposure scenario due to runoff events was modelled for the entire productive season of 2010. Macrobenthos community was sampled monthly in both streams and taxa abundance was counted.
The SPEARpesticides index was used to analyze differences between the community composition of the two rivers, in order to verify if those differences were due to pesticides exposure. SPEARpesticides indicates a clear shift of the community composition over time in the impacted river. The comparison with the reference site shows clearly that this alteration is not driven by natural factors and it is likely to be caused by exposure to pesticides. The last sampling, performed more or less one month after the last treatment, shows a consistent recovery of the community of the impacted river. The fast resilience of the community can be probably linked to high input of organisms from non-polluted areas that are present upstream.

**TU 374**

**Indirect effects of Carbendazim in freshwaters. A laboratory study using a simple detritus based food web.**

LT Pestana[1], DMG Campos[1], M Lemos[1], JAM Pedrosa[1], A Alves[1], A Correia[1], C Barata[2], AMVM Soares[1]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Department of Environmental Chemistry Institute of Environmental Diagnosis and W, BARCELONA, Spain

An ecologically grounded understanding of food webs (considering the conceptual framework of density- and trait-mediated indirect effects) and of species interactions in the system of interest is essential for understanding the ecological effects of contaminants on population dynamics, community structure and vital ecosystem functions. Few studies exist on indirect effects concerning facilitator species or trophic cascades within detritus based food webs (i.e. shredder-collector interactions). Detritus processing is vital for river ecosystems with detritivores and the microbial community contributing for the decomposition of coarse particulate organic matter into fine particulated matter and for recycling of nutrients that can be transported downstream and used by other organisms. This means that monitoring of the ecological quality of river ecosystems should incorporate assessment of toxic effects on processing and consumption of detritus.
This work contributes with an example of how indirect effects of fungicides on leaf litter decomposition process can be measured and to what extent microbial communities, shredders; collectors and their interactions might be affected.
A gradient of Carbendazim concentrations (0; 5µg/L and 50 µg/L) was used to show differential microbial conditioning of alder leaf litter over a 14 day conditioning period. Effects of Carbenzim on microbial community structure (Fungi and Bacteria) were assessed with denaturant gradient gel electrophoresis (DGGE), a polymerase chain reaction (PCR)-based fingerprinting technique. A microbial functional endpoint was also assessed by assessing the oxygen consumption of the leaf microbial communities. Afterwards, leaf discs conditioned in the different fungicide concentrations were used in multispecies systems with the shredder Sericostoma vittatum (Trichoptera) and the collector Chironomus riparius (Diptera) to assess changes in leaf degradation rates through effects on invertebrate feeding and consequent changes in collectors' growth due to differences in food availability and quality. Results are discussed in terms of how carbendazim contamination can affect detritus food webs by disrupting ecological interactions and have significant effects on aquatic macroinvertebrate communities and ecosystem function.

**TU 375**

**Ecological vulnerability of macroinvertebrates, comparing sensitivity to vulnerability for chlorpyrifos**

HJ de Lange, RPA van Wijngaarden, GHP Arts
Alterra, Wageningen UR, WAGENINGEN, The Netherlands

The ecological vulnerability of a population (or higher level) expresses some intrinsic characteristics which are likely to influence the response of the considered population or system to a given stressor. The Ecological Vulnerability Analysis previous developed at Alterra, uses species traits of wildlife species to estimate likelihood of exposure to a contaminant, internal regulation mechanisms, and population recovery mechanisms. Specific for chlorpyrifos, the data on wildlife species showed that vulnerability for chlorpyrifos was mostly determined by exposure through habitat. Further, r-strategic species were more vulnerable and K-strategic species were less vulnerable to chlorpyrifos. However, for the set of wildlife species used in the original analysis there were no toxicological data available to include in the analysis. But for aquatic macroinvertebrates toxicological sensitivity data for chlorpyrifos are more readily available. It is therefore interesting to compare the sensitivity data to the vulnerability data, and compare different ways to include the sensitivity data in the vulnerability assessment. This is analyzed for the pesticide Chlorpyrifos. Vulnerability results for the aquatic macroinvertebrates will be discussed in light of the results of the vulnerability of wildlife species.

**TU 376**

**Preliminary ecotoxicological assessment of the vulnerability of groundwater ecosystems to plant protection products**

MA Daam, E Silva, S Leitão, MJ Trindade, MJ Cerejeira
ISA/UTL, LISBON, Portugal

The present EU groundwater legislation has often been disputed for only considering groundwater as a source of drinking water and not as an ecosystem with an intrinsic value and vulnerability. In the present study, preliminary groundwater threshold values were calculated for all plant protection products (PPPs) currently included in Annex I to Directive 91/414/EEC. Due to the very low availability of toxicity data for true groundwater organisms, data for surface water organisms from taxonomic groups known to be well represented in groundwater were used as surrogates. Three different approaches were used: (1) 'first-tier' (*Daphnia magna* and *Vibrio fischeri*), (2) species sensitivity distributions, and (3) the case-based model PERPEST. For the majority of the PPPs, the trigger value of 0.1 µg/L appears to be sufficiently protective. However, it may not fully protect groundwater life from side-effects of several insecticides. Implications for the environmental risk assessment of groundwater and recommendations for future research are discussed.

**TU 377**

**Influence of a municipal solid waste landfill in the surrounding environment: toxicological risk and odour nuisance effects**

M Palmiotto, V Paiano, G Celeste, E Fattore, E Davoli, G Bianchi
Istituto Mario Negri, MILANO, Italy

The environmental impact produced by municipal solid wastes has received special social and environmental attention in recent decades. Communities concern is driven mainly by possible toxic emissions causing human health concern, but also for general environment degradation due to induced heavy traffic load, landscape appearance and odour. Landfills are a strong environmental stressor. Waste treatment plants are now large, complex realities where different biological processes take place under controlled conditions. Still the results are, mainly due to the large amounts of waste material treated, that areas in the proximity of landfills are vulnerable not only to emissions, to possible toxic compounds, but also to nuisance such as odour pollution. All these factors have a dramatic impact in the local environment producing environmental quality degradation.
Most of the human health problems come from the landfill gas (LFG), from its non-methanic volatile organic compounds (NMOCs). The most practiced control technologies for landfill gas are flares but several hazardous air pollutants (HAP) are present in LFG, some of these being carcinogen for humans.
In MSW, as well as in LFG several odorants are present and both emissions during landfill operations and LFG uncontrolled emissions are responsible for environmental odour pollution.
In this work we present an integrated risk assessment for carcinogenic emissions and odour pollution study, to describe environmental quality in the landfill proximity. The study is based on sampling campaigns to acquire emission values both for carcinogenic compounds (dioxins and related compounds, PAHs, benzene and vinyl chloride) and odour.
This risk assessment and odour emissions were based on the current management of the facility. In particular all concentration values in the emissions from the landfill were measured and used in a simulation model (AEROMOD) to estimate maximum concentrations and depositions in correspondence to five sensitive receptors. The impact of leachate contamination was not been evaluated as the landfill is situated in a non aquifer with no drinking water supplies or surface water receptors (UK EA, 2004).
Results for the different scenarios and cancer and non cancer effects always showed risk estimates which were orders of magnitude below those accepted from the main international agencies (WHO, US EPA) and those due to background contamination. Odour might be significant for a limited downwind area.

**TU 378**

**Another interpretation of classical multiple comparison procedures used in ecotoxicology**

ML Delignette-Muller, C Forfait, E Billoir, S Charles
University of Lyon, VILLEURBANNE CEDEX, France

Even if the misuse of p-values to define toxicity thresholds from No Observed Effect Concentration (NOEC) is now recognized - both statistically and biologically -, this old habit still remains firmly fixed in the ordinary run of things. The purpose of this work is to convince NOEC advocates to change their mind. With the estimation of x% Effective Concentrations (ECx) or No Effect Concentrations (NEC), some well-known alternatives based on dose-response curve modelling could have been enough attractive, but here we propose another alternative: an innovative interpretation of classical multiple comparison tests. Our approach consists in calculating simultaneous 95% confidence intervals (CI) for mean ratio-to-control associated to a Dunnett-type procedure. Our "selling"propositions are: the easiness of implementation through turnkey R packages, the solid statistical bases of the approach, the independence towards any model assumption underlying the dose-response curve, and the establishment of toxicity thresholds as the x%

Effective Concentration (ECx) values with their uncertainty intervals whatever the x, even 0. Our talk will detail the complete approach (from a theoretical and a practical point of view), from raw data until the calculation of 95% CI on ECx, with x equal to 0, 5 and 10. Four data sets, concerning different type of toxic compounds and collected during standard 21-day Daphnia magna bioassays, are analysed. To support our demonstration, 95% CI on ECx calculated with our approach are compared to those estimated with a classical fit of the 3-parameter log-logistic model. Both methods are in good agreement.
Of course, some cons could be argued against our approach like rather large intervals, inevitably bounded by concentrations tested in the experimental design, or intervals on EC0 always left bounded by 0. Nevertheless, the most sceptical potential users will grant us that our approach is an easy and statistically convenient way to overstep the misuse of p-values which are certainly not dedicated to establishing thresholds, values of which strongly depending on the sample size without to be associated with their uncertainty.

**Defining relevant ecological endpoint in the context of integrated environmental assessment of chemicals**
S Sala[1], M Vighi[2]
[1]Joint Research Center European Commission, ISPRA (VA), Italy
[2]University of Study Milano Bicocca, MILANO, Italy
The recent developments of ecotoxicological risk assessment are oriented toward an increased attention on approaches characterized by growing "ecological realism", with the objective of a better assessment of the possible effects on ecosystem health.
The traditional approaches, focused more on chemicals than on the site-specific environment, tend to be adapted and modified with more focus on the structure and functions of communities and ecosystems subject to complex and combined stress factors.
In the present European regulation, ecotoxicological risk assessment, refers mainly to production and use of chemicals, with a few attention to other contexts, such as strategic environmental assessment of plans and policies or life cycle assessment of products and good.
Therefore, several issues are still critical to perform a comprehensive assessment of chemicals: extrapolation of results from laboratory to field; spatial and temporal distribution of risk ; relevant archetypes and emission scenarios (in a life cycle perspectives that requires to include raw material, production, use phase and end of life); assessment of ecological vulnerability from population to community and ecosystems; role of integrated indices to consider impact along the trophic chain; role of ecological indirect effects on ecosystem functioning; role of statistical tools ( such as Species Sensitivity Distribution) with respect to the role of key species; framework and methods for assessing uncertainty and indirect ecological effects of chemicals.
A critical review of endpoint adopted in the above mentioned tools and methodologies will be presented, highlighting the relevance of multidisciplinary approach to define new paradigm in the dialogue among ecotoxicology, ecology and other disciplines involved in the integrated assessment.

**Assessing the effects of ammonia on aquatic communities in the field**
C Simpson[1], A Peters[1], L Surl[1], M Crane[1], P Whitehouse[2]
[1]WCA environment, FARINGDON, United Kingdom
[2]Environment Agency, WALLINGFORD, United Kingdom
Ammonia can act as both a toxicant to animals and a nutrient for plants. We used recently developed tools for assessing the degree to which aquatic communities are impacted by their environment, relative to unstressed reference conditions, to assess the effects of ammonia on different components of aquatic ecosystems in the UK. The approach uses a dataset of spatially matched chemical and ecological data. Quantile regression is then used to analyse the datasets, which accounts for other stressors (such as chemical toxicants or habitat degradation) that may have caused impacts on the communities. Thresholds for the effects of ammonia on fish, invertebrates, macrophytes and algae are derived for different forms of ammonia exposure (total ammonia or unionised ammonia, expressed as average or 90th percentile concentrations). The results are compared against the quality standards for ammonia that are applied in UK freshwaters.

### TU 381
**High functional redundancy in a herbicide-exposed planktonic community**
F de Laender[1], PJ van den Brink[2], CR Janssen[1]
[1]Ghent University, GHENT, Belgium
[2]Alterra and Wageningen University, WAGENINGEN, The Netherlands
A mechanistic food web model was used to predict functional effects of the herbicide linuron from microcosm data. On a functional group level, our analysis showed that a reduction in carbon uptake rates of sensitive primary producers caused a density decrease of the latter with increasing linuron concentrations. In response, heterotrophs started feeding on more abundant tolerant primary producers which allowed them to maintain feeding rates at control levels - indicating functional redundancy within the planktonic community. On an ecosystem level, total gross primary production (GPP) was up to hundred times lower in the linuron-treated microcosms than in the controls. However, this could be explained by herbicide effects on macrophytes - the main contributor to total GPP. In contrast, linuron did not change planktonic GPP more than a factor 2 and did not alter bacterial production. We conclude that the planktonic community exhibited high functional redundancy when facing herbicide stress.

### TU 382
**Unexpected Malachite Green sediments and fish contamination originated from a wood panel factory**
S Lombardo[1], A Mao[1], M Maniero[1], A Cecchin[1], G Perin[2], A Giacometti[1]
[1]IDEAS Centre - University of Venice, VENICE, Italy
[2]IDEAS Centre - University of Venice - Archives of Environmental/Human Toxicology, VENICE, Italy
Malachite Green (MG) is an extensively used biocide in the aquaculture industry world-wide. It is highly effective against important protozoal and fungal infections. Basically, it works as an ectoparasiticide: it has also been used to control skin flukes and gill flukes. Aquaculture industries have been using malachite green extensively as a topical treatment by bath or flush methods without paying any attention to the fact that topically applied therapeutants might also be absorbed systemically and produce significant internal effects.
Malachite green has become a highly controversial compound due to the risks it poses to the consumers of treated fish including its effects on the immune system, reproductive system and its genotoxic and carcinogenic hazard. Though the use of this dye has been banned in several countries it is still being used in many parts of the world due to its low cost, ready availability and efficacy. There is concern about the fate of MG and its reduced form, leucomalachite green, in aquatic and terrestrial ecosystems since they occur as contaminants and are potential human health hazards.
Some fish samples (trout) exported by a large fish farm in Friuli (Northern Italy), controlled by food quality control officers, showed a substantial amount of MG, not enough for killing the fishes but largely exceeding the food safety limits. Mass balance of MG in the fish farm, however, indicated that the pollution source should have been search in a different site, located quite upstream the fish farm.
Going backwards, after a labor intensive and deep investigation, the scientists found that sediments each time were more and more polluted by MG. Finally, the MG main source, was located upstream a factory using MG as dye for manufacturing custom-colored wood panels. The regulatory intervention of the authority forced the factory to eliminate MG in the industrial processes. The sediment data provided the scientific basis for river recovery.

**A comparison between natural and alternative sea water piling materials merging ecological and ecotoxicological issues**
A Volpi Ghirardini[1], GL Libralato[1], CL Losso[1], EK Keppel[2], MS Sigovini[2], DT Tagliapietra[2]
[1]Cà Foscari University of Venice, VENICE, Italy
[2]Consiglio Nazionale delle Ricerche, Istituto di Scienze Marine, Sistemi Marini e, VENICE, Italy
Wood is extensively used for maritime works, above all mooring piles, docks, bulkheads and navigation channel marks ("briccole"), especially in estuarine and marine coastlines. In Venice lagoon (Italy), it has been evidenced a great acceleration in the decay of traditional natural piling materials mainly due to the wood borers in addition to the water mechanical and bacterial action. In the lagoon it has been estimated that along the shipping channels there are about 22,000 wooden piles constituting the briccole and around 10,000 are present for boats mooring. Each year, a large number of them must be replaced. Local authorities in order to keep navigation safety and increase environmental protection identified a set of potentially ready-to-use piling materials concerning allocthonous wood, traditional wood with specific add-ins or treatments and others that are completely synthetic. The aim of this study is to fill the gaps in the knowledge about the lagoon distribution and ecology of the main species of wood boring invertebrates through in situ and ex situ activities, defining a preliminary model of habitat suitability. Simultaneously, ecotoxicological analysis have been carried on leachates generated from the proposed materials considering various exposure scenarios. The purpose is to ascertain if their toxicity was significantly different from that of historically used timbers. A battery of toxicity tests composed of sensitive saltwater species was taken into account (i.e. *Vibrio fischeri*, *Phaeodactylum tricornutum*, *Crassostrea gigas*, *Amphibalanus amphitrite* and *Tigriopus fulvus*). Species-specific toxicity scores and a final index were generated on the basis of some literature suggestions to facilitate toxicity data interpretation. The merge of data from ecological and ecotoxicological surveys, bearing in mind the hints of local and national authorities (i.e. cultural heritage protection), will promote the identification of the most suitable piling materials for the proper application.

### TU 384
**Cellular changes in microalgae exposed to effluent from pulp and paper mill**
HL Soares, E Baptista
Universidade Federal de Santa Catarina, FLORIANOPOLIS, Brazil
Pulp and paper mill effluents, especially those from processes using molecular chlorine, which produce organochlorine compounds derived from lignin and resin acids which have been pointed out as very toxic to many organisms such as fish, algae and microcrustaceans. The aim of this study was to characterize the possible changes in the ultrastructure of unicellular microalgae - Scedesmus subspicatus - using transmission electron microscopy (TEM). The microalgae were grown in different concentrations of effluent (0-6-25 and 50%, with 0% as control) for 72 h under constant aeration, at 25 oC and under continuous illumination (1500 lux). Samples containing algae were fixed with glutarandeído (2.5%) and washed with phosphate buffer - pH = 7.1. Post-fixation and washes, the samples were treated with osmium tetroxide, diluted with 1% sodium phosphate buffer 0.1 M for 3 hours and then washed with phosphate buffer - pH = 7.1. Dehydration was performed with acetone (30-100%) and infiltration with Spurr resin. Algae cells exposed to the effluent showed significant changes in the plasma membrane and cell wall, chloroplast morphology and increased concentration of the starch stored. Additionally, morphological cell alterations were observed such as the elongation in a given direction. The observed changes are more intense in samples containing higher concentrations of effluent.

### TU 385
**Toxic effects of effluent from pulp and paper mill on photosynthetic capacity of microalgae**
HL Soares, E Baptista
Universidade Federal de Santa Catarina, FLORIANOPOLIS, Brazil
Several studies have demonstrated toxic effects of effluent from pulp and paper mill for microalgae. These effluents contain many substances with toxic potential for these organisms, for example, chlorophenols, resin acids, lignin derivatives, among others. The aim of this study was to assess the photosynthetic capacity of microalgae Scedesmus subspicatus in medium containing different concentrations of effluent from the production of bleached pulp through conventional process. It was evaluated the rate of algal growth, the kinetics of oxygen production, changes in concentration of chlorophyll a and b, quantum yield and maximum fluorescence intensity, rate of quenching photochemical and non-photochemical quenching. The algal growth rate was evaluated during 72 h under continuous illumination (1500 lux) at a temperature of 25 oC and constant air flow. Photosynthetic parameters were measured using a PAN fluorometer, in samples collected after 48 and 72 h of exposure to the effluent (0, 6, 12, 25, 50 and 100%, 0% used as control). The toxic effects were indicated by the reduction of algal growth rate correlated to increasing effluent concentration. The alteration of photosynthetic capacity was shown by the reduced maximal fluorescence intensity, slower production of oxygen as well as lower values of oxygen concentration in the stationary phase. We also observed a reduction in the concentration of chlorophyll depending on the effluent concentration used. The results indicated significant changes in the photosynthetic system of microalgae, especially in their PR system.

### TU 386
**Intraspecific competition delays recovery of population structure**
EF Liess, K Foit
UFZ, LEIPZIG, Germany
Ecotoxicological field studies have shown that total abundance and biomass often recover shortly after pulsed toxicant stress. In contrast, population structure showed comparatively long-term alterations before reaching pre-treatment conditions. We investigated two mechanisms that may explain the prolonged recovery of population structure: latent toxicant effects on life-history

traits on the individual level and competition on the population level. To test these hypotheses we exposed populations of Daphnia magna to a pulse of the pyrethroid Fenvalerate. For several generations the populations were kept at two different degrees of competition: strong competition at carrying capacity and reduced competition main- tained by simulated predation. After disturbance due to Fenvalerate exposure, biomass recovered after 14-17 days. In contrast, size structure characterised by a lack of large and dominance of small organisms recovered after 43 days in populations with strong competition. Size structure recovered twice faster in populations with reduced competition. We explain this as follows: due to toxicant induced mortality, food availability and consequently birth rate increased and populations were dominated by small individuals. In populations without predation, these cohorts grew and eventually exerted high intraspecific competition that (i) stopped further growth of juveniles and (ii) increased mortality of adults. These demographic processes were mainly responsible for the prolonged recovery of size structure. In con- trast, for populations with predation, the regular harvest of individuals reduced competition. Juveniles developed continuously, allowing a fast recovery of size structure in these dynamic populations. In risk assessment the duration for populations to recover from (toxicant) stress, is crucial for the determination of ecological acceptable effects. We conclude that competition needs to be considered in order to understand and predict recovery of size structure.

### TU 387

**The secret in the sauce: the effects of varying environmental conditions on the toxicity of mine effluent constituents to coldwater fish**

DL Moore[1], D Poirier[2], P Sibley[1], K Solomon[1]
[1]University of Guelph, GUELPH, Canada
[2]Ontario Ministry of the Environment, ETOBICOKE, Canada

Due to method standardization, current regulations may not afford protection against adverse effects of mine developments under non-standard pH, temperature, and hardness conditions of arctic waters. These effects may be due to liberated minerals, processing by-products, and service community wastes. Canadian mines are controlled under the Fisheries Act, regulating "Any substance that is[3DOTS]deleterious to fish or fish habitat or to the use by man of fish that frequent that water". These regulations limit effluent parameters based on toxicological evidence produced via assay methods published by Environment Canada. For coldwater fish, rainbow trout is used as a surrogate and employs conditions optimal to that species. In contrast, locations of concern exhibit temperatures 10°C colder than standard test conditions, hardness 2-10 times lower than dechlorinated water, and variable pH due to contamination and natural geology.
The study aims to characterize the variability of effluent toxicity across a range of species and conditions while assessing whether the current standard test is protective enough to cover this variation by comparison of standard and 'amended standard' (varied conditions) assays. Eighteen contaminants (NaCl, NaNO2, NaNO3, Na2SO4, KCl, CaCl2, Cd, Cr, As, Cu, Zn, Mg, Ni, Al, MoO4, Se, NH4OH, NaClO, and toluene) were tested using five species of fish native to Northern Canada (arctic charr, lake trout, lake whitefish, round whitefish, and arctic grayling) across a range of pH (5.5, 6, 6.5, 7, 7.5, and 8), temperature (5,10, and 15ð-ðC), and hardness (30, 60, and 120ppm) conditions and their observed effects modeled as 24,48,72, and 96-hour LC50 values.
By comparing these results to each other and to those of the standard rainbow trout test, we have assessed the effect of pH, temperature, and water hardness on contaminant toxicity and time-to-toxic effect within and between species while characterizing the ecological protection afforded by current regulations. The data suggests that, in some instances, the standard has failed to capture the potential toxicity exhibited in non-standard species and non-standard, real-world conditions. Should this variability of non-standard conditions exceed the resiliency of the standard test to act as a surrogate, the mandate of the Fisheries Act to provide adequate protection to fish, fish habitat, and human use of fish will not be met. This potential risk is guiding the project's second phase of research.

**Asellus aquaticus as a sensitive test organism**

GG Gonsior, KW Weber, T Klug
Eurofins Agroscience Services GmbH, NIEFERN-ÖSCHELBRONN, Germany

Toxicological test with Agrochemical showed that Asellus is one of the most sensitive species. Acute toxicity on Asellus aquaticus compared to effect on Daphnia magna, Chironomus riparius, Hyalella azteca, Lumbriculus variegatus and Gammarus pulex will be presented.

### TU 389

**The case of Phaeodactylum tricornutum in wastewater toxicity monitoring**

G Libralato, EG Gentile, AVG Volpi Ghirardini
Cà Foscari University of Venice, VENICE, Italy

Marine phytoplankton is highly productive in coastal ecosystems where it generally occurs the major exposure and uptake of contaminants associated with anthropogenic pollution discharges. Phytoplankton presents very high surface-to-volume ratio and may respond rapidly to suspended contaminants. Therefore, some phytoplanktonic species are frequently used as pollution bioindicators, providing information about potential impacts on the supported marine-coastal food webs. The diatom Phaeodactylum tricornutum is commonly used in toxicity testing according to the standardised protocol UNI EN ISO 10253:2006. Unfortunately, it seems that a complete inventory of the tested substances and matrices has not been compiled yet. The purpose of this study has been to review scientific literature about P. tricornutum and to specifically assess its sensitivity and reliability towards wastewater samples. More than a hundred wastewater samples were taken into considerations. They originated from domestic, industrial and mixed domestic-industrial sources and were treated according to two main wastewater treatment technologies (Activated Sludge Sequencing Batch Reactor and Ultra-Filtration Membrane Biological Reactor). Results showed the existence of two main effect scenarios: biostimulation and toxicity. The main question was about how to weigh biostimulation compared to toxicity and if it was possible to merge both of them in a wastewater toxicity score to rank samples and provide some management tools. Referenced and improved approaches were taken into consideration.

### TU 390

**Assessing effects of Ultraviolet B radiation on Physa fontinalis using biochemical biomarkers**

MD Pavlaki, NGC Ferreira, S Mesquita, F Ribeiro, AMV Soares, S Loureiro
University of Aveiro, AVEIRO, Portugal

Biomarkers are widely used in order to detect stress in organisms as early warning tools after exposure to different environmental conditions. In addition, biochemical biomarkers can help to understand stressors mode of action. The aim of this study is to evaluate the effects of UVB radiation in different biomarkers of the aquatic snail Physa fontinalis. Incident UV-B levels are increasing due to ozone depletion and can penetrate to significant depths in aquatic environments having a major impact on organisms both directly and indirectly, inducing among other effects DNA damage, mortality, and mutagenesis. 96 hours acute tests were conducted using different shell lengths of the organism to different exposure times of UV-B showing that survival was significantly affected. Biomarkers activity (e.g. AChE and GST) was determined and correlated with the observed mortality.
This study shows the importance of including UV-B exposure and the inherent effects in environmental risk assessment procedures. UV-B induces changes in aquatic organisms as in their role in the environment, and therefore these effects can be transposed to ecosystems, possibly jeopardizing their services.

**Physiological measurements in Cerastoderma edule (Bivalvia: Cardidae) at contaminated sites at the northwest Portuguese coast**

J Nilin[1], GC Ferreira[2], JLT Pestana[2], S Loureiro[2], LV Costa-Lotufo[1], AMVM Soares[2]
[1]Universidade Federal do Ceara, FORTALEZA, Brazil
[2]CESAM,Department of Biology University of Aveiro, AVEIRO, Portugal

Ria de Aveiro is a highly productive coastal lagoon in Portugal, and it receives a diverse input of contaminants derived from industrial and urban effluents, port and shipyards activities and agriculture runoffs. The purpose of this investigation was to evaluate the physiological parameters, as rates of oxygen consumption and clearance, survival in air exposure and energy reserves with cellular energy allocation (CEA), of the common cockle *Cerastodema edule* collected at six stations along Ria de Aveiro. Animals (20-30 mm) were collected in July-10 during the low tide and acclimatized at laboratory in artificial seawater, one hour before the assays. Oxygen consumption was determined by simple static respirometry, using cockles (n=10) held for one hour in 50mL gastight syringes filled with artificial seawater and one animal per syringe. To measure clearance rate cockles were individually placed in 200 mL chambers (n=5 per station) filled with Neutral Red solution (1.5 mg.L-1) prepared in seawater. This method was based on the rate of absorption of Neutral Red by animals, that was recorded at 15min-intervals for 45 minutes at 530nm. To analyze the capacity of air survival, animals (n=21 in triplicate) were kept in 1L glass jar at 20ºC and 100% humidity during eight days. Deaths by means of extended shell gape were recorded every day. Finally, the CEA in *C. edule* tissues (n=10) was measured based on the energy reserves available and the energy consumed during the assay. The results of this study intended highlight the importance of physiological parameters analyzes as good indicator of animal fitness and its evaluation could be used as biomarker.

### TU 392

**Effects of copper on the life cycle traits of Physa fontinalis**

MD Pavlaki, AMV Soares, S Loureiro
University of Aveiro, AVEIRO, Portugal

Copper is an essential metal to several organisms but like other metallic elements can cause toxicity when in excess. Copper can enter into the aquatic system through industrial effluents, agriculture runoffs and domestic wastewaters. This study aimed to assess the survival, egg hatching, growth and reproduction of the freshwater pulmonate snail Physa fontinalis after exposure to copper sulfate in laboratory conditions. A 96h survival test using adult and juvenile snails with different shell lengths showed increasing toxicity as the shell length decreases. Significantly low copper values (~1μg/L) appear to adversely affect the hatching and survival of egg masses as well as the reproduction and growth of the aquatic snail suggesting that P.fontinalis is more sensitive compared to other aquatic snails (e.g. Lymnaea luteola L, 96h EC50 ~ 28μg/L) or even other aquatic organisms usually used as model organisms in ecotoxicological approaches.

## CS02 - Environmental disasters & oil spills

### WE 002

**Do oil droplets matter? Oil spill effects on North East Arctic cod larvae**

F de Laender[1], I Overrein[2], AJ Olsen[3], D Altin[4], WLG Johansen[2], WLG Johansen[2], BH Hansen[2], N Nordtug[2]
[1]Ghent University, GHENT, Belgium
[2]SINTEF, TRONDHEIM, Norway
[3]Norwegian University of Science and Technology, TRONDHEIM, Norway
[4]Biotrix, TRONDHEIM, Norway

Oil exploration and production in the Atlantic moves northwards towards spawning and nursery areas of fish species that sustain some of the world's largest fisheries. Models are therefore needed that can simulate the effects of oil dispersions on early life stages of fish. In this study, we calibrated a newly developed individual based model (IBM) to experimental data to infer effects of the water soluble fraction (wsf) and of an oil dispersion (wsf and droplets) on two key endpoints of North East Arctic cod (Gadus morhua) larvae: feeding rate and survival probability. The model was calibrated on data from two experiments that had identical chemical composition and concentration of the wsf ($\Sigma$PAH = 0.03 to 30 μg L-1) and only differed in the presence/absence of oil droplets. Both exposure types (wsf and dispersion) decreased feeding rate (control: 0.4 d-1) and survival probability (control: 0.96). Decreases occurred in a concentration-dependent fashion and did not significantly differ between exposure types, with EC50s of 2 (feeding) and 7 μg/L $\Sigma$PAH (survival probability). Additionally, the fit of the IBM model to growth and survival data was not significantly different between the two exposure types. Our results thus indicate that oil droplets did not significantly contribute to oil toxicity towards ingestion and survival of cod larvae. More complex models that consider oil droplet toxicity in addition to the toxicity of the wsf are therefore concluded not to be more accurate than simpler models that neglect oil droplet toxicity.

### WE 003

**Do oil dispersants make spilled oil more toxic to fish?**

PV Hodson
Queen's University, KINGSTON, Canada

The recent Deepwater Horizon disaster was the world's largest unintentional oil spill. It was unprecedented in its duration, volume spilled, and the technology applied for control and clean-up. Among these unique features was the continuous and wide-spread application of oil dispersant, at the surface and at the discharge, 1500 m deep, generating public concern about dispersant toxicity and the effects of dispersion on oil toxicity. Recent USEPA reports claim little difference in acute toxicity to marine fish and invertebrate species among commonly available dispersants and between dispersed and non-dispersed Louisiana Sweet Crude. The EPA reports were technically correct: the toxicity of waterborne hydrocarbons does not vary with chemical dispersion. However, the agency did not tell the entire story, omitting any consideration of loading. Our research on the chronic toxicity of dispersed oil to fish embryos demonstrates that toxicity expressed as oil loading increases by a factor of 10 to 1000 times with dispersion, primarily because 10 to 1000 times more oil enters the water column. From a practical perspective, the risk of oil toxicity to fish increases an equivalent amount because the action of dispersant is on the exposure component of the risk equation, not on the potency of the toxic components of oil. Wise decisions on the application of dispersants requires that all contributors to risk be considered including toxicity, exposure, receptor and the modifying effects of the receiving environment.

**WE 004**

**Marine environmental impact of oil spill on vertebrate: gene expression changes in marine medaka, Oryzias javanicus**

S Woo, S Yum
Korea Ocean Research & Development Institute, GEOJE-SI, South-Korea

The accidents like an oil spill give the enormous effects on marine and coastal ecosystem as well as individual organism. In December 2007, an oil spill in marine crane Hebei Spirit polluted the mid west coast and it spread very fast throughout the whole west coastal regions. In this study we aimed to discover the marker genes which expressions were changed by exposure to ecotoxicants or pollutants using the marine medaka (Oryzias javanicus) microarray and to develop as biomarkers for the detection of environmental pollution like oil spills. Also, we investigated the effects of organic pollutant on transcriptional changes after fishes were exposed to bisphenol A, polychlorinated biphenyl, 17beta-estradiol as well as WAFs (water accommodated fractions) from crude oil and compared the profiles. These results suggested that transcriptional changes of genes could be good biomarkers to detect stress levels in O. javanicus and provided the general translation about effect of oil contamination on marine organism. And the compact microarray chip development including new biomarkers could be very helpful in detecting of ecotoxicological stress responses.

**WE 005**

**Temporal and geographical trend in the genotoxic effect of the extracts of accidentally oil-spilled marine sediments on the blood cells of striped beakperch (Oplegnathus fasciatus)**

HJ Lee[1], W Yang[1], GB Kim[1], J Lee[2], U Yim[3], WJ Shim[3]
[1]Gyeongsang National University, TONGYEONG, South-Korea
[2]NeoEnBiz, BUCHEON, South-Korea
[3]Korean Ocean Research and Development Institute, GEOJE-SI, South-Korea

To investigate the genotoxic effect of marine sediment on aquatic organism, sediment samples were collected from 13 sites along the coastal line of Taean Country, Korea after the Hebei Spirit Oil Spill had accidentally occurred. Striped beakperch (Oplegnathus fasciatus) blood cells were exposed to sediment extracts and DNA single strand breakage in the blood cell was examined using the comet assay. Thirteen days after the spill, Levels of DNA damage in the blood cells to sediment extracts were 3.86 in mean tail moment. The highest DNA damage of 13.75 was found at Sinduri, one of heavily oiled sites. One and half year after the spill, DNA damage decreased at most sites analyzed with mean tail moment of 1.58. From this decreased DNA damage, this study area was supposed to be very quickly recovered from oil spill just within one and half year. The samples showed a significant ($p<0.001$) correlation between concentrations of polycyclic aromatic hydrocarbons (PAHs) in sediments and DNA single strand breakage in the blood cell during both spatial and temporal sampling periods. Therefore, the comet assay could be a successful tool in assessing genotoxicity of PAHs in marine sediment affected by oil spill.

**WE 006**

**Soil and groundwater contamination analysis and assessment to identify the responsibility of a chemical company in an environmental disaster**

G Perin[1], F Iadarola[2], A Cecchin[3], S Lombardo[3], M Maniero[3], A Giacometti[4]
[1]IDEAS Centre - University of Venice - Archives of Environmental-Human Toxicology, VENICE, Italy
[2]Studio Tecnico Iadarola, GORIZIA, Italy
[3]IDEAS Centre - University of Venice, VENICE, Italy
[4]Environmental Science Dept - University of Venice, VENICE, Italy

In an area in the North of Italy, nearby a chemical plant site, high levels of organic and inorganic pollutants in groundwater have been detected, determining a potential health and environmental hazard. This work followed a public authority investigation; we carried out an analysis and evaluation of a large set of pollutants in soil and groundwater in order to identify which amount of environmental contamination is chargeable with that factory. A large survey of almost 600 samplings (soil and water) has been planned and carried out in an area close to the facilities, monitoring organic and inorganic compounds (i.e. arsenic, cadmium, mercury, nickel, benzo(a) pyrene, benzene, toluene, hexachlorobenzene, polychlorinated byphenyls); geostatistical modelling allowed to determinate the spatial distribution of pollutants in groundwater system.
The research has demonstrated the cause-effect relationship between the industrial activities and the kind of pollution detected in the soil and groundwater.

**WE 007**

**Risk assessment of residual concentrations derived from a blow out of a crude oil well in Italy: a tool to achieve the complete release of the impacted areas after years of bioremediation activities**

S Verdelocco[1], E Sordini[2], G Andreotti[1], A Battaglia[1], S Sandri[2]
[1]AECOM Italy srl, MILANO, Italy
[2]Eni esploration & production - SIAM - AMTE, SAN DONATO MILANESE (MI), Italy

In 1994 the site located in Piedmont, Northern Italy, was the scene of a large inland crude oil spill following an oil well blow-out. The event resulted in approximately 15,000 m3 of light crude oil being released overland contaminating both soil and groundwater.
Land use in the area is agricultural with the majority used for the production of rice. The area, just beneath a thin loamy superficial layer is underlined by 60 m of fluvioglacial materials constituting a high permeability/high yield phreatic. Groundwater levels at the site fluctuate by 6 m seasonally with higher levels during the summer period due to surface recharge from agricultural irrigation practices. Lenses of non-aqueous-phase-liquids (LNAPLs) were detected floating on the water table ever since the blow-out.
Since the regulators and farmers requested that the impacted soil be remediated without altering its agricultural and biological properties, bioremediation was selected as the preferred approach. Landfarming and biopile were used for surface soils, bioventing for contaminated vadose zone soils, bioslurping for LNAPL floating on the water table and natural attenuation for dissolved-phase hydrocarbons. This integrated approach lasted 5 years and lead to the reclamation of the original impacted area. The regulators allowed the usual agricultural activities to be resumed all over the impacted area.
A risk assessment was performed using the software RBCA Tool kit 1.3b (2000). The unsatured soils and groundwater were selected as the secondary source of contamination. The selected receptors were on site workers (farmers) and off-site residents;the migration pathways were outdoor vapour inhalation and dermal contact and ingestion of surface soil. The groundwater was considered as an environmental receptor. Two exposure scenarios were assumed based on the cycle of cultivation of rice: Scenario 1 comprising activities during which the ricefields are dry and the water table is around 11 m below ground; Scenario 2 comprising activities during which the ricefield are flooded and the water table is around 6 m below ground. A study was also performed on mais and rice samples to assess the effects of the residual concentrations on the quality of the crops and the possible consequences to humans of their consumption.
The risk assessment allowed the complete release of the areas. A monitoring period for the groundwater and a campaign of outdoor air measurements are being planned with the regulators.

**WE 008**

**Environmental factors affecting the toxicity of dispersed oil for herring embryos (Clupea sp.)**

SE Johnson[1], SC Courtenay[1], M Boudreau[2], K Lee[3], PV Hodson[4]
[1]Fisheries and Oceans Canada at the Canadian Rivers Institute, University of NB, FREDERICTON, Canada
[2]Gulf Fisheries Centre, Fisheries and Oceans Canada, MONCTON, Canada
[3]Bedford Institute of Oceanography, DARTMOUTH, Canada
[4]Queen's University, KINGSTON, Canada

When oil spills occur, chemical dispersants can be used to break up oil slicks in an effort to mitigate the negative impacts on organisms. However, the dispersed oil in the water column may expose pelagic and benthic organisms to the toxic constituents of the oil. Environmental factors, such as salinity and temperature, may effect the solubility and therefore, the concentration of polycyclic aromatic hydrocarbons (PAH) being delivered into the water column. To best treat oil spills, managers need to know how dispersed oil may affect the early life stages (embryos and larvae) of coastal fish species at different environmental conditions. Therefore, the toxicity of Water Accommodated Fractions (WAF) and Chemically Enhanced Water Accommodated Fractions (CEWAF) of Alaska North Slope (ANS), Medium Grade South American (MESA) and Arabian light crude oils were tested during the embryonic development of Pacific herring (Clupea pallasi) from two different populations. Toxicities of Arabian light crude oil CEWAF and WAF at 7.5”ð, 15”ð and 30”ð were tested during the embryonic development of Atlantic herring (Clupea harengus) from a spring spawning population; and at 7°C, 10°C, and 15°C from a fall spawning population. Toxicity of test solutions was assessed based on percent survival, percent developing normally, and prevalence and severity of morphological abnormalities. The most commonly observed morphological abnormalities were those associated with PAH exposure: spinal curvature, pericardial and yolk sac edemas, cranio-facial malformations and skin lesions. Abnormalities were produced by both WAF and CEWAF of all oils tested and were observed in both Pacific and Atlantic herring. Exposure to colder water increased spinal curvatures and cranio-facial malformations while warmer water increased yolk sac edemas and skin lesions at lower concentrations. Embryos exposed to crude oil also suffered from increased mortality, reduced heart rates, and slightly reduced lengths compared to control embryos. This study suggests that managers of oil spills considering dispersant use can minimize toxicity to coastal fish by incorporating information on salinity and temperature of the receiving environment.

## EC03 - Biodegradation and bioremediation of organic pollutants

**WE 010**

**Enhanced biodegradation screening tests: Degradation potential natural environmental media**

S Fiebig, N Mendel, L Geisler, U Noack
Dr.U.Noack-Laboratorien, SARSTEDT, Germany

To improve the environmental relevance of persistency assessments without moving up to the level of simulation tests, several potential enhancements to the ready biodegradation tests are given by the REACH guidance. Substances that degrade in these enhanced biodegradation screening tests are not considered as ready biodegradable but the results are used in persistency assessments. The inoculum used for ready biodegradability tests is derived from sewage treatment plants, e.g. activated sludge, sewage or secondary effluent, whereas for the enhanced screening tests only the use of natural environmental media as source of inoculum is allowed. As the biodegradation potential and environmental realism depends on a representative diversity of bacteria in the inoculum test strategies that can maximize the diversity and adaptation of the micro-organisms were developed. The test duration can be prolonged up to 60 days, the test volume and with it the probability of introducing competent bacteria can be increased or the biomass concentration can be increased. Furthermore low-level pre-adaption and semi-continuous assessments are possible. So far only little experience is available on the use of these approaches and the degradation potential of natural environmental media like marine or fresh water. As the inoculum can be derived from different sources and environments the degradation potential may vary distinctly. The degradation potential of different inocula derived from different environmental sources in the context of persistency assessment of chemicals was compared and the results will be presented.

**WE 011**

**Investigation of the role of adaptation in the biodegradation of chemicals in the impact zone of an untreated discharge using OECD 314E**

C Finnegan, D Sanders, RA van Egmond, O Price
Unilever, BEDFORD, United Kingdom

In many parts of the world, particularly in developing regions, untreated wastewater is routinely emitted directly into surface water bodies. This scenario is typically associated with high levels of suspended solids, biochemical oxygen demand (BOD), nitrite and unionised ammonia in receiving waters, resulting in significant ecological impairment. The receiving water will treat the untreated discharge through a mixture of physical, chemical and most importantly biological "self-purification"processes. This scenario presents a number of difficulties for conventional risk assessments for 'down-the-drain' chemicals. Most fundamentally, in the absence of removal by secondary sewage treatment, the predicted environmental concentration (PEC) will often exceed the predicted no-effect concentration (PNEC). However, since the ecosystem in the receiving environment will already be significantly impacted by other constituents present in raw wastewater, an assessment of the biodegradation during "self-purification"is required.
A guideline now exists for simulating this scenario in a laboratory, OECD 314(E) 'Biodegradation in an untreated - surface water mixing zone'. The guideline has been developed to determine the final extent and rates (primary and ultimate) of a chemical upon its release in an untreated

discharge scenario. It also allows a comparison of the relative rate of removal of the test chemical in relation to the key water quality parameters which can be used to define the impacted zone in the receiving water. These guidelines are relatively new (2008) and little data have been published on the fate of chemicals in studies of this nature.
This guideline was used to investigate the fate of 14C radio-labelled test chemicals incubated with 1 part wastewater to 2 parts surface water, using a batch system. As well as looking at the "non-adapted"situation, a two phase test design was also investigated. Here, a preadaptation period of 14 days was used during which the water quality parameters were monitored, before renewal of a portion of the test medium spiked with the 14C labelled test material. This allowed the determination of the influence of a pre-exposure cycle on biodegradation rates of the test chemical and also the nitrification cycle. These results are discussed in relation to risk assessment in the impact zone.

**WE 013**
**Assessment of persistence of chlorinated paraffins using OECD biodegradability tests (ready and enhanced)**
G Ginkel van, A Louwerse, R Geerts
AkzoNobel, ARNHEM, The Netherlands
Tetradecanes with varying degree of chlorination have been synthesized to assess their persistence. Tetradecanes with 41.3, and 45.5% chlorine reached >60% biodegradation at day 28 in Closed Bottle tests. The tetradecanes with a higher degree of chlorination are not readily biodegradable. In the prolonged Closed Bottle tests biodegradation percentages of chlorinated tetradecanes were of >60 at day 56 (chlorinated tetradecane (50.0%)) or close to 60 (chlorinated tetradecane (55.0%)). The chlorinated tetradecane (60.2%) reached a biodegradation percentage of 40 at day 84. Chlorinated tetradecane (41.3, 45.5 and 50.0% Cl) should therefore not be considered as persistent. The biodegradability of chlorinated tetradecanes is retarded by increasing degree of chlorination resulting in partial degradation of tetradecanes with higher degrees of chlorination.

**WE 014**
**Degradation of the artificial sweeteners acesulfame, cyclamate, saccharin, and sucralose in soils**
IJ Buerge, M Keller, MD Müller, T Poiger
Agroscope Changins-Wädenswil Research Station ACW, WÄDENSWIL, Switzerland
Artificial sweeteners are consumed in substantial quantities as sugar substitutes and were previously shown to be ubiquitously present in the aquatic environment. Sweeteners may also end up in soils through various pathways. Wastewater-polluted surface water may be used for irrigation of agricultural fields. In certain countries, digested sewage sludge is applied as fertilizer in agriculture. Furthermore, untreated wastewater may seep into subsoils through leaky sewers. The sweetener saccharin is also registered as additive in piglet feed and the compound may get into agricultural soils via application of manure. Finally, saccharin is a major soil metabolite of certain sulfonylurea herbicides. We studied the degradation of four artificial sweeteners in six different soils. The soils were selected to cover a wide range of properties, in particular pH (4.0-7.5), organic carbon (1.2-18%), and texture. Batch incubation experiments were conducted at 20°C and 34-60% of the maximum water holding capacity. Cyclamate, saccharin, acesulfame, and sucralose were degraded with half-lives of 0.4-6 d, 3-12 d, 3-49 d, and 8-124 d, respectively. A first-order kinetic model fitted the concentration data reasonably well. The fast degradation of cyclamate and saccharin in soils is consistent with the extensive elimination observed in wastewater treatment plants (WWTPs, ≈ 90 and ≈ 99%, respectively). Somewhat less expected was the fairly rapid degradation of acesulfame and sucralose in soils, which is in contrast to their persistence in WWTPs. These differences may be rationalized by the presence of different microbial communities in activated sludge and soil. Furthermore, residence times in activated sludge of typically a few hours are obviously much shorter than contact times in soils.

**WE 015**
**Bacterial degradation of 1H-benzotriazole**
B Morasch, V Heesel, D Ilieva, SB Haderlein
University of Tuebingen, TUEBINGEN, Germany
The complexing agent 1H-benzotriazole (BT) is a widely-used corrosion inhibitor in cooling and heating fluids, dishwashing detergents, and aircraft de-icing fluids. BT, as a high production volume chemical, is among the compounds with the highest detected concentrations in wastewater effluents and surface waters. Due to its apparent persistence against biodegradation, it is ubiquitously present in the aquatic environment. This is even more alarming since the compound might have ecotoxic effects. Generally, BT was considered non-biodegradable by bacteria under oxic and anoxic conditions.
In this study, we investigated the presence of an intrinsic biodegradation potential for BT in two environmentally relevant compartments: sewage sludge and deep aquifer sediments. An aerobic sewage-sludge-derived mixed culture coupled BT degradation with bacterial growth. During biodegradation of BT, N-methylaniline and further transformation products with absorption maxima at 367 and 550 nm were formed. This is the first report on bacterial growth with BT at mesophilic temperatures and underlines that sewage sludge is a habitat of the respective microorganisms. The anaerobic intrinsic biodegradation potential for BT was studied in deep aquifer sediments eventually contaminated by heat transfer fluids leaking from borehole heat exchangers. Concentrations of BT and its derivative tolyltriazole stayed constant over a period of 200 days indicating that no intrinsic biodegradation potential was detectable under the various redox conditions investigated.

**WE 016**
**The isolation and characterisation of bacteria capable of degrading the strobilurin fungicide, azoxystrobin**
CC Howell[1], KT Semple[2], GD Bending[1]
[1]University of Warwick, WARWICK, United Kingdom
[2]Department of Environmental Science, Lancaster University, LANCASTER, United Kingdom
Azoxystrobin [methyl (E)-2-{2-(6-(2-cyanophenoxy)pyrimidin-4-yloxy)phenyl}-3-methoxyacrylate] was the first of the strobilurin group of fungicides to be released in 1996. It has a broad spectrum of activity and has been approved for use in over 80 different crop types, which equates to greater than 400 crop/disease systems in total.
A major route of azoxystrobin degradation is considered to be due to microbial action, beginning with the demethylation of one of the side chains to produce the metabolite, azoxystrobin acid. However, the extent to which azoxystrobin is completely mineralised to carbon dioxide (CO2), and the identities of organisms that are potentially involved with the degradation process remain unknown.
In this study azoxystrobin-degrading cultures were produced from a sandy loam soil from the UK by a sequential enrichment series. Comparisons were made between the degredative capabilities of soils that had had no previous exposure to azoxystrobin and soil that had been exposed to a 25mg/kg dose of the compound 4 months prior to the start of the study.
Bacteria were isolated and tested for their degradative capabilities. The 16S rRNA from isolates that degraded azoxystrobin to a high level were sequenced. Degrading organisms were then characterised using assays to determine whether the following aspects impact degradation: 1) The media used to grow the colonies 2) The presence of alternative carbon and nitrogen sources.
The results of the sequential enrichments show that in the first enrichment the soil which had previously received azoxystrobin showed a greater capacity to degrade the compound. However, after the first enrichment there was no difference between the two soils.
Two strains capable of degrading azoxystrobin were isolated. Sequencing identified them as Cupriavidus basilensis and Rhodanobacter sp. Characterisation assays showed that solid growth media type had no significant impact on azoxystrobin degradation. Both of the degrading organisms required an additional nitrogen source to be present for degradation to occur. The presence of an alternative carbon source reduced azoxystrobin degradation by approximately 40%.

**WE 017**
**Isolation of Vibrio sp. in marine sediment from the NW coast of Baja California, Mexico and its growth in the presence of DDT**
VB Orozco, EG Gutiérrez, AB Muñoz, RM Cajal, VZ Macías
Instituto Investigaciones Oceanológicas Universidad Autónoma de Baja California, ENSENADA, Mexico
Studies have shown that bacteria can survive in contaminated environments and contribute to the biotransformation of persistent organic pollutants like DDT in marine sediments. The bacteria possess enzymes such as dioxygenases, that are able to modify the benzene ring of organochlorine compounds; for example, the gene VFA0416 DOPA 4, 5 introduces two oxygen atoms in the benzene ring, displacing the chlorine atom by a hydroxyl. This gene has been found in *Vibrio fisheri* ES114. Because of the importance of DDT, a bacterium was isolated from marine sediment from the NW coast of Baja California, Mexico and identified biochemically and molecularly as belonging to the genus *Vibrio*. Laboratory assays were run in triplicate using minimal salts medium containing DDT and minimal salts medium without DDT at 28°C and 8°C for 96 hours. Bacteria were stained with DAPI and counted under a fluorescence microscope, and their specific growth rates (μ) and duplication times (g) determined. To search for the gene VFA0416 DOPA 4, 5 in *Vibrio* sp., the genomic and plasmid DNA was extracted and amplified by PCR, using Vibrio fisheri ES114 as positive control. Highest specific growth rates and lowest duplication times occurred in both culture media at 28°C because temperature accelerated cell metabolism. Plasmid DNA of Vibrio sp., contained VFA0416 DOPA 4, 5, which is known to degrade DDT. The concentrations in the minimal salts medium did not affect the growth of Vibrio sp. since the specific growth rates were similar to those obtained in the medium lacking this compound.

**WE 018**
**Quantification of Alkane monooxygenase genes to monitor the biodegradation process in environmental field**
E Nardini, AB Burchardt, TL Lettieri
EU JRC/Institute for Environment and Sustainability, ISPRA, Italy
Prediction of pollutant biodegradation is essential for the correct management of the process. With the aim to find suitable methods to monitor bioremediation strategies, within the large collaborative project of 16-member consortium, BACSIN (Bacterial Abiotic Stress and Survival Improvement Network 1), we studied environmental samples from an area located in the Czech Republic. Hradcany is a former military airport highly contaminated with petroleum hydrocarbons and under air sparging bioremediation treatment (bioventing) since 1997. Alkanes (saturated hydrocarbons of different sizes and structures) are major components of oil spills, that can be efficiently degraded by several microorganisms. We focused on alkane (Alk) monooxygenases, a family of important enzymes involved in alkane degradation which catalyse the initial oxidation of the alkane substrate to a 1-alkanol in aerobic conditions. Could these genes be good candidates to monitor bacterial catabolic activities in bioremediation strategies? More than 60 homologues of Alk genes with high sequence diversity are known 2. We developed a molecular method based on TaqMan quantitative Real Time PCR (qRT-PCR) to quantify Alk genes of bacterial strains present in the Hradcany area. We analyzed 12 soil samples at different depths (3 from a clean area, 3 from a low contamination area, 3 from a medium and 3 from a high contamination area) and 4 groundwater samples from clean, low, medium and high contamination areas. Alk genes quantification is expressed related to microbial biomass levels in each sample and an increase of gene copy number is clearly detectable in some samples. This molecular method is very accurate and precise and allows identification and quantification of Alk genes during the degradation process in environmental samples e.g. groundwater and soil, contaminated by hydrocarbons. Our molecular approach can be used to assess the progress of bioremediation in a contaminated site.

**Microbial ecology approach for evaluating the effects of contaminants on soil and water ecosystems**
P Grenni, A Barra Caracciolo
Water Research Institute, National Research Coucil, MONTAROTONTO (ROME), Italy
Traditional parameters used for the Environmental Risk Assessment (ERA) of environmental contaminants are principally chemiodynamic and physico-chemical properties. Furthermore ecotoxicological effects on organisms in water and soil are assessed with standard acute and chronic ecotoxicologic tests on freshwater, marine and soil organisms.
Microbial communities are valuable indicators of the occurrence of disturbances due to exogenous physico-chemical stressors. The assessment of variations in microbial community structure is of basic importance in order to evaluate the impact of an environmental stressor.
Complex microbial communities may serve as ideal and ecologically relevant toxicity indicators. A number of microbiologically driven processes has been proposed to evaluate the effects of xenobiotics on ecosystems. Proteins, genes, metabolites, or lipids that, when expressed, present a pattern of molecular change in an organism in response to a specific environmental stressor, can be defined as environmental biomarkers.
The number of techniques to study microbial communities has increased exponentially over the last 20 years and the advent of culture-independent methods, such as molecular biological techniques, has changed the view of microbial diversity. Among these techniques epifluorescence microscopy ones, such as direct count of bacterial abundance (DAPI count), vitality (Live/Dead

cell viability assay), and Fluorescence In Situ Hybridization (FISH) have been showing effective tools for studying specific microbial populations in soil and water ecosystems. We show how the applications of these techniques to contaminated soil and water ecosystems allow to highlight the presence of particular bacterial groups involved in chemical degradation.

**WE 020**

**Root exudates from sunflower as a powerful chemoattractant for pollutant-degrading bacteria and its effect in bacterial dispersal**

C Jimenez Sanchez, JL Sanchez Quinones, M Cantos, JJ Ortega Calvo
Institute for Natural Resources and Agrobiology of Seville, SEVILLE, Spain

Bacterial movement through saturated porous media may be restricted by several factors, including increased path lengths (tortuosity), bacterial adhesion to surfaces, and geometrical restrictions due to pores of small diameter and dead ends. We propose bacterial chemotaxis as a mechanism that could enhance bacterial transport through saturated porous media. Chemotactic bacteria can therefore constitute a useful vector for relevant catabolic activities and/or nutrients in bioremediation projects.

We studied the chemotactic response of *Pseudomonas putida G7* towards root exudates of *Helianthus annuus* and its individual components (organic acids and aminoacids) by capillary assays. In well-controlled column systems, we studied the effect of these compounds on bacterial transport in porous media.

Our data suggest that *Helianthus annuus* exudates are a powerful chemoattractant for *Pseudomonas putida G7* and it could be used in bioremediation, improving bacterial dispersal.

**WE 021**

**Chemoeffectors change the swimming pattern of chemotactic bacteria and its transport in porous media**

C Jimenez Sanchez, JJ Ortega Calvo
Institute for Natural Resources and Agrobiology of Seville, SEVILLE, Spain

Bacterial chemotaxis causes movement to higher (attraction) or lower (repellency) compound concentrations. Our working hypothesis was that positive and negative chemoeffectors change the bacterial motility pattern of individual cells and this has a direct effect on deposition in porous materials. We studied the chemotaxis response of a naphthalene-degrading strain (*Pseudomonas putida G7*) to several compounds by capillary assay and its motility behavior by computer-assisted motion analysis. We also assessed the influence of these chemoeffectors on bacterial strain deposition in sand. When bacteria detected a positive chemoeffector, changes of direction of individual cells were less frequent and smooth movement increased. The bacterial deposition on the surface sand was low, thus promoting bacterial transport through sand. However, when bacteria detected a negative chemoeffector, the changes of direction were much more frequent and abrupt. This also had a direct effect in bacterial transport, promoting collision efficiency and bacterial deposition.

Positive or negative chemoeffectors may modulate bacterial transport in terms of pollution to be treated.

For localized and surface contamination in soils and aquifers, negative chemoeffectors would help to confine chemotactic bacteria in the contaminated site. In contrast, treatment of more dispersed areas of contamination and at a certain depth can be benefited with the use of positive chemoeffectors that increase the transport of chemotactic strains.

**WE 022**

**Influence of rhizosphere and root tissues on mineralisation of 14C-hydrocarbons in a pristine pasture soil**

AE Ite, OO Igunnugbemi, N Murray, KT Semple
Lancaster Environment Centre, LANCASTER, United Kingdom

Many plant species enhance the biodegradation of petroleum hydrocarbons, but the specific mechanisms by which this occurs are not clearly understood. Rhizospheres and crushed root tissues from 4 plants were screened in soil spiked with 12C/14C-hydrocarbons (phenanthrene, naphthalene, hexadecane or octacosane) dissolved in toluene to achieve a concentration of 10 mg kgð'1 and activity of approximately 83.3 Bq g-1, respectively. Among the plants tested include Reed Canary Grass (Phalaris arundinacea), Channel Grass (Vallisneria spiralis), Black Raspberry (Rubus occidentalis) and Goat Willow (Salix caprea). The effects of rhizosphere and root tissues addition on the catabolism of 14C-phenanthrene, 14C-naphthalene, 14C-hexadecane or 14C-octacosane to 14CO2 by indigenous microbial communities was assessed in freshly spiked soil slurry. It was found that rhizospheres amendment was as effective as crushed root tissues. Comparison of the degradation potential of the effective root tissues suggested that phytochemicals were the major substances that stimulated the apparent constitutive activities involved in degradation of PAHs. For a better understanding of the plant-microbe interactions involved in rhizosphere-stimulated mineralisation, the hypothesis that phytochemicals stimulate PAHs degradation will be investigated further by examining degradation of phenanthrene and naphthalene in soil amended with α-pinene, p-cymene or a mix of monoterpenes (α-pinene, limonene and p-cymene in 1:1:1 ratio). This study supports the claims that the abilities of various plant species to stimulate mineralisation of organic contaminants in soil are highly variable ranging from negative or no effect to highly stimulatory effects. These findings provide insight into the mechanisms by which plants enhance degradation of PAHs, and may have practical application for remediation of PAH contaminated soils.

**WE 023**

**Biodegradation of a polycyclic aromatic hydrocarbon in a soil co-contaminated with metals**

IS Obuekwe, KT Semple
Lancaster University, LANCASTER, LANCASHIRE, United Kingdom

Polycyclic aromatic hydrocarbons (PAHs) and heavy metals are among mixed pollution of major concerns in the soil environment. Overtime PAHs and metals become less bioavailable. In this present study, the impact of metals (zinc and copper admixture) on phenanthrene biodegradation was investigated over 63 day incubation period. The effects of zinc and copper concentrations (0, 50, 100, 500 and 1000mg/kg) on phenanthrene biodegradation, the effects of 'ageing' on bioavailability of these contaminant mixtures and their impact on bacteria measurement during phenanthrene biodegradation in soil were assessed, using respirometry and bacteria enumeration. The presence of zinc and copper at low concentrations (50 and 100mg/kg) had no significant effect on phenanthrene biodegradation, but phenanthrene biodegradation was significantly reduced at higher Zn and Cu concentrations, 'Ageing' significantly increased phenanthrene catabolism in Zn and Cu-amended soil at low concentrations, but the development of phenanthrene biodegradation was significantly reduced by the presence of Zn and Cu at higher concentrations. Bacterial cell counts decreased significantly as contaminants aged in soil but phenanthrene biodegradation correlated with increase in bacteria enumeration. Biodegradation efforts to remove polycyclic aromatic hydrocarbon in the presence of high concentrations of mixed-metals might be impeded. An insight into longer term ageing of metals and PAHs in the soil is necessary in order to assess the risk of these co-contaminants in soil.

**WE 024**

**Impact of biochar and wood vinegar on the sorption/degradation of glyphosate in fine sandy soil**

M Hagner[1], L Fagernäs[2], HM Setälä[1], K Tiilikkala[2], OP Penttinen[1]
[1]University of Helsinki, LAHTI, Finland
[2]Technical Recearch Centre of Finland, ESPOO, Finland

Burning of wood in the absence of oxygen produces three end products: gases, solids (biochar) and liguids (wood vinegar). When biochar is returned to soil several positive effects on soil quality can take place, such as reduced leaching of N fertilizers, enhanced plant growth, and altered pesticide behaviour in soils. Wood vinegar is a new innovation in plant protection working against various weeds, harmful insects and molluscs. It consist of over 10 000 chemicals, such as asetic asic, formaldehyde, ethyl-valerate and furfural. In our preliminary studies we observed that BOD addition had positive effects on soil microbial activity. However, nothing is known about the combined influence of biochar and wood vinegar on the soil processes.

The purpose of our study was to explore the effects of biochar and wood vinegar (both originated from Betula sp.) additions on soil organisms and plants. The effects of the two substances on the retention/degradation of nutrients (N, P, K, Ca, Mg and S) and a herbicide (glyphosate) in an arable soil was also investigated. The experiment, conducted in a green house, consisted of 80 flower pots (1,5 l) filled with sandy arable soil. At the initiation of the study four treatments were established, each with 20 replicates: soil mixed with 1) biochar, 2) biochar and wood vinegar, 3) wood vinegar and, 4) control (neither biochar nor wood vinegar). The volume of the added biochar was 25000 kg/ha and that of wood vinegar 5000 kg/ha. English ryegrass (Lolium perenne) seeds were sown on half of the pots in each treatment and after 45 days half of the pots were treated with glyphosate (4 L/ha). Soil samples were taken 3, 48 ja 87 days after initiation of the study for the analysis of microbial activity, biomass of nematodes, nutrient and glyphosate concentrations. Furthermore, after each soil sampling the pots were irrigated with 3 dl of tap water, and the percolates were analysed for nutrients and glyphosate. The biomass and glyphosate concentration of plants were measured 88 days after the initiation of the study.

## EC06 - Fate and exposure modelling including scenario analysis

**WE 029**

**Applicator risk assessment of pesticides used in Korean orchard**

SS Hong
Rural Development Administration, SUWON-SI, South-Korea

This research was carried out to propose the Korean method for estimating the agricultural occupational pesticide exposure level and estimate the risk of pesticide applicators who use high toxicological pesticides in korean orchard. The UK-POEM (UK-Predictive Operator Exposure Model) was proposed as a bench-marking model and analysed its performance properties. To extrapolate the Korean agricultural conditions, application equipment, application method, work rate per day, application volume and spraying time of pesticide was surveyed for Korean 204 orchard farmhouse. This survey indicate that the major application equipments are speed sprayer(64.9%) and motor sprayer(33.9%). When they sprayed the pesticide with a speed sprayer, they worked for more than 4 hours on area of 4 ha per day. In case of using motor sprayer, they worked for more than 4 hours on area of 1 ha. Based on the above survey result, Korean method for estimating the pesticide exposure level of agricultural worker was proposed finally.

The risk of pesticide applicators was calculated as above method. The class II (highly hazardous) pesticides used in korea were 17 products, and 11 products were spray type pesticides. The using information based on the pesticide label and the data searched through survey of actual condition on pesticides were used for calculate the pesticide applicator exposure dose. The risk quotients of these pesticides against the pesticides applicator were calculated as devide pesticide exposure dose by reference dose which were presented by EFSA(European Food Safety Authority), JMPR( Joint FAO Meeting on Pesticide Residues), and US/EPA(United States Environmental Protection Agency). Omethoate showed the highest risk quotient and the values were 338 and 75 when the applicator spray using speed sprayer and motor sprayer respectively. Risk quotients of all class II pesticide were above 1. This result means that the risk potential of these pesticides is very high. These pesticides will be revaluation as Korean re-registration system.

**WE 030**

**Development of environmental fate model for herbicides of paddy fields using grid-catchment integrated multimedia modeling system (G-CIEMS) for all Japan area**

Y Imaizumi, N Suzuki, J Kobayashi, T Sakurai, H Shiraishi
National Institute for Environmental Studies, TSUKUBA, Japan

In Japan, monitoring data were actively used for representative values of chemical concentrations in environment in order to estimate risk analysis. Although observed values have higher reliability compare to calculated values by an environmental fate model, observed values have temporally-spatially specific information for limited numbers of chemicals. In order to cover temporally-spatially variable concentration for enormous amount of chemicals, model calculation should be applied for extensive ecological risk analysis.

Pesticides are absolutely necessary for steady supply of crops and efficient management of farmers. However, pesticides should be carefully controlled because of its original purpose of herbicidal, insecticidal, or fungicidal actions. Rice is a most major crop plant in Japan. Since schedules of rice transplanting collect to a specific period in each region, pesticides are also intensively used and run off to rivers. Herbicides are especially need to be regarded because these are thrown in paddy water and that why have high run-off ratio. For improving ecological risk analysis of pesticides, it is important to calculate weekly variation of pesticide concentrations in all rivers in Japan for many kinds of pesticides. To improve prediction accuracy is especially important during high level period that continuing from several days to about two weeks.

We had developed the multimedia environmental fate model G-CIEMS (Grid-Catchment Integrated Multimedia Modeling System) and Japanese GIS data set used for this model. In this study, we developed the method to predict daily variation of concentrations of many herbicides to paddy fields in all area in Japan. For developing the method, we collected, analyzed, and make a database of various kinds of relative information. We calculated daily emission amount of 5 kinds of herbicides for each river segment and air mesh, which data suitable for G-CIEMS model. In order to validate this model, we used national river survey results performed by the Ministry of Environment in Japan. To evaluate the reliability of this model, peak concentration and peak days were compared between predicted variations and observed variations for seven sites. Concentration differences between predictions and observations were almost less than one order of magnitude ( 16 sets / 18 sets ). Peak day differences between predictions and observations were almost less than two weeks ( 16 sets / 18 sets ).

**WE 031**

**Realism of common approaches for normalisation of degradation rates - How to derive soil moisture?**

D Gericke[1], G Wiedemann[1], H Kage[2]
[1]RIFCon GmbH, HEIDELBERG, Germany
[2]Christian-Albrechts-University of Kiel, KIEL, Germany

Degradation rates of plant protection products derived from field degradation studies have to be normalised to reference soil moisture and temperature (pF 2.0, 20°C) in order to make half lives comparable. These half lives can then be used for environmental fate modelling as recommended by the FOCUS work group on degradation kinetics (2006) or the EFSA panel (2010). Soil moisture and temperature are usually not (or only occasionally) measured in field degradation studies. Thus, they have to be calculated by hydraulic models like PEARL using the pedo-transfer function of van Genuchten-Mualem. In this project we compared different approaches (Rosetta, Hypres, German guideline, inverse modelling with PEST, best-fit to measured data) for the estimation of the soil hydraulic parameters needed for the van Genuchten-Mualem equation, and we compare the calculated soil parameters with measured values. Based on the different approaches we calculated the soil moisture and temperature for all FOCUS scenarios in PEARL 3.3.3 and derived correction factors needed for the normalisation.
The results show that the estimated soil hydraulic parameters vary strongly and consequently lead to significantly different correction factors for the soil moisture normalisation, resulting in different normalised half lives. The comparison between observed and simulated soil moisture showed partly huge differences and implausible results for simple approaches (e.g. Rosetta texture for soil type sand), but it could also be shown that parameters derived from measured water retention curves gave not the best fit to measured soil moisture. Thus, the most realistic way for normalisation would be to measure the soil moisture on a daily basis during the field experiments. Since such measurements are quite cost and time intensive, a convenient method for a realistic estimation of soil moisture is inverse modelling, e.g. with the software PEST, based on gravimetric water contents available from the residues analysis.

**WE 032**

**Influence of climate data on estimated substance parameters of field accumulation studies**

GM Kahl[1], K Hammel[2]
[1]DR. KNOELL CONSULT GmbH, MANNHEIM, Germany
[2]Bayer CropScience AG, MONHEIM, Germany

Realistic degradation (half life $DT_{50}$) and sorption (Freundlich coefficient $K_{om}$) parameters of plant protection products may be derived from field experiments using inverse methods. For such evaluations soil and weather data are a necessary input. Ideally, climate data (rainfall, temperature, humidity[3DOTS]) are measured directly on the experimental site. However, often only data are available from weather stations some distance away (often about 10-15 km). In this study the potential error in $DT_{50}$ and $K_{om}$ is investigated due to the use of off-site rainfall data.
Two different error types are considered: (a) cumulative rainfall is different (± 10 and 20%) but the temporal rainfall pattern is identical for on- and off-site stations and (b) cumulative rainfall is identical, but the daily rainfall varies significantly.
Error type (a) is addressed by increasing/decreasing daily rainfall systematically by up to ± 20%. This represents the expected maximum difference in cumulative rainfall over a distance of 10-15 km. Error type (b) is addressed by creating artificial rainfall sets with identical statistical properties (e.g. wet/dry cycles, monthly rain distribution) as the on-site rainfall, but with very different daily rainfalls.
Changing the cumulative rainfall has only small influence on the water content of the soil (relative change < 5%). Larger changes were observed in the pressure head (>10%) and the cumulative percolation. From those hydraulic variables $DT_{50}$ is essentially driven by soil water content. This explains why the $DT_{50}$ is hardly influenced.
On the other hand $K_{om}$ is expected to be more sensitive because the time to reach a certain soil depth is approximately proportional to the quotient of retardation and water flow. Thus an increase in water flow, i.e. rainfall, can be compensated by an increase in retardation, i.e. $K_{om}$, and vice versa. Differences in daily rainfall have only small influence on both parameters as long as the cumulative rainfall is identical. Only differences in the cumulative rainfall lead to evident changes of $K_{om}$.
It is concluded that the use of weather data from off-site stations is acceptable as long as differences in cumulative rainfall are sufficiently small. This can be expected for weather stations some distance away but located within the same geographical region. Substantial differences in daily rainfall (as can occur even within small distances) had only minor influence on the substance parameters obtained.

**WE 033**

**The FOOTWAYS Pro online risk assessment platform: first real-world application in a French basin**

S Reichenberger, IG Dubus, M Lambeau, S Tellier, R Talva
FOOTWAYS S.A.S., ORLÉANS CEDEX 2, France

*FOOTWAYS Pro* is an online platform for pesticide exposure and risk assessment connecting a web portal with a high-performance computing cluster fully dedicated to pesticide fate modelling with MACRO and PRZM. The *FOOTWAYS Pro* approach builds partly on the FOOTPRINT methodology, but alleviates the existing limitations of the FOOTPRINT tools with respect to regulatory applications. In *FOOTWAYS Pro*, MACRO and PRZM results are newly and specifically generated in each assessment (“modelling on demand”). This leads to a much larger flexibility in model input and parameterisation compared to the pre-modelling approach in FOOTPRINT.
A *FOOTWAYS Pro* assessment consists of three major steps: 1. Assessment setup by the user through the web portal, 2. Modelling activities on the cluster; 3. Visualisation of outputs on the web portal (maps, CDFs, descriptive statistics and single time series of the different output variables, and the newly developed water quality management indicator PITSA).
A first real-world application of *FOOTWAYS Pro* has been implemented for an 800 $km^2$ basin, an area under intensive agricultural use which is also a major drinking water source. Local input data (1 : 250000 soil map, crop statistics at municipality level, local weather time series) were used to set up the agro-environmental scenarios for the study area.
On the web input interface, the user can choose between a number of local cropping practices with different levels of plant protection intensity and different combinations of applied products. It’s also possible to specify new pesticide application programmes with a new combination of existing products. With the results provided on the web output interface, the user can i) compare the environmental performance of the various programmes for the different crops, ii) compare the risks to ground- and surface water due to crop protection measures between crops, iii) identify problematic areas and iv) explore the effect of mitigation measures. The study has a pilot character for the implementation of the Sustainable Use Directive and the national ÉCOPHYTO 2018 action plan in France.

**WE 034**

**Fate of bifenthrin applied in pepper field-lysimeter**

CS Kim, H Sun-Seong
Rural Development Administration, SUWON, South-Korea

To investigate runoff and erosion loss of bifenthrin from the field by rainfall, the influence of slope degree and length, ridge direction and plastic film mulching on runoff rate of bifenthrin from the pepper field were measured. The EC type formulations was applied at the rate of 5.6 g a.i./ha on June 21 2003 and it rained two and four days after the application. The wash-off rate was 2.1% of the applied bifenthrin. The average runoff losses of bifenthrin from a series of pepper grown-lysimeter plots were 0.33% for the mulched contour ridge plots, less than 0.1% for the mulched up-down direction ridge plots and 0.66% for the no-mulched contour ridge plots(control). The runoff concentrations of bifenthrin ranged from less than 0.1 μg L-1 to 0.2 μg L-1 for the mulched contour ridge plots, less than 0.1 μg L-1 for the mulched up-down direction ridge plots and from 0.1 μg L-1 to 0.2 μg L-1 for the controls. The average erosion rate of bifenthrin were 1.1% for the mulched contour ridge plots, 6.9% for the mulched up-down direction ridge plots and 1.2% for the controls. The average erosion rate of plots except the mulched up-down direction ridge plots were 0.39% for 10% slope-plots, 0.54% for 20% slope-plots and 2.51% for 30% slope-plots with different slope lengths. Residues of bifenthrin in soil at nine days after the application ranged from 0.006 mg kg-1 to 0.024 mg kg-1 except the soil under the mulch, and decreased to from 0.007 to 0.012 mg kg-1 at seventy one days after the application.

**WE 035**

**Development of a GIS integrated dynamic surface water model to predict environmental concentrations of pesticides in an alpine stream located in Northern Italy**

I Trenti[1], D Ghirardello[1], M Semplice[1], M Morselli[1], A Ippolito[2], M Carolli[3], A di Guardo[1]
[1]University of Insubria, COMO, Italy
[2]University of Milano-Bicocca, MILAN, Italy
[3]IASMA Research and Innovation Centre, S. MICHELE ALL’ADIGE TN, Italy

The use of pesticides in agricultural areas can determine a chemical loading to surface water, which could be relevant in the exposure of non-target organisms such as macroinvertebrates. In order to evaluate such exposure, predictive approaches are needed together with tools to assess the risk for the aquatic ecosystem. A new dynamic aquatic model (DynaNet), which integrates a previously developed model (Dyna) with GIS tools, was developed and applied in order to calculate pesticide concentrations in water and sediment of an alpine stream located in the Non Valley of Trentino Alto Adige Region (Northern Italy), in which apple orchards are predominant. The environmental scenario was developed dividing the catchment in sub basins and classifying the stream in different links according to the Strahler order. The segmentation was done in a GIS environment and streams were connected by a downstream flow. Loadings data of water and pesticides deriving from treated orchards were obtained using the SoilPlus model, which was parameterized to describe average soil conditions for two pesticides. Pesticide use statistics in the valley were acquired from local authorities. Links were then parameterized using available environmental parameters and water flow rate data at a hourly time step. DynaNet model was then developed to predict fate of pesticides in the water/sediment system using a new adaptive time-step algorithm for the numerical solution of the mass balance differential equations. The model uses the variable volume storage method to calculate water flow variation during the rain events and to perform concentration calculations. Finally, the model was evaluated comparing predicted pesticide concentrations with concentrations measured at a sampling point located near the stream outlet.

**WE 036**

**Site-specific theoretical risk assessment for pesticides: a case study**

A Ippolito[1], M Carolli[2], M Vighi[1]
[1]University of Milano-Bicocca, MILANO, Italy
[2]E. Mach Foundation, Innovation and Research Centre IASMA, S. MICHELE ALL’ADIGE (TN), Italy

Current procedure for the Ecological Risk Assessment are based on the comparison between a Predicted Environmental Concentration (PEC) and a toxicological end-point (L/EC50, PNEC, etc.). In Europe this methodology is usually applied for regulatory purpose on standard scenarios, assumed as representative of different European regions. Site-specific approach are nevertheless encouraged by new regulations (the Water Framework Directive is the first and best known example), in order to reduce the uncertainty factors due to environmental generalization.
In this work we employed classic ERA methods to a small scale scenario. We considered a mountain stream (Novella River) of Trentino-Alto Adige region, in the northern Italy. The watershed of Novella River is extensively used for the cultivation of apple orchards, and only narrow buffer zones are present between the river and the orchards; runoff events are then likely to cause significant loads of pesticides in the river. The PECs of all active ingredients used in the Novella basin were calculated with suitable models. Details are described elsewhere (Trenti et al., this meeting). Theoretical risk assessment approaches, based on the laboratory toxicity data available in the literature, were applied to the individual chemicals and to the mixtures of different composition that may occur in the river during the whole productive season. Risk was assessed using traditional approaches proposed by the European regulation on plant protection products as well as by applying suitable risk indices. Where possible, an SSD curve was built using the actual taxa of the considered community. Zoobenthos community of the river was monitored monthly before, during and after the treatment application period. The results of theoretical risk assessment are compared with changes in the natural community.

**WE 037**

**TOP-RICE model: simulation of leaching to groundwater and exposure in ponds due to pesticide use in paddy rice fields**

EL Wipfler, M ter Horst, JJTI Boesten, F van den Berg, W Beltman, PI Adriaanse, J Deneer, I Roessink, G Fait
Wageningen UR, WAGENINGEN, The Netherlands

The Pesticide Environmental Risk Assessment Project (PERAP) is a cooperation platform between Chinese and Dutch government bodies, research institutes and private sector. The

TOP-RICE model has been developed in the framework of PERAP. It enables the prediction of concentrations leaching to groundwater and of exposure concentrations in surface water (secondary ditches and natural ponds) due to pesticide use in paddy rice fields. The model will be used in pesticide registration in China.
The TOP-RICE model is based on the pesticide fate models PEARL and TOXSWA. PEARL simulates the fate of pesticides and metabolites in soils. With PEARL the concentrations leaching to groundwater can be calculated as well as concentrations in run off from paddy fields. PEARL uses the SWAP model to simulate water flow and heat transport. Processes covered by PEARL are pesticide transport, sorption, transformation, wash-off from plants and volatilization. TOXSWA simulates the exposure concentrations in surface water and sediment of pesticide and metabolites. TOXSWA incorporates processes such as transport, transformation, sorption to sediment and suspended solids and volatilization. Considered sources of contamination of the surface water and sediment are drainage, runoff and spray drift.
To account for a paddy water layer on top of the soil column, PEARL has been modified. PEARL now accounts for the water and mass balance of a paddy water layer and includes degradation processes in the water layer and runoff to pond and ditch. The dynamics of the paddy water layer is driven by the irrigation schedule and the crop cycle. TOXSWA has been extended with new concepts regarding the water and mass balance of a natural pond located in a lower area with no in- or outlet. Both models are coupled such that the runoff from the paddy rice field calculated by PEARL is input for the surface water calculations by TOXSWA.
Two scenarios were developed for pesticide use in paddy rice in China (one close to the Yangtze River and one in south China). These scenarios aim to represent 90th percentile exposure concentrations both for groundwater and surface water.
The TOP-RICE user interface enables the user to calculate environmental concentrations for these scenarios and for user-defined application schemes and substances. A special substance database has been developed that contains all relevant substance properties. This database can be used as a stand alone program or coupled to the TOP-RICE model.

**WE 038**

**Using an integrated watershed model to identify potential measurement sites for passive pesticide sampling**

S Julich, T Galle, C Braun
CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg

In the poster we present the concept and first results of a multiple-tiered study carried out in two catchments in Luxembourg. In this study we use an integrated watershed model to identify sites in the river course which are likely to have high risks of pesticide exposure according to the regional agricultural practice. The identified sites are then monitored with a passive sampler campaign in the coming year in order to test the model results. If the results of the passive sampling campaign agree with the modeling, the model outputs are further linked to an ecotoxicological model in order to evaluate the effects of pesticide exposure on the river biology.
For the watershed modeling we selected the widely known SWAT model which has also been applied in several pesticide fate simulation studies before. The model will be applied to the Wark and to the Mamer catchments. Both watersheds have an area of around 85km2 and a comparable share of arable land on the watershed area with 19% and 21% respectively. According to the official agricultural statistics winter cereals (mainly wheat and barley) as well as corn and oilseed rape are the main cultivated crops in the two watersheds. Both watersheds exhibit different geologic and hydrogeologic settings. In the Wark catchment soils are mainly underlain by impermeable bedrocks such as schist and marl. Here lateral subsurface flow and a quick catchment response to rain storms are expected. The Mamer catchment shows more heterogeneous conditions with soils underlain by permeable sandstone in the north and the centre of the catchment and soils underlain by impermeable marls in the south. Here the catchment discharge could be characterized by a mixture of groundwater contribution and lateral subsurface flow. Based on the different hydrologic conditions we expect also differences in the dynamics of pesticide exposure in both rivers.

**WE 039**

**Recommendations for simulation calculations with FOCUS PELMO to predict environmental concentrations of plant protection products and their metabolites in groundwater (PECgw) in Germany**

I Bonath[1], A Nehls[1], G Holdt[1], P Gallien[1], A Osterwald[1], W Koenig[1], B Gottesbueren[2], B Jene[2], H Resseler[3], R Sur[4]
[1]Federal Environment Agency, DESSAU-ROSSLAU, Germany
[2]BASF, LIMBURGERHOF, Germany
[3]Syngenta, MAINTAL, Germany
[4]Bayer CropScience, MONHEIM, Germany

In the national authorisation procedure in Germany the leaching behaviour of a plant protection product is determined in a stepwise procedure as described in the FOCUS Groundwater report (2009). The recommendations given in this paper are related to tier 1 and tier 2 of the FOCUS 2009 guidance.
The tier 1 assessment in the EU is based on the FOCUS 2009 standard scenarios. In the member state evaluation for Germany, a subset of the standard scenarios with climatic and soil conditions found to be relevant for Germany are taken into account (Hamburg and Kremsmuenster). The soils of the two scenarios cover the pH-ranges of agricultural soils and allow addressing the pH-dependent behaviour of compounds.
Normalised degradation rates may be used from either laboratory or from field dissipation studies. For the parameterisation of the degradation behaviour of an active substance and its metabolites in soil the recommendations of FOCUS with respect to the number of available DT50-values in different soils should be followed.
For the parameterisation of the sorption behaviour of an active substance and its metabolites in soil the recommendations of FOCUS should mainly be considered. With respect to the correlation of sorption to soil properties (pH, OC) additional detailed recommendations are given on the choice of appropriate sorption parameters for leaching assessment.
Furthermore recommendations are given on how to use other modelling parameters e.g., crop rotation, plant uptake factor, formation of metabolites, correlations / multi-correlations of substance parameters to soil properties, and application of statistical methods.
Tier 2 of the leaching assessment consists of more refined modelling approaches. This includes on the one hand providing data on specific processes e.g., surface degradation or non - equilibrium sorption and on the other hand the use of refined scenarios. The latter one is appropriate when the standard tier 1 scenarios are not representative of a specific crop or the relationship between compound and scenario properties.
The approach presented here should contribute to a future harmonisation of exposure assessment and risk management for plant protection products at European level.
In the abstract presented here tier 1 and tier 2 leaching assessments are described. Further recommendations are planned for the tier 3 and tier 4 assessments.

**WE 040**

**Modelling and monitoring of short chain chlorinated paraffins in the Nordic environment**

IS Krogseth, K Breivik, M Schlabach
Norwegian Institute for Air Research, KJELLER, Norway

Short chain chlorinated paraffins (SCCPs), also called polychlorinated n-alkanes, are mixtures of compounds of molecular formula $C_xH_{2x+2-y}Cl_y$ containing 10-13 carbon atoms and usually 30-70 % degree of chlorination. They have a range of industrial applications, and have been detected in numerous environmental compartments. There is concern regarding SCCPs due to their environmental persistence and their potential for bioaccumulation, adverse effects and long-range transport. SCCPs have been included in the UNECE LRTAP Convention, the priority substance list of the European Water Framework Directive, and are under consideration for the Stockholm Convention on Persistent Organic Pollutants. However, the behaviour and fate of SCCPs remain poorly understood, in part as the technical mixtures consist of thousands of isomers, enantiomers and diastereomers, which make analysis and modelling of these compounds very challenging. The purpose of this study was to explore a complementary modelling and monitoring approach to evaluate the overall understanding of the link between emissions of SCCPs, environmental levels and human exposure in the Nordic environment and to identify the more critical knowledge gaps. Data for emissions and physicochemical properties of SCCPs were gathered or estimated, and used to parameterize an integrated, non-steady state environmental fate and bioaccumulation model (CoZMoMan). Specific congeners of SCCPs were selected for the study to assess the extent of expected variation of environmental fate and behaviour within the multitude of compounds. Model results were next compared to reported environmental levels in the Nordic region. For compartments where environmental levels were scarce or lacking, targeted sampling and analysis was carried out to further evaluate the model predictions. Results from this study will be presented and discussed with emphasis on the more critical research needs with respect to the overall fate and exposure of SCCPs.

**WE 041**

**Linking multimedia environmental and PBPK models to assess health risks of lead associated to drinking water - A case study**

S Maurau[1], P Ciffroy[1], C Brochot[2], Y Roustan[3], L Marang[1]

Human exposure to chemicals through multiple pathways is classically estimated by the so-called 'multimedia models', calculating the distribution of contaminants among products of interest for humans (like drinking water, inhaled air, vegetables, meat, milk, etc). Combined to data describing human behavior (diet composition, time spent outside, etc), such multimedia models provide an estimation of the daily quantity inhaled or ingested by the population of interest. Once the exposure scenario is identified, the dose-response assessment is typically achieved by comparing exposure outputs (*e.g*, the daily intake) to reference doses, estimated from toxicological data. Coupling multi-media models for different exposure pathways with a generic physiologically based pharmacokinetic (PBPK) model for the human population enables to assess directly the impact of the exposure scenarios on the chemical's concentration in the target tissues.One aim of the European 2-FUN project (Full-chain and UNcertainty Approaches for Assessing Health Risks in FUture ENvironmental Scenarios) was to develop an integrated 'multimedia-PBPK' toolbox that also incorporates uncertainty and inter-individual variability analyses by Monte Carlo simulations, and different kinds of sensitivity analysis.In the present study, an integrated modeling approach was demonstrated for predicting internal tissue concentrations of chemicals by coupling a multimedia environmental model and a PBPK model. A case study was designed for a region situated on the Seine river watershed, downstream of the Paris megacity and for lead emitted from industrial zones in the region. The limited monitoring datasets of lead concentrations in bottom sediment and in raw river water, obtained at the downstream of Paris, were used to re-construct long-term daily concentrations of lead in river water. The re-construction of long-term series of lead level played a key role for the intermediate model calibration (conducted in multimedia model), and thus for improving model input to PBPK model. In order to take into account the parametric uncertainty in the model inputs, some input parameters relevant for the multimedia model were given by probability density functions (PDFs); some generic PDFs were updated with site-specific measurements by a Bayesian approach.This case study demonstrated the feasibility of a full-chain assessment combining multimedia environmental predictions and PBPK modeling, including uncertainty analysis.

**Scenario analysis for reducing priority pollutants in receiving water using integrated dynamic urban fate models**

AM Verdonck[1], V Gevaert[2], W de Keyser[2], L Benedetti[2], B de Baets[2]
[1]Arche, GENT, Belgium
[2]UGent, GENT, Belgium

The Water Framework Directive (WFD, 2000/60/EC) has the objective of a catchment oriented water quality protection for all European waters with the purpose of achieving a good ecological and chemical quality status by the year 2015. To that end, necessary measures should be identified and implemented, with the aim of progressively reducing pollution from priority substances. The objective of this poster is to demonstrate how a dynamic model of the integrated urban wastewater system (IUWS) can be used to test different emission reduction strategies for organic priority pollutants (PPs) in a semi-generic case study on DEHP. The IUWS is composed of coupled entities: sources, urban catchment surface (run-off/infiltration), sewer system, stormwater treatment unit, wastewater treatment plant (WWTP) including sludge handling, and receiving surface water (river). State-of-the-art dynamic fate models were selected from literature. Dynamic DEHP release profiles were estimated and inputted in the model to predict the fate and concentration of DEHP in each IUWS sub-system. The model was then used to test eight scenarios on environmental performance, namely (1) reduction of impervious urban area, (2) reduction of infiltration in the sewer system, (3) input reduction (excluding the main pollutant sources), (4) separating the combined sewer system, (5) treatment of stormwater by stormwater infiltration ponds (separate sewer systems), (6) placement of retention basins at main sewer junctions, (7) sand filtration of secondary effluent, and (8) pre-precipitation of phosphorous. The simulation results revealed that the most effective measure in terms of river water quality improvement for DEHP (annual average and spikiness reduction) and PP concentration in the disposed WWTP sludge heavily depends on the parameterisation of the scenarios. It can be concluded that dynamic modelling tools are very useful in the WFD context, as they allow to check compliance of the PP's river concentration with both types of environmental quality standards (the maximum allowable MAC-EQS and the annual average value AA-EQS). Furthermore, these models can be used to test the impact of different emission reduction strategies on the river water quality status. Testing different measures before their actual implementation in real life can help to make better choices in terms of resources, and as such costs can be saved.

**WE 043**

**Multimedia assessment of pollutant pathways in the environment - European scale screening model (MAPPE-Europe)**

DT Marinov[1], A Pistocchi[2], P Vizcaino[3], G Zulian[1], G Bidoglio[1]
[1]Institute for Environment and Sustainability, Joint Research Centre, European Co, ISPRA (VA), Italy
[2]GECOsistema srl, VIALE G.CARDUCCI, 15, 47023 CESENA, Italy
[3]ECOHIDRAULICA S.L., CALLE RODRÍGUEZ SAN PEDRO 13, MADRID, Spain

The work gives an updated overview of the structure, functions and algorithms used in development a modelling tool for pollutants pathways in air, soil and surface and sea water at the European continental scale. The algorithms are implemented as an extension for ESRI ArcGIS 9.3. The tool is called MAPPE after Multimedia Assessment of Pollutant Pathways in Environment of Europe.

The purpose of the model is to provide a user-friendly way to convey the wealth of geographic data available to model the fluxes and concentrations of pollutants emitted by industrial activities and other point emissions, or chemicals widespread use within households, urban environments or agriculture. The intended applications include organic contaminants such as pesticides, pharmaceuticals, VOCs, and other industrial POPs.

The maps of chemical concentrations and fluxes produced by the model can be used for screening level assessment, at continental scale, of risks to human health and ecosystems, evaluation of policies and scenarios. The model is a complement both to more detailed, site specific assessment procedures, and to generic tools such as EUSES, aimed at non-spatial risk assessment in contexts such as the management of priority substances of concern for soil, water and air, the control of effects of environmental pollution on human health and ecosystems, and the sustainable management of agro-chemicals.

The original version of MAPPE has been used in several case studies - e.g. for PCBs, dioxins, gamma-HCH, while model variants served in investigations of Pyrethroid pesticides, PFOS/PFOA or common surface water contaminants including pharmaceuticals and personal care products.

**WE 044**

**Multimedia assessment of pollutant pathways in the environment: a Global spatially explicit fate and exposure model (MAPPE-Global)**

DT Marinov[1], A Pistocchi[2], S Pontes[1], G Zulian[1], G Bidoglio[1]
[1]Institute for Environment and Sustainability, Joint Research Centre, European Co, ISPRA (VA), Italy
[2]GECOsistema srl, VIALE G.CARDUCCI, 15, 47023 CESENA, Italy

The work describes a spatially explicit fate and exposure model with global coverage for Multimedia Assessment of Pollutant Pathways in the Environment (MAPPE Global). The model computes removal rates of a substance with given physico-chemical properties in an evaluative environment, composed of atmospheric boundary layer, soil, inland and seawater, in the form of maps with a spatial resolution of 1°x1°, by capitalizing on a comprehensive global data set of landscape and climate parameters.

The maps of removal rates enable the computation of concentrations from emissions of a chemical in one or more environmental compartments using a simple box model, except for the stream network where a plug flow scheme is adopted. Four types of environmental processes are included, namely: chemical degradation; advective transport; diffusive transport; and sinking to deep ocean.

MAPPE Global does not compute explicitly chemical transport in space, but only the fate of a substance at each location by calculating mass fluxes of chemical that are available for transport outside of the cell, in addition to concentrations from local emissions.

Grounding on these features, the model can be only used when at least one of the following conditions is met: (1) emissions are uniform in space; (2) the effects of emissions away from the emission location are not of interest. However, the model could answer questions related to the spatial differentiation of fate in response to variability of emissions and chemical fate processes. Moreover, the estimates of mass fluxes available from each cell for global transport can be used to feed more complex global ocean and atmospheric transport models. Therefore, in principle the model output can be compared to any other spatially explicit fate model.

The model was run for a set of 34 representative organic chemicals under different emission scenarios, such as multiple source vs. point source emissions, in order to identify situations for which spatial differentiation in the life cycle impact assessment of toxic chemicals should be considered relevant, especially in the interest of practitioners.

**WE 045**

**EUSES, ECETOC-TRA, IUCLID-CHESAR, EASYtra: which regulatory environmental risk assessment tool to use?**

CF Perazzolo, LD Steiner, EG Saouter
Science & Environnement, GENEVA, Switzerland

In June 2007, the new European regulation REACH entered into force. One of its aims is to improve the protection of human health and the environment from possible effect of chemical compounds. In order to achieve this goal, the so called risk assessment has to be performed for each substance. In general, RA is based on the knowledge of the chemical hazard, i.e. the intrinsic properties of a chemical, and the so called exposure which depends on many parameters such as the amount used, the type of process, the percentage release. Briefly, once the amount of exposure and the hazard are known, their ratio constitutes the risk assessment: if the exposure is higher than the hazard there is a risk and further investigation are necessary.

Although the main principles of RA are easily understandable, there are a great number of parameters and scenarios to consider to obtain the risk assessment. For this reason, over the last years free, commercial and homemade software appeared to perform the risk assessment. Among them, which is the best software? Does it exist a software which is robust, easy to use and regularly updated?

To attempt to answer these questions a critical evaluation of three free softwares (Chesar, EcetoxTRA, EUSES) and a commercial one (easyTRA) using several environmental risk assessment scenarios has been carried out. Several parameters have been evaluated; among them user friendly, minimum number of data needed, external need for simulated data, output and cost. Our results indicate that an ideal software does not yet exist: the best choice still rely on the parallel utilisation of more than one software, thus increasing the weight of the "personal preference"factor in the final choice of the ERA tool.

**WE 046**

**BETR Global - a geographically-explicit global-scale multimedia contaminant fate model**

M Macleod[1], H von Waldow[2], P Tay[2], JM Armitage[3], H Wörnschimmel[2], W Riley[4], TE Mckone[4], K Hungerbuhler[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Swiss Federal Institute of Technology, ZURICH, Switzerland
[3]University of Toronto at Scarborough, TORONTO, Canada
[4]Lawrence Berkeley National Laboratory, BERKELEY, United States of America

Multimedia mass-balance models are well-established as scientific and decision-support tools for understanding the behavior of chemical pollutants in the environment, especially persistent organic pollutants. Global-scale multimedia mass balance models have been particularly important in establishing the link between chemical emissions in temperate, industrialized regions and their presence in the Arctic. Global models that were developed to study transport of persistent chemicals to the Arctic describe the environment as a set of latitudinal zones, and are spatially discretized only along a north-south axis. In 2005, the first version of the BETR Global multimedia contaminant fate model was introduced. It described the global environment as a set of linked multimedia regions on a 15o [GREEKX] 15o grid. Several modifications have been made to the BETR Global model since 2005, including changes to the model algorithms and updates of the model's database of environmental characteristics. Here, we introduce two new software implementations of the BETR Global model, BETR Global V.2.0, and BETR-Research. Both new versions incorporate all model updates made since 2005, and both are being made publically available for direct download as open-source software. BETR Global 2.0 is coded in Visual Basic for Applications (VBA) as an add-on for Microsoft Excel, and is based on the same code-base as the 2005 version of the model. BETR-Research is a new implementation of the model in Python that is more accessible for model modifications and thus more versatile, but that lacks the graphical user-interface of the VBA version. During development of these new versions of the model a thorough code-review was performed, which increased the quality and validity of both BETR implementations. We illustrate the new version of the model using a case study of the global fate and transport of decamethylcyclopentasiloxane (D5), which can be replicated using the VBA version of BETR Global 2.0 by following the tutorial on the BETR Global website, http://sites.google.com/site/betrglobal/home. The BETR-Research Python implementation of the model can be downloaded from http:// betrs.sourceforge.net.

**WE 047**

**A dynamic vegetation model: development and integration with an existing dynamic air/soil model**

E Terzaghi[1], M Morselli[1], BEL Cerabolini[2], A di Guardo[1]
[1]University of Insubria, COMO, Italy
[2]Universitry of Insubria, VARESE, Italy

Plant biomass has been shown to exert a decisive influence on the fate of chemicals in the air/soil system. Uptake and clearing rates of a number of species have been experimentally determined in the past decade as well as the role of forest canopies, capable of filtering air and transfer chemicals from air to the litter/soil environment. Recently, plant/air partition coefficients for several species were determined in field conditions and the parameters describing the biomass development with time were measured for a number of forest types. Additionally, a multimedia fate model (AirFug) which incorporates a rather dynamic air system was developed and showed that air concentrations could considerably change during a diel cycle. AirFug allows to predict concentrations in soil and in two air compartments, which change in height and volume according to the variation of mixing height, predicted basing on meteorological observations. Such dynamic atmospheric compartment is capable to show rapid air concentration changes. To evaluate the influence of such rapid changes on vegetation behaviour, a dynamic bioaccumulation model of organic contaminants in vegetation biomass was developed in order to calculate leaf contaminants uptake from air. In this model, formulated in terms of fugacity, the vegetation compartment is composed by a multi-specific forest canopy. The bioaccumulation equations employed to simulate uptake by leaves calculate the plant/air partition coefficient (Kpa) using Koa (octanol-air partition coefficient) and some forest structural parameters such as specific leaf area (SLA) and leaf area index (LAI), which vary with time, environmental and ecological conditions. This vegetation biomass model was finally integrated with AirFug to predict the effect of plants in regulating the fate of organic contaminants in a system where a double-layered air compartment interacts dynamically with multi-layered litter and soil compartments. Simulations were performed for some Semivolatile Organic Compounds (SVOCs) in order to evaluate the role of air concentration variations and soil degassing in influencing the change of foliar biomass concentrations with time.

**WE 048**

**Aquatic exposure models - Where do we stand in Switzerland?**

P Aldrich, T Poiger, O Daniel
Research Station Agroscope Changins-Wädenswil ACW, WÄDENSWIL, Switzerland

For the aquatic risk assessment in the context of pesticides registration, concentrations in surface waters are predicted using deterministic models. The idea is that a realistic worst-case exposure of aquatic organisms is calculated in order to assess a generalized risk and to formulate risk mitigation measures for the whole country.

In this poster we challenge such calculations by investigating the variability of the factors affecting run-off and drainage. The loading of pesticides to surface waters via run-off and drainage depends on numerous factors, such as the application rate, crop interception, degradation in soil, timing of rain events, distance to the water body, size of the water body and dilution due to rain water and flow velocity. Some of these factors vary with local conditions, such as intensity and frequency of rain events, topography, application technology and the size of the water body, but are treated as constants in the model calculations.

Switzerland is a country with very diverse climatic and topographic conditions. Therefore, a generalization of these diverse regions to a single scenario leads by default to over- or underestimation of the concentration in surface waters and potentially to inadequate risk mitigation measures. We show the range of some parameters and its effect on the predicted concentration in order to verify the assumption that the model leads to the calculation of a worst-case exposure.

[2]University of Insubria, COMO, Italy
[3]University of Milano-Bicocca, MILAN, Italy
[4]Copernico Srl, UDINE, Italy
The rupture of underground storage tanks and accidental oil and fuel spills are two of the most common causes of soil and groundwater contamination. Remediation often represents a time consuming and expensive task and requires different approaches depending on a number of parameters, such as the types of contaminants involved, their distribution in the impacted media and the present or future targets potentially exposed to hazards. Some in situ remediation technologies are directed to enhance the degradation of chemicals; however, a precise timing for such operations is often difficult to estimate and frequent measurements must be performed in order to verify the adequacy of the adopted measure. In this context, models could represent a helpful tool in planning management strategies. In order to develop and calibrate an integrated modelling approach capable of quantifying the effectiveness of different remediation technologies, a monitoring campaign was started in a site located in the Mantua Province (Po Valley, Northern Italy), where an accidental diesel spilled had occurred. Soil and groundwater samples were collected during three times, in order to assess (1) the role of natural attenuation after two months from the first sampling and (2) the effect of the multi-phase extraction (MPE) technology after two additional months. The site was also monitored for a number of parameters, such as groundwater level, dissolved oxygen and temperature, etc. Bench-scale biodegradation experiments in pulsed flow conditions were also carried out to assess the biodegradation of some of the hydrocarbons detected in soil under natural and oxygen-rich conditions. In the present work, a preliminary version of the model, which couples a multimedia fate box model describing the air/soil system (SoilPlus) and a water flow model (MODFLOW-2005) and incorporates equations capable of describing the diesel pure phase movement, is presented. The model can be used to evaluate the fate of single chemicals in soil unsaturated and saturated zones and to predict the enhanced degradation/volatilization consequent to an MPE treatment. Results of the model were also evaluated in the context of the risk analysis required by the Italian legislation.

**WE 050**

**Predictive performance of mercury fate model for multimedia environment**

Y Kim[1], HW Lee[2], JE Jung[3]
[1]E&WIS Inc., SEOUL, South-Korea
[2]Biohousing Research Institute, Chonnam National University, GWANGJU, South-Korea
[3]Department of Environmental Planning, GSES, Seoul National University, SEOUL, South-Korea
The predictive performance of Mercury Fate Model for Multimedia Environment (MFM-ME) was developed and evaluated for the mercury compounds. The MFM-ME Model is a multi-box dynamic multi-compartmental model to simulate the fate of the mercury compound. The modeling region is the Andongho watershed that is located in the eastern midpart of Korean peninsula. The model was evaluated by comparing the predicted relative concentrations with the measured relative concentrations. The relative concentration (Ci/Csoil) in this study refers to a ratio of the concentration in a medium i (Ci) to that in soil medium (Csoil) and was proposed to use to avoid the problems of uncertainties or lack of emission estimates. The concentrations of the mercury compounds in air, water, sediment, and soil media are predicted within an order of magnitude. The fluxes of the mercuty compounds between media are predicted within an order of magnitude. The predicted compositions of mercury compounds in air, water, sediment, and soil media is similar with those of the measured data of Andongho watershed. The assessment of MFM-ME model indicated that main source of mercury compounds in water is deposition process in air media and run-off process from soil media. The sediment of Andongho is final sink of the mercury compounds

**WE 051**

**Screening and prioritizing organic chemicals based on far-field human exposure**

A Arnot[1], TN Brown[1], K Breivik[2], F Wania[1], MS Mclachlan[3]
[1]University of Toronto Scarborough, TORONTO, Canada
[2]University of Oslo, OSLO, Norway
[3]Stockholm University, STOCKHOLM, Sweden
Globally, scientists and regulatory programs seek to identify chemical substances that may pose risks to humans and the environment. Measured chemical property and monitoring data are limited compared to the large number of chemicals requiring evaluation making it necessary to develop, evaluate and apply models and Quantitative Structure-Activity Relationships (QSARs) for screening and priority setting. The Risk Assessment, IDentification And Ranking (RAIDAR) model is an evaluative, regional scale, multimedia mass balance model that combines chemical emissions, fate, and aquatic and terrestrial food web bioaccumulation to estimate concentrations in ecological receptors and humans. This holistic modeling framework is being applied to screen and rank approximately 13,000 chemicals for far-field human exposure using concentrations in an adult human as a comparative endpoint. Guidance for improving mass balance model input requirements to reduce uncertainty in predicted human concentrations was obtained through sensitivity and uncertainty analyses conducted in concert with the initial screening and ranking. The analyses highlighted a need to reduce uncertainty in key parameters, most notably chemical emissions estimates and biotransformation half-lives in humans. New methods and models have been developed in an effort to reduce uncertainty in the model input parameters for emissions estimates and degradation half-lives. The updated ranking of the 13,000 chemicals is compared with the initial ranking results. Future plans to further reduce uncertainty in the combined mass balance and QSAR screening approach are discussed.

**WE 052**

**Further development of open source routines for fitting kinetic models to chemical degradation data**

J Ranke, D Weber
Harlan Laboratories Ltd, ITINGEN, Switzerland
One of the cornerstones of environmental fate modelling is the derivation of kinetic rate constants from experimental studies. Two extension packages for kinetic evaluations written in the R programming language have been previously presented. They facilitate the evaluation of experimental data from environmental degradation and metabolism studies for the parent compound (kinfit) or for parent and metabolites (mkin) with a focus on the evaluation procedures used in the registration of pesticides in the European Union.
One feature not present in other kinetic modelling tools is the ready-to-use implementation of the single first-order reversible binding (SFORB) model for metabolites. This entails the possibility to use formation-decline kinetics for metabolites also in cases where the metabolite decline does not follow single first-order (SFO) kinetics.
Other kinetic models that describe a change in net degradation rate over time that are commonly used in the kinetic evaluation of pesticide degradation are not easily adaptable for the description of metabolite kinetics. The implications of the use of the SFORB kinetic model for environmental fate modelling of metabolites are discussed.

**WE 053**

**A high-throughput method to screen organic chemicals in commerce for emissions**

K Breivik[1], JA Arnot[2], TN Brown[2], F Wania[2], MS Mclachlan[3]
[1]University of Oslo, OSLO, Norway
[2]University of Toronto at Scarborough, TORONTO, Canada
[3]Stockholm University, STOCKHOLM, Sweden
"There are thousands of organic chemicals in commerce, yet the environmental fate and effects of most substances remain largely unknown". This is probably among the most well-known clichés within environmental chemistry and toxicology. Accordingly, a hot topic on both the research and regulatory agendas is trying to identify organic chemicals which may represent a hazard to the environment and humans, based on individual attributes such as persistence, bioaccumulation, toxicity and long-range transport potential - or combinations thereof. However, only chemicals which combine these harmful properties with emissions in significant quantities are expected to represent a real risk. Here, we present an attempt to develop a high throughput method to screen chemicals in commerce for emissions, building upon the approach outlined in the EU Technical Guidance Document. While doing so, efforts were directed towards proving estimates of the uncertainty in the resulting emission scenarios. This is considered vital, not only because important input data are fragmented or inaccessible, but also because screening or categorization methods which solely rely on threshold values are susceptible to generating a significant number of false positive and false negative categorizations. The emission screening tool is being integrated into a large effort to screen for exposure that also seeks to account for the uncertainty in other input parameters. The latter results are, in turn, expected to identify a sub-set of substances for which more accurate emission estimates are needed at consecutive tiers.

**WE 054**

**Climate variability and POPs environmental behaviour: a focus on the organic carbon content in marine systems**

L Lamon[1], MM Macleod[2], AM Marcomini[3]
[1]Centro Euro Mediterraneo per i Cambiamenti Climatici, VENEZIA, Italy
[2]Stockholm University, STOCKHOLM, Sweden
[3]Università Ca' Foscari, VENEZIA, Italy
Understanding and predicting the environmental distribution of persistent organic pollutants (POPs) in the environment under different climate scenarios requires that both primary emissions and re-emissions to the atmosphere from reservoirs in the environment are taken into account. Another important factor to be taken into account in studying POPs fate and transport is given by the coupling of air and phytoplankton systems, where biologically driven cycles can act to remove POPs from the atmosphere into the deep sea.
A level III fugacity model was developed and applied on the Adriatic Sea to study the environmental fate and transport of polychlorinated biphenyls (PCBs) under a present climate scenario and under a future climate change scenario. The objective of this study was to evaluate the effect of a climate change scenario on the environmental PCBs distribution considering also PCBs' primary emissions and re-emissions. This study aimed also at quantifying the mass of PCBs associated with the carbon pool under the two climate scenarios in order to address the role of the marine compartment as a sink for atmospheric pollutants under a warming climate.
This model application highlighted a clear need to further improve our understanding of the fate of PCBs related to the organic carbon (OC) content trends in the marine environment.
There is indeed an ongoing discussion on the OC trend content under a climate change conditions, in fact biogeochemical models' results do not always agree on the estimation of the OC content under a warming climate. Model comparisons show that the reason for this is mainly dependent on the nature of observations taken into account by the different biogeochemical studies.
Results from the study on the fate and transport of selected PCBs in the Adriatic Sea under a climate warming scenario show that OC content plays an important role in driving chemicals' concentrations in the marine environment, hence it is of interest to identify the trend of OC content under warming climate conditions. Here we want to compare the different results found in literature starting a discussion on OC content trends under climate warming in the marine ecosystems.

**WE 055**

**Long range transport versus source region exposure potential: effect of dynamic climactic scenarios**

TN Brown, A Kumarappah, F Wania
University of Toronto Scarborough, TORONTO, Canada
Rainfall patterns exert a strong effect on the chemical fate and transport of a large range of water soluble and particle bounds chemicals. Heavy rainfall in source regions prevents long range transport of these chemical species to remote regions, and heavy rainfall in remote regions efficiently deposits them in surface media. However, long range transport is most effective if there are primarily dry conditions in the intermediary regions. When the correct rainfall conditions exist in the source, intermediary and remote regions then chemicals we would normally expect to be strictly source region problems can be quite effectively transported and deposited in remote regions. An attempt is made to quantify this effect and describe the sensitivity of chemical transport to variable climactic scenarios.
On a regional scale the interaction of climatic factors such as rainfall and temperature with the seasonal cycling of organic matter leads to peaks and valleys of chemical concentrations in air and other exposure relevant media. Extrapolated to a global scale this means that some climactic zones contribute more significantly to long range transport of chemicals during particular seasons but may be more susceptible to local emissions during other seasons. Chemical fate simulations have been performed on global and regional scales and the results are used to quantify the human exposure potential to remote and local emissions during different seasons and under different climatic conditions.

**WE 056**

**Screening-level exposure scenarios for personal care products in China and India**

CM Holmes[1], V Vamshi[1], D Mao[1], J Mortimer[2], O Price[2]
[1]Waterborne Environmental, Inc., LEESBURG, VA, United States of America
[2]Unilever - Safety and Environmental Assurance Centre, SHAMBROOK, United Kingdom

The development and application of models to predict in-river concentrations of down-the-drain chemicals (i.e. those used in household and personal care products and pharmaceuticals) are important components of the environmental risk assessment process. While such models (e.g. EUSES and GREAT-ER) exist in Europe, there are currently no available models to estimate exposure of personal care products many developing countries. To this end, work was performed to create a GIS-based system that develops scenarios used to predict the fate of "down the drain"chemicals into freshwater and marine ecosystems.
Predicted Environmental Concentrations in surface water (PECsw) were generated for China at the county level (sub-province) and for India at the district level (sub-province). These geographic units were considered the smallest appropriate spatial analysis unit for each country. PECsw were based on both user supplied product information, as well as other geographically-linked socio-economic and environmental information from official census and other data sources. Product information such as category (e.g., hair, skin, etc.), composition (e.g., ingredient fraction) and "take off "values (GDP threshold under which the product would not be purchased) were used to distribute total tonnes of individual ingredients used in each country. Product use information was available at a regional level (6 regions in China and 4 regions in India). These data were combined with county-level economic information, population density (including urban and rural separation), dilution factors, and disposal mechanism (e.g., STP, septic, direct discharge to river, etc.) to estimate ingredient-level PECs in surface water.
The method presented incorporates the inherent spatial variability of the model inputs so that patterns can be identified and used in the risk assessment. Results identify combinations of model inputs resulting in PECsw distributions, with the ability to identify realistic high-exposure scenarios in the context of the overall country-wide distribution. The results from this modelling are at a more spatially detailed level than previously possible in thes countries. The approach was standardized so it can be applied with very few changes to generate refined datasets for other developing countries with similar data availability challenges.

## EC08 - Tracking community consumption of illicit drugs and other substances by measuring human metabolic residues in urban wastewater

**WE 060**

**Year-long community level measurement of drug use using passive methods with in situ calibration**

C Harman, M Reid, K Langford, KV Thomas
Norwegian Institute for Water Research, OSLO, Norway

The determination of the exposure of a population to a chemical by analysis of metabolites in wastewater (sewage epidemiology) is a relatively new field within environmental chemistry. Fluctuating, trace concentrations of these polar organic compounds in a complex environmental matrix presents a significant analytical challenge. Passive sampling is a monitoring tool that may overcome these difficulties by offering time integrated sampling over a period of several weeks and also achieving lower detection limits. Challenges in applying these techniques include the lack of both an exposure correction method and an adequate uptake model. The aims of this study were therefore to calibrate a passive sampling device in situ for narcotics and their metabolites and to furthermore use these methods to estimate community drug use over a period of one year. Polar organic chemical integrative samplers (POCIS) were exposed at the sewage treatment system for western Oslo (Norway) over a 5 week period. Subsequently POCIS were exposed in exactly the same manner at exactly the same place for two week periods over the course of a whole year in order to determine trends in drug usage. Following exposure, POCIS were extracted and analysed for target compounds by LC-MSMS. Most of the target compounds were accumulated in POCIS and showed linear uptake during the exposure period. Sampling rates were in the order of tens to hundreds of mL d-1 allowing detection limits below ng L-1 in most cases. Results from the year long survey are discussed in terms of the challenges faced by implementing these techniques in a quantitative way, i.e. from passive sampling accumulations to acceptably accurate estimations of drug use per unit population per unit time. Furthermore ongoing work characterising other similar compounds such as the tentative identification of controlled steroids in POCIS extracts is briefly presented. Passive sampling techniques may offer significant advantages over traditional grab sampling methods for measuring polar compounds in wastewater. The current sampling device was able to accumulate most of the target compounds, metabolites of commonly used narcotics and can likely be applied to many more similar compounds. However, more work is required characterising the uptake kinetics of these samplers under varying conditions in order that data can be used quantitatively.

**WE 061**

**Selective determination of illicit drugs by mixed-mode solid-phase extraction and quadrupole-time-of-flight liquid chromatography-mass spectrometry**

JB Quintana, I González-Mariño, I Rodríguez, M González-Díez, R Cela
University of Santiago de Compostela, SANTIAGO DE COMPOSTELA, Spain

In 2005, Zuccato et al. related sewage measured levels of benzoylecgonine, the main cocaine metabolite, to local drug abuse, beginning a trend that has been extended to other illicit drugs and followed by many other researchers. But indeed, the accuracy of this strategy depends on the quality of the analytical methodology employed for the measurement of drugs in wastewater. Most published analytical methods rely on solid-phase extraction (SPE) for analytes' enrichment and liquid chromatography-tandem mass spectrometry (LC-MS/MS) on triple quadrupole instruments (QQQ) for quantification. However, one of the main drawbacks of LC-MS/MS is the occurrence of matrix effects during determination. Also, at least a second confirmation transition is necessary in order to properly identify a positive on a QQQ system, which can also be problematic in complex samples, e.g. for amphetamines due to their low *m/z*. Thus, the main objective of this work was the increase in selectivity during the sample preparation process and LC-MS determination, in order to minimize the aforementioned problems, for the determination of 24 drugs of abuse and metabolites in wastewater. This was achieved by the use of a mixed-mode SPE sorbent (Oasis MCX) with a fractionated elution protocol, where the neutral and acidic compounds were eluted first with methanol and the basic analytes were eluted subsequently with basified methanol. This protocol resulted in less matrix effects (15% to 40% mean signal suppression) as compared to others employed in the literature (ca. 50% to ca. 60% mean signal suppression). Additionally, the performance of the quadrupole-time-of-flight (QTOF) instrument was evaluated, in order to improve the selectivity of LC-MS/MS determination. Due to its high resolution and mass accuracy, only a single MS/MS transition is required, but even the second one can be recorded with a higher mass accuracy than a QQQ. Moreover, the modern Agilent system tested provided an excellent linearity ($R2>0.99$) in the 1-1000 ng/mL range and LODs in the 0.2-4.3 ng/mL range. Overall, the method provided recoveries in the 80-120% range for most analytes and LODs, after SPE, between 1 and 20 ng/L. A further advantage of the QTOF system is the fact that it acquires simultaneously full scan MS and targeted MS/MS data. Thus, a database of accurate masses of more than 90 illicit drugs and metabolites was created and samples could be screened for the presence of new drugs reaching the black market.

**Monitoring of drugs of abuse in Dutch sewage water by LC-LTQ FT Orbitrap MS**

L Bijlsma[1], E Emke[2], R Serrano[1], F Hernández[1], WP de Voogt[3]
[1]University Jaume I, CASTELLON, Spain
[2]KWR Watercycle Research Institute, Chemical Water Quality and Health, NIEUWEGEIN, The Netherlands
[3]Institute of Biodiversity and Ecosystem Diversity, University of Amsterdam, AMSTERDAM, The Netherlands

The presence of drugs of abuse in the water cycle has spurred researchers to monitor their occurrence in wastewater, surface waters and drinking water. Data obtained have been used to calculate environmental loads and removal efficiencies of sewage treatment plants (STPs), and also to estimate consumption and usage trends in the population. The objective in this work is to illustrate the potential of LC coupled to an LTQ FT Orbitrap MS for qualitative and quantitative analysis at ng/L level and to present, for the first time, results of an extensive monitoring study of 25 drugs of abuse and relevant metabolites in urban wastewater from the Netherlands.
From five different STPs of the Netherlands, 24-h composite samples were collected from 32 influents and 32 effluents, along one whole week. Sample pre-treatment consisted of SPE using Oasis HLB cartridges. The chromatographic separation was achieved within 30 min. Full-scan accurate mass spectra, from 100 to 600 Da, were obtained in positive-ion mode (ESI+) at a resolution of 30,000 FWHM. Along the complete chromatographic run, the mass spectrometer operated in a data-dependent-acquisition (DDA) mode, in which both MS and MSn spectra were acquired. In this way, highly confident information for identification, quantification and confirmation could be obtained in a single analysis.
In various influent wastewater samples, concentrations higher than 300ng/L were found for cocaine, benzoylecgonine, codeine, oxazepam and THC-COOH. Relatively high concentrations of amphetamine (~500 ng/L) and ketamine (~ 20 ng/L) were found in influents from a STP located in the south of the Netherlands. In general, concentrations of drugs of abuse in effluents were lower than those of influents, except for benzodiazepines and occasionally MDMA.
By performing additional PCA the analytical results could be evaluated semi quantitatively and allowed to have a better insight on drugs abuse and sewage water treatment efficiency in the Netherlands.

**WE 063**

**Monitoring and uncertainty assessment of cocaine and benzoylecgonine wastewater loads in Switzerland**

C Mathieu[1], JD Berset[2], J Rieckermann[3], S Schürch[3], R Brenneisen[1], C Ort[4]
[1]University of Berne, BERNE, Switzerland
[2]Water and Soil Protection Laboratory (WSPL), BERNE, Switzerland
[3]Swiss Federal Institute of Aquatic Science and Technology (EAWAG), DÜBENDORF, Switzerland
[4]The University of Queensland, BRISBANE, Australia

To check the effectiveness of campaigns preventing drug abuse or indicating local effects of efforts against drug trafficking, it is beneficial to know consumed amounts of substances in a high spatial and temporal resolution. The analysis of drugs in sewage has the potential to provide this information. Here, we present two analytical procedures to determine cocaine (COC) and its main metabolite benzoylecgonine (BE) in sewage treatment plant (STP) influent and effluent water. One is based on solid phase extraction followed by gas chromatography-mass spectrometry (GC/MS), the other uses direct injection high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS). In addition, we provide novel experimental data from several Swiss STPs and suggest a simulation-based method to assess the total uncertainty of the monitored substance loads from flow measurements, sampling, and analytics. The GC/MS method was then applied to acquire a 14-days profile of COC and BE in the STP wastewater (WW) of Berne. In addition, weekend and Wednesday samples were analyzed from the STPs of Zurich, Basel, Geneva, and Lucerne. With 1521 ng/L, the highest COC concentration was found in Geneva WW. With 2900 ng/L, the maximum BE concentration was measured in Zurich WW, collected after a mass rave event. For Berne, the estimated mean daily consumed amount was 107 ± 21 g of pure COC, corresponding to 321 g of street-grade COC. We were able to show that for WW loads of COC and BE in catchments with more than 100'000 inhabitants, the analytical uncertainty is the dominating influence factor and that random errors from sampling are expected to be in the same range as that of flow measurements.

**WE 064**

**Potential of LC-QTOF MS for investigation of drugs of abuse in the aquatic environment**

JV Sancho, L Bijlsma, C Boix, F Hernández
University Jaume I, CASTELLON, Spain

In this work, liquid chromatography coupled to a quadrupole time-of-flight mass spectrometers (QTOF MS) has been used for the investigation of emerging contaminants (e.g. drugs of abuse (DOA)) in the aquatic environment. QTOF MS offers interesting features in this field: full-spectrum acquisition with satisfactory sensitivity, accurate mass measurements of the analyte molecule and its main fragments, strong potential for screening purposes, and the possibility to investigate fragmentation pathways in order to appoint specific fragments.
A large-scope screening was made in water samples. The use of a QTOF instrument enables the simultaneous application of two acquisition functions with different collision energies: a low energy (LE) function, where none or poor fragmentation takes place, and a high energy (HE) function, where fragmentation in the collision cell is promoted. Data obtained are processed after MS acquisition using specialized software and databases allowing the search of a large list of LC-MS amenable contaminants.
A compound database was created, including theoretical exact masses and empirical formulas of around 1000 potential emerging contaminants (including 80 DOA). Since the software first processes data of the LE function, the database mainly consists of exact masses of the parent compounds (typically the protonated molecule). Mass error and isotopic fit of accurate mass data compared with theoretical information indicate possible positives samples. Then, HE spectra with accurate mass fragmentation data are used for a reliable identification. Reference standards were available for 250 compounds (20 DOA), and experimental data (e.g. retention time and fragmentation data) could be obtained in these cases, facilitating an unequivocal confirmation. Besides strong identification purposes, accurate-mass data allows elucidation of the chemical formulae of product ions and is therefore of great value for correct interpretation in the study of

fragmentation pathways. Correct interpretation also permits more rational selection of structural specific fragments, which can be used for searching related compounds, such as metabolites and TPs. In this way, a possible TP of cocaine was discovered after performing chlorination under controlled laboratory conditions.
LC-QTOF MS is highly suited for screening of DOA in aquatic samples and to discover potentially hazardous related compounds.

**WE 065**

**The stability of illicit drugs and metabolites in the aquatic environment - implications for sewage epidemiology**

ALN van Nuijs[1], JF Mougel[2], I Tarcomnicu[1], L Bervoets[1], R Blust[1], PG Jorens[1], HMG Neels[1], A Covaci[1]
[1]University of Antwerp, WILRIJK, Belgium
[2]Aquiris, BRUSSELS, Belgium

The stability of nine illicit drugs and metabolites (cocaine (COC), benzoylecgonine (BE), ecgonine methyl ester (EME), amphetamine (AMP), methylenedioxymethamphetamine (MDMA), methamphetamine (METH), methadone (MTD), 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), and 6-monoacetylmorphine (6-MAM)) in surface and wastewater was evaluated in 36-hour experiments at representative pH-values and temperatures. Blank surface and wastewater was spiked with relevant concentrations of each compound, based on published concentrations in surface and wastewater. At fixed time intervals (e.g. each hour), 100 mL aliquots were collected, internal standards were added for quantification and the aliquots were stored at -20°C in the dark until analysis. Analysis was done with a validated method based on solid-phase extraction and liquid chromatography tandem mass spectrometry (LC-MS/MS) method. All collected aliquots were analyzed in duplicate the day after the collection. The stability for each compound at each time was calculated as a percentage of the initial concentration present in the water. Generally, BE, METH, MDMA, MTD and EDDP showed a high stability while for COC, EME, AMP and 6-MAM significant degradation was observed. As could be expected, a faster degradation occurred with higher temperatures of the water. Differences between surface and wastewater were observed; a higher degree of degradation in wastewater was observed possibly due to the higher content of micro-organisms. A thorough evaluation of the stability of illicit drugs and metabolites in the aquatic environment is of great importance in sewage epidemiology. If degradation during the transport from the place of excretion to the wastewater treatment plant occurs, measured concentrations in wastewater should be corrected for this. Ignoring stability issues in wastewater can lead to serious underestimations in sewage epidemiology.

**WE 066**

**Estimation of the collective consumption of illicit and licit drugs in the city of Zagreb using sewage epidemiology approach**

S Terzic, I Senta, M Ahel
Ruder Boskovic Institute, ZAGREB, Croatia

The work presented in this paper reports on the application of sewage epidemiology approach for the estimation of the collective consumption of illicit and licit drugs in the city of Zagreb
The study was performed in 2009 at the central wastewater treatment plant of the city of Zagreb. Selected illicit and licit drugs were monitored in 24h-composite samples of untreated wastewater over a period of eight months. The analytical procedures used for the determination of selected drug target residues (DTRs) included solid phase extraction and subsequent analysis by liquid chromatography-tandem mass spectrometry (LC-MS-MS). The collective consumption of a number of selected drugs, including 5 illicit drugs (cannabis, heroin, cocaine, amphetamine, MDMA) and several licit drugs belonging to therapeutic opiates and antimicrobials was estimated for the city of Zagreb, based on the representative mass loads of the corresponding DTRs, and the average excretion rates, reported in the literature. The average daily mass loads of studied DTRs varied in the range 1.6 -122 g/day. The observed mass loads were relatively uniform during the investigated period for most of the studied drugs. However, stimulating illicit drugs, including cocaine and amphetamine-type drugs, exhibited a clear weekday-dependant pattern, characterised by an enhanced consumption during weekends. The consumption of the illicit and licit drugs determined in this study was compared with the available official figures and observed agreements and disagreements were discussed.

## EP01 - Alternative flame retardants: Environmental exposure, fate and trends

**WE 069**

**Biodegradability and toxicity of halogen free flame retardants**

SL Waaijers[1], PD González[2], AM Soeter[1], MHS Kraak[1], JR Parsons[1], W Admiraal[1], WP de Voogt[1], SAE Kools[3]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]Universidad Autónoma de Madrid, MADRID, Spain
[3]Grontmij, AMSTERDAM, The Netherlands

Several halogenated flame retardants have been banned due to their persistency, bioaccumulation potential and toxicity (PBT) and probable environmental risk. Hence, alternative flame retardants are required and a range of new flame retardants have been proposed. The PBT properties of most alternative flame retardants, however, have not been tested. Therefore, the aim of the present study was to experimentally determine the ready biodegradability and aquatic toxicity of halogen free flame retardants (HFFRs). Thirteen HFFRs were selected, including 6 organic phosphates (Aluminium Diethyl Phosphinate, Bisphenol A bis(diphenyl phosphate), Dihydro Oxa Phosphaphenanthrene, Melamine Polyphosphate, Resorcinol bis(diphenyl phosphate), Triphenyl Phosphate) and 7 inorganic compounds (Aluminium Trihydroxide, Ammonium Polyphosphate, Antimony Trioxide, Magnesium Hydroxide, a silicate based nanoclay, Zinc Hydroxy Stannate and Zinc Stannate). To estimate the persistency of the organic HFFRs, we applied a modified standardized ready biodegradability test, using the RespicondTM apparatus to make the test suitable for a higher number of chemicals. To determine the acute toxicity of the 13 HFFRs, the compounds were subjected to 48 h immobility tests with Daphnia magna. To test the effects of the HFFRs on a primary producer, we performed a 4 h acute test with the alga Scenedesmus subspicatus, using Pulse Amplitude Modulation Fluorometry to quantify impairment of photosynthesis. These three tests combined provide a relatively fast and effective approach for screening a selection of HFFRs on ready biodegradability and acute aquatic toxicity. Testing the persistency and toxicity is the first step in assessing the environmental safety of these alternative flame retardants.

**WE 070**

**Identification of the flame retardants Ethylene bis(tetrabromophtalimide), TBBPA diallyl ether and TBBPA bis(2,3-dipropyl ether) in environmental samples using LC-APPI-tandem-MS/MS**

L Andersson[1], HPH Arp[2], T Moskeland[3], R Grabic[1], J Nyholm[1]
[1]Umeå University, UMEÅ, Sweden
[2]Department of Environmental Engineering, Norwegian Geotechnical Institute, OSLO, Norway
[3]Det Norske Veritas, OSLO, Norway

An analytical method using liquid chromatography atmospheric pressure photoionization tandem mass spectrometry (LC-APPI-MS/MS) was developed for analysis of the current use brominated flame retardants (BFRs) Ethylene bis(tetrabromophtalimide) (ETBPI), Tetrabromobisphenol A diallyl ether (TBBPA AE) and Tetrabromobisphenol A bis(2,3-dibromodipropyl ether) (TBBPA DBPE). The developed method was applied on diverse environmental samples obtained from three regions in Norway, including waste water, sewage sludge, seepage water, and sediment. ETBPI was detected in seepage water taken close to a metal recycling facility; TBBPA AE was detected both in seepage water and sediment, and TBPPA DBPE in waste water and seepage water. The identities of the BFRs were verified by accurate mass measurements using LC-APPI coupled with high resolution mass spectrometry. The analytes were found in few samples in ng/L levels. To our best knowledge this is the first detection of ETBPI and TBBPA AE in environmental samples. The analyzed samples were taken during a survey of new BFRs in the Norwegian environment and in these samples we also quantified PBDEs and other more hydrophobic BFRs. Reported levels of ETBPI, TBBPA AE, and TBBPA DBPE are thus compared with the regularly monitored BFRs including BDE209.

**WE 071**

**Hexabromocyclododecane (HBCDD) - a brominated flame retardant of high concern**

AA Jensen[1], A Bergman[2]
[1]Nordic Institute of Product Sustainability, FREDERIKSBERG, Denmark
[2]Stockholm University, STOCKHOLM, Sweden

Brominated hexabromocyclododecane (HBCDD or HBCD) is used mainly as a flame retardant in polystyrene-based insulation products. Of particular concern is the capacity of this lipophilic and persistent organic pollutant to accumulate in the food chain, leading to progressively increasing levels in human tissues and in wildlife. The extent of accumulation correlates directly with its ever-more prevalent use. Despite this alarming trend, only limited toxicological information is available to assess its long-term implications for health or the environment. Nevertheless, HBCDD continues to be used despite the availability of alternatives. The European Chemicals Agency has recently in 2008 identified HBCDD as 1 of 14 substances of "Very High Concern", and in September 2010 HBCDD was added to REACH Authorisation List. In October 2010 a committee under the Stockholm Convention has assessed the risks from HBCDD and concluded that HBCDD fulfils the criteria of a persistent organic pollutant (POP), and the committee recommended a global ban of HBCDD use. This presentation provides a succinct up-to date overview of HBCDD's properties and discusses the risks associated with its prevalence in our homes and immediate environment.

**WE 072**

**Levels and distribution of Dechlorane Plus in sediments from three coastal bays, North China**

Z Zhao[1], G Zhong[1], A Möller[1], Z Xie[1], R Sturm[1], J Tang[2], G Zhang[3], R Ebinghaus[1]
[1]Helmholtz-Zentrum Geesthacht, Centre for Materials and Coastal Research, GEESTHACHT, Germany
[2]Yantai Institute of Coastal Zone Research, CAS, YANTAI, China
[3]Guangzhou Institute of Geochemistry, CAS, GUANGZHOU, China

Dechlorane Plus (DP), which was first synthesized in 1970s, has widely been used as a substitute for Dechlorane and brominated flame retardants. Both syn- and anti-isomer have widely been detected in air, water, sediment, biota and human serum, but little information is available for marine sediment which is one of the major sinks for persistent organic pollutants (POPs).
This study focused on DP levels and distribution in marine sediments from three Chinese bays ,i.e. Jiaozhou, Sishili and Taozi Bay in North China.
The top 5cm of the sediments were collected at 48 sampling sites of the three bays. The DP concentrations ranged from 0.6 to 189 ng/kg dw (mean 24.1 ng/kg dw) in Jiaozhou Bay, 0.3 to 138 ng/kg dw (mean 64.8 ng/kg dw) in Sishili Bay and 0.6 to 67 ng/kg dw (mean 34.1 ng/kg dw) in Taozi Bay, respectively. The contamination level was comparable with that of rural river sediments from China ( ~160 ng/kg dw) and of sediments from Lake Winnipeg (30±3.2 ng/kg dw), and it was dramatically lower than that in the sediments close to manufacturing plants, for example, Huai'an canal, China, (1860 to 8000 ng/kg dw) and Lake Ontario, Canada. (2.23 to 586 ng/g dw).
The fsyn value is defined as the syn-isomer/(syn-+ anti- isomer) to identify possible sources of DP in the environment. The fsyn values of sediments from Jiaozhou Bay (mean 0.29) were close to technical mixture (0.35 to 0.40), probably indicating a local usage of DP as a flame retardant. In contrast, sediments in Sishili and Taozi Bay showed much lower fsyn values (mean 0.17). Sishili and Taozi Bay were more open than the semi-closed Jiaozhou Bay, and receive sediment input from the Bohai Sea.
The sedimentation rates were 0.704 cm/a in Jiaozhou Bay and 1.24 cm/a in Taozi and Sishili Bay. The DP inventories from 2006 to 2010 were estimated to be 0.33 kg for Jiaozhou Bay, 0.49 kg for Sishili Bay and 0.37 kg for Taozi Bay, respectively.

**WE 073**

**Seasonal trends in concentrations of organophosphorous flame retardants in coastal surface water**

UE Bollmann[1], A Möller[1], Z Xie[1], R Sturm[1], JW Einax[2], R Ebinghaus[1]
[1]Helmholtz-Zentrum Geesthacht Centre for Materials and Coastal Research, GEESTHACHT, Germany
[2]Friedrich-Schiller-University of Jena, JENA, Germany

In the late 1970s organophosphorous flame retardants (OPFR) were detected in the environment for the first time. Due to the fact that OPFR are used as substitutes for the prohibited polybrominated diphenylethers (PBDE) an increase in the OPFR production is expected.
Varying alkyl- and aryl-ester groups, some of them halogenated, lead to a large variation in the physico-chemical properties - ranging from very polar and volatile (e.g. trimethyl phosphate) to non-polar and non-volatile (e.g. tri(ethylhexyl) phosphate). Therefore they can be transported in different environmental media and have been detected in various environmental compartments. Especially the halogenated OPFR are supposed to be highly persistent in the environment. Several OPFR are known to be toxic (e.g. carcinogenicity) and additionally, the lipophilic OPFR

have the potential to bioaccumulate.
This study focused on the seasonality of OPFR concentrations in the estuary of the River Elbe and the German Bight (North Sea).
Surface water samples were taken during four cruises of RV Ludwig Prandtl in the estuary of the Elbe in March, May, August and October 2010 and three cruises of RV Heincke in the North Sea in March, July and September 2010. The samples were extracted using solid phase extraction (SERVA SERDOLIT PAD III, dichloromethane) and analysed by GC-(EI)-MS. Quantification of 19 different OPFR was done using 5 deuterated OPFR as internal standards (TMP-d9, TEP-d15, TPrP-d21, TBP-d27, TPhP-d15).
14 and 11 OPFR were detected in the Elbe and the German Bight respectively. The decreasing concentrations of OPFR towards the open sea is mostly due to mixing processes with sea water which is approved by the linear correlation of OPFR concentration to salinity. In August an additional depletion probably due to enzymatic reactions might occur. Concluded from the ratio of halogenated to non-halogenated OPFR halogenated OPFR seem to be more stable to this depletion. In the German Bight the sum concentration of OPFR is higher in spring than in summer (100-300 ng/L in March and 20-60 ng/L in July), but the number of individual OPFR compounds is lower. In the non tidal influenced part of the Elbe the sum concentration of OPFR ranged from 200 (May) to 700 ng/L (August).
In conclusion, this study shows a seasonal variation of OPFR in riverine and marine surface water. In summer, non-halogenated OPFR are affected by biodegradation leading to decreasing concentrations while halogenated OPFR are more stable.

**WE 074**

**Occurrence of chlorinated organophosphate flame retardants in soil**

IJ Mihajlovic[1], MV Vojinovic-Miloradov[2], E Fries[1]
[1]Institute of Environmental System Research, University of Osnabrück, OSNABRÜCK, Germany
[2]Department of Environmental Engineering and Occupational Safety and Health, NOVI SAD, Serbia

Restrictions on the use of some polybrominated diphenyl ethers (PBDEs) have resulted in an increased consumption of chlorinated organophosphate esters (OPEs) as alternate flame retardants. This resulted in a ubiquitous detection of chlorinated OPEs in the environment but, surprisingly, we have found no published data that address their occurrence in soil.
In this study, the spatial distribution of tris(2-chloroethyl) (TCEP) and tris(2-chloroisopropyl) phosphate (TCPP) in soil samples was investigated. Soil samples were collected between April and November 2010 from four different locations in Germany: (i) Frankfurt, city centre (ii) Osnabrueck, city centre, (iii) Osnabrueck, 6 km distant from the city centre, and (iv) 3 km distant from the village Jengum. The selected sampling locations were each surrounded by different building and traffic densities which decreased from sampling location (i) to sampling location (ii), (iii), and (iv).
Samples were freeze dried and sieved (2 mm), equilibrated for 24 h, and extracted for 12 h using 150 mL of toluene in a Twisselmann apparatus. Extracts were evaporated to dryness, resolved again in a mixture of 1 mL methanol and 13 mL of tap water, ultrasonicated for 60 min and filtered. 7 mL aliquots were spiked with TnBP-d27 and analysed by solid phase microextraction (SPME) and gas chromatography-mass spectrometry (GC-MS). A one way ANOVA ($p > 0.05$) was performed to analyse the influence of the sampling location on the concentrations of TCEP and TCPP in soil.
Mean concentrations (n=3) varied between 1.75 and 13.5 ng g-1 for TCEP between 1.23 and 8.33 ng g-1, for TCPP. Mean TCEP concentrations decreased from sampling location (ii) to (iii), and (iv) whereas mean TCPP concentrations (n=3) decreased from sampling location (i) to (ii), and (iii). Results of ANOVA demonstrated a significant influence of the sampling location on the concentration of TCEP (F2.6=127.6) and TCPP (F2.6=102.4). Our results demonstrated that atmospheric deposition leads to a contamination of soil with chlorinated OPEs with a significant influence of building and/or traffic density. However, these are the first data on OPEs in soil and more data are needed to clarify the atmospheric deposition processes. The results indicate that atmospheric deposition must be considered in existing risk assessments for TCEP and TCPP.

**WE 075**

**Study of novel brominated flame retardants (nBFRs) in biota and sediment samples from the UK**

S Losada, L Barber, T Maes, J Law, P Bersuder
Centre of Environment, Fisheries and Aquaculture Science (Cefas), LOWESTOFT, United Kingdom

Brominated flame retardants (BFRs) have been widely used to avoid or control fires. The most used BFRs have been the polybrominated diphenyl ethers (PBDEs) and biphenyls (PBBs), tetrabromobisphenol-A (TBBP-A) and hexabromocyclododecane (HBCD). In recent years, many studies have shown their widespread distribution, persistence and bioaccumulation capacity in different food webs [1]. For this reason, several directives and regulations have recently restricted or banned the use of some of these compounds. As their replacements, a range of 'novel' brominated flame retardants (nBFRs) are being used, including decabromodiphenyl ethane (DBDPE), bis(tribromophenoxy) ethane (BTBPE), ethylhexyl-tetrabromobenzoate (TBB or EHTBB), bis(ethylhexyl)-tetrabromo-phthalate (TBPH), tetrabromoethyl cyclohexane (TBBPA-DBPE), hexachloro-cyclopentadienyl dibromocyclooctane (HCDBCO), pentabromotoluene (PBT), pentabromoethylbenzene (PBEB) and hexabromobenzene (HBB). Although little is known about these nBFRs, recent papers have shown the presence of some of these compounds in the Artic [2] and also their bioaccumulation capacity in the aquatic environment [3].
The analysis of nBFRs is usually carried out using analytical methods optimised for other BFRs, making the results obtained less reliable. For this reason, the need for development of improved multi-residue analytical methods for nBFRs has been highlighted [4]. Our study has focused on the development of analytical methods for the analysis of 17 novel BFRs (including allyl-tribromophenyl ether (ATE), bromoallyl-tribromophenyl ether (BATE), tetrabromo-p-xylene (pTBX), pentabromobenzylacrylate (PBBA), pentabromobenzylbromide (PBBB), tetrabromo-o-chlorotoluene (TBoCT), pentabromochlorocyclohexane (PBCC), octabromotrimethylphenylindane (OBIND) and tris-(tribromophenoxy)-triazine) in environmental samples. Different extraction and clean-up methods have been evaluated, including PLE, SPE and GPC, and an optimised method has been produced. This validated method will be used for the analysis of biota and sediment samples from the UK.

**Comparison of PBDE and brominated flame retardant toxicity in zebrafish**

Y Usenko, ED Bruce
Baylor University, WACO, TX, United States of America

New flame retardant chemicals are being developed and used in consumer products due to the banning and phasing out of polybrominated diphenyl ethers (PBDEs). Unlike PBDEs, however, the toxicity and potential for environmental release of these newer compounds is largely unknown. The purpose of this study was to investigate the toxicity of a wide range of PBDEs in comparison to several brominated flame retardants. A variety of PBDEs were chosen for evaluation with varying numbers of bromines and varying locations of bromines (BDEs 28, 47, 99, 100, 153, 183, and 209). In addition, several non-PBDE brominated flame retardant, such as tetrabromobisphenol A (TBBPA) and its ethanol-derivative (TBBPA-OHEE) as well as hexabromocyclododecane (HBCD) and tetrabromophthalic anhydride (PHT4) were also examined. Embryos were exposed to a concentration gradient from 6 hours post fertilization (hpf) until 168 hpf. There was an inverse correlation between LC50 and log Kow for PBDEs. BDEs 28, 47, 99, and 100 induced increases in spontaneous movement, curved body axis, and mortality. BDEs 153, 183 and 209 did not elicit an effect at any concentration tested (up to 20 ppm). Tetrabromobisphenol A (TBBPA) and TBBPA-OHEE decreased spontaneous movement in a concentration-dependent manner. Furthermore, these two compounds induced different malformations than typical malformations (i.e., fin malformation, pericardial and yolk sac edema) seen with PBDE exposures. TBBPA induced adverse effects at lower concentrations and earlier in development than TBBPA-OHEE. HBCD, however, elicited similar responses in zebrafish as did PBDEs, although it did not induce mortality at any concentration over the seven-day exposure study. PHT4 did not alter behavior or induce malformations at any concentration tested; however, at 20 ppm it induced 100% mortality. As PBDEs are continued to be phased out, the flame retardants that replace them may pose new risks with unknown modes of action and biological activity.

**WE 077**

**Effects of latitude and diet on levels and patterns of PBDEs in the eggs of a marine top predator in the North Atlantic**

EHK Leat[1], AT Fisk[2], K Borgå[3], RW Furness[1], JO Bustnes[4]
[1]University of Glasgow, GLASGOW, United Kingdom
[2]Great Lakes Institute for Environmental Research, WINDSOR, Canada
[3]Norwegian Institute for water research, OSLO, Norway
[4]Norwegian Institute for Nature research, TROMSØ, Norway

In contrast to organochlorines, little is known about the factors which affect concentrations and patterns of PBDEs in biota. PBDEs have been detected in temperate latitudes and the high Arctic, however few comparisons exist of PBDE concentration and pattern across a range of different latitudes in the same matrix. The Great Skua (Stercorarius skua) is a long lived seabird, and as a top predator has the potential to bioaccumulate high levels of persistent organic pollutants. Its breeding range across the North East Atlantic has allowed comparison of PBDEs in eggs from 3 colonies; Shetland, Iceland and Bjørnøya, ranging from 60 to 74°N, to investigate the effects of latitude. Confining comparisons to one species controls for potential differences in ability to metabolise PBDEs, however Great Skuas are generalist predators so diet composition may also affect PBDE concentrations and patterns. Here we analyse PBDE data from eggs collected in 2008, in conjunction with diet data from pellet collection and stable isotope (δ13C and δ15N) analysis to allow further exploration of PBDE variation between the three colonies. Concentrations of PBDEs in the eggs are generally higher than those found in similar species in the North Atlantic. Although diet varied within and between colonies no relationships were found between trophic level (assessed using δ15N) and PBDE concentration. The pattern of PBDE varied between colonies with proportionally more congeners with a higher degree of bromination in the most northerly colony, in contrast to predictions based on global fractionation theory. However great skuas are migratory and pollutants in eggs may reflect wintering areas in addition to breeding colony. Geolocator data has identified two main wintering areas for the Icelandic and Bjørnøya birds, the Grand Banks in North America and Southern Europe and North Africa. In contrast Shetland great skuas winter only in Southern Europe and North Africa. Greater variation in PBDE pattern within the Icelandic and Bjørnøya colonies may be an indication of the influence of members of these populations wintering in geographically diverse areas.

**WE 078**

**In utero exposure to polybrominated diphenyl ethers (PBDE); hair analysis to examine link to cryptorchidism**

K Aleksa[1], A Carnavale[1], D Bägli[1], R Jednak[2], C Goodyer[3], G Koren[1]
[1]Hospital for Sick Children, TORONTO, Canada
[2]The Montreal Children's Hospital, MONTREAL, Canada
[3]McGill University, MONTREAL, Canada

Cryptochidism, or undescended or maldescended testis, is the most common birth defect of male genitalia. Its prevalence has been increasing over the past few decades. This may be due to an increase in the prevalence of anti-androgenic chemicals such as polychlorinated biphenyls, organochloride pesticides, plasticizers and fungicides. A newer group of chemicals, brominated flame retardants (BFR), are being implicated as endocrine-disrupting chemicals these chemicals are used worldwide in polymers that are incorporated into a variety of consumer products (e.g., textile, computers and televisions, insulating foam, electrical equipment and kitchen appliances). In order to quantify BFRs we will use hair levels of polybrominated diphenyl esters (PBDE's) as a biomarker of systemic exposure. This approach will allow for the determination of BFR levels that the baby was exposed to in utero. Thus our hypothesis is that there may be a link between the incidence of cryptorchidism in new born males and chronic exposure of the pregnant mother to environmentally relevant BFRs. To evaluate this we have developed gas chromatography with mass spectrometry assay in which we analyzed the hair of children ranging in age from newborn to 15 years of age for the presence of BDE-28, 47, 100, 99, 153, 154, 183 and 209. Twenty to 50 mg of hair was used for the analysis. The greatest variability was found with BDE-47 (49.9 pg/mg) and BDE-99 (35.4 - 1180 pg/mg) and BDE-209 was found in 75% of the samples. Further BDE's were found in all of the newborn hair samples tested suggesting that transplacental transfer of these xenobiotics does occur.

**WE 079**

**Estimation of the content of brominated flame retardants in end of life products in Mexico**

**and the potential emissions**
A Gavilan, IG Gavilán-García, ES Santos-Santos
UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, MEXICO, Mexico
Brominated flame retardants (BFRs) are synthetic additives that have been used in a variety of manufactured products, including foam cushioning used in furniture and plastic housings for televisions and computers, automobiles and large and small household appliances. The polybrominated diphenyl ethers (PBDEs) are a group of chemicals used as flame retardants that have persistent organic pollutants properties and are suspected to cause adverse health and environmental effects. For this reason, in May, 2009 were included in the Stockholm Convention as one of the chemicals of global concern. Currently, a large number of goods manufactured or imported to Mexico contain an unknown percentage of PBDEs since many of them are manufactured in other countries. In addition, the environmental fate of these substances is unknown and an inappropriate management might represent a potential risk to human health and the environment. In this study, the patterns of consumption, use and disposal of PBDE containing materials and products in Mexico from 1998 to 2008 in order to estimate potential risk from emissions along the life cycle of these materials. The methodology included: 1) review of official databases (INEGI, Customs, Economy Bureau, PRTR, US and Canada databases), 2) Official reports (OECD, Basel & Rotterdam Conventions, 3) Industry reports, 4) Polymer applications, 5) substance flow analysis, and 6) International regulatory framework. Preliminary results estimated that PBDEs released at the end of life of products might range from 5.6 tons in 1997 to 457.5 tons in 2008 with a mean yearly value of 237.40 tons for the period 1996-2009. As conclusion, restrictions on the import of PBDE containing materials might be implemented and disposal in landfills might be restricted.

**WE 080**
**Polybrominated diphenyl ethers analysis in plastics using ultrasound assisted extraction**
I Gavilán-García, ES Santos-Santos, AG Gavilan
FACULTAD DE QUIMICA, UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, MEXICO CITY, Mexico
Polybrominated diphenyl ethers (PBDEs) are a group of compounds used as additives in a wide range of materials to reduce the risk of fire. PBDEs comprise a total of 209 isomers. The IUPAC nomenclature consist in assigning a number to each compound (BDE-1 to BDE-209) conventionally called congeners and they are organized into 10 groups (mono to deca brominated). Three commercial mixtures of PBDEs are applied as flame retardants, Penta-BDE (45% Tetra-BDE, 45% penta-BDE, 10% other isomers), Octa-BDE (45% hepta-BDE, 33% octa-BDE, 12% hexa-BDE, 10% nona-BDE) and Deca-BDE (98% deca-BDE and 2% other isomers). PBDEs have been used in a variety of manufactured products at different proportions according to the manufacturer and according to the product they are used in. The aim of this study was to determine the content of polybrominated diphenyl ethers in samples of the plastic casing of a laptop computer using Soxhlet & ultrasound-assisted extraction (UAE). Analysis was developed by gas chromatography coupled to mass spectrometry (GC/MS) using toluene, ethyl acetate and methanol-isopropanol (1:1 v/v) as extraction solvents. The PBDEs: BDE-47, BDE-99, BDE-100, BDE-153, BDE-209 were characterized and quantified with good linearity (0.987-0.999) and repeatability (RSD, 0.7-2.8. The toluene was shown to be the best solvent for extraction of PBDEs in the analyzed samples. Different content of PBDEs were found in the samples ranging from 4.8 µg g-1 to 23.98 µg g-1. UAE showed equivalent results to Soxhlet with the benefit of requiring of a reduced time for the extraction stage.

**WE 081**
**A comprehensive analysis of brominated, chlorinated and organophosphorus flame retardants by Gas Chromatography/Mass Spectrometry: optimization of ionization and detection techniques**
J Cristale[1], R Chaler[1], F Ventura[2], S Lacorte[1]
[1]IDAEA - CSIC, BARCELONA, Spain
[2]Aigües de Barcelona, BARCELONA, Spain
A multiresidue method based in gas chromatography coupled to quadrupole mass spectrometetry was developed to determine organophosphorus flame retardants (TCEP, TCPP, TDCPP, TPhP), PDBEs (BDEs 28, 47, 99, 100, 153, 154, 183 and 209), non-PBDEs flame retardants (PBEB, DPTE, HBB, HCDBCO, EHTBB, BTBPE, BEHTBP, DBDPE), bromophenols, bromoanilines, bromotoluenes and bromoanisoles. Two ionization techniques (electron ionization, EI and electron capture negative ionization, ECNI) and two acquisition modes (selected ion monitoring, SIM, and multiple reaction monitoring, MRM) were compared as regards to identification, sensitivity and quantification capabilities. Highest sensitivity, at expenses of identification capacity, were obtained by ECNI MS/SIM for most of the compounds analyzed, mainly for PBDEs and DBDPE, while 3 and 4 bromophenol, and TCEP and TCPP were not detected. The GC-MS in MRM was the most selective technique and permitted the identification of target compounds at the pg/uL level, and identification capabilities increased when real samples were analyzed. This method was further used to evaluate the presence and degradability of flame retardants in water within a waterwork facility. TCEP, TCPP, TDCPP and TPhP were detected in influent waters, and TCEP and TCPP were not degraded throughout the different treatment stages and were identified in finished water.

## EP02 - Antimicrobial resistance in the environment

**WE 084**
**Occurrence of antibiotic resistance and characterization of resistant genes and integrons in gram-negative bacilli (GNB) isolated from integrated fish farms in Zhongshan, southern China**
GG Ying, HC Su, R Tao, RQ Zhang
Guangzhou Institute of Geochemistyr, GUANGZHOU, China
Gram-negative bacilli (GNB) isolated from four integrated fish farms in Zhongshan, South China were tested for antibiotic resistance, tetracycline resistance genes, sulfonamide resistance genes and class 1 integrons. The Kirby-Bauer disk diffusion method and PCR assays were carried out to test antibiotic susceptibility and resistance genes. High antibiotic resistances were found, especially for ampicillin (86%), tetracycline (73%), oxytetracycline (73%) and trimethoprim (58%). Out of 477 GNB isolates, 98.5% were resistant to one or more antibiotics tested. Multiple antibiotic resistance was found highest in animal manures. Tetracycline resistant genes and sulfonamide resistant genes were detected; tetA, tetC and sul2 were detected with a percentage of more than 50%. The intl1 gene was found in 416 isolates (87.2%). Four gene cassettes, aadA5, aadA22, dfr2 and dfrA17 were detected. To the best of our knowledge, this is the first report for molecular characterization of antibiotic resistance genes in gram-negative bacilli isolated from integrated fish farms in China and gene cassette array dfrA17-aadA5 was first detected in integrated fish farms in China. Results of this study indicated that fish farms may be a reservoir of highly diverse and abundant ARGs and gene cassettes. Integrons may play a key role in multiple antibiotic resistances with the antibiotic selective pressures, posing potential health risks to the general public and aquaculture.
Keywords: fish farm, antibiotic resistance, resistance genes, integrons, gene cassettes.

**WE 085**
**Pollution Induced Community Tolerance (PICT) as a tool for environmental risk assessment of antibiotics**
M Hangler[1], E Boriani[2], KK Brandt[1], J Sørensen[1]
[1]University of Copenhagen, FREDERIKSBERG, Denmark
[2]Mario Negri Institute for Pharmacological Research, MILAN, Italy
Pollution Induced Community Tolerance (PICT) is a concept where toxicant-induced succession in a microbial community is quantified by an increase in tolerance of the total community to the compound in question. This increase is thought to reflect three possible effects; (i) the disappearance of sensitive species through direct intoxication and the proliferation of more tolerant species, (ii) the physiological changes that render the organisms less sensitive or, (iii) genetic changes such as acquiring mobile genetic material encoding more resistance. Traditionally, PICT has been used to study microbial communities based on physiological profiling or growth parameters and is often presented as dose-response curves. However, the causative effects explaining the PICT-responses are not uncovered using the traditional methods. In this presentation, we evaluate PICT as a tool for assessing the risk of introducing antibiotics into the soil environment using the synthetic antibiotic sulfadiazine as a model compound. The potential hazard of exposure of SDZ on a time scale was calculated using experimental and predicted properties of motility, volatility, persistency, bioconcentration and solubility of the compound. Finally, a preliminarily ecotoxicological and human risk assessment was conducted using both traditional methods and the PICT assays.

**WE 086**
**Antibiotic resistance profiles of bacterial strains isolated from a treatment plant receiving waste-water from the manufacture of pharmaceuticals**

[1]National Center for Cell Science, PUNE, India
[2]Institut Mediterrani d'Estudis Avançats (CSIC-UIB), PALMA DE MALLORCA, Spain
[3]University of Gothenberg, GOTEBORG, Sweden
Environmental antibiotic contamination presents the potential to select for resistance factors that can be transferred between bacteria, contributing to the establishment of multidrug-resistant variants. In the present study we have investigated the antibiotic sensitivity pattern of bacterial strains isolated from a treatment plant that receives waste-water from 90 different Indian bulk drug producers. In the treated effluent from this plant, we have previously reported very high levels of antibiotics, predominantly fluoroquinolones, at concentrations up to 1,000,000 times greater than those normally observed in treated sewage effluents. The taxonomic identities of all isolates were determined by 16S rRNA gene sequencing, followed by screening their sensitivity to 39 antibiotics belonging to 11 different classes. All isolates were resistant to, at least, 4 antibiotics, thus conferring a 100% multi-drug resistant population, and the majority were resistant to more than 20 antibiotics. Our study suggests that the waste-water treatment plant studied is potentially serving as an enrichment site for multidrug-resistant bacteria, which could pose a major public health issue in the future.

**WE 087**
**Influence of sulfadiazine on the dynamics of bacterial resistance genes in manure and manured soil**
A Focks[1], H Heuer[2], M Lamshöft[3], K Smalla[2], M Matthies[1], M Spiteller[3]
[1]Institute of Environmental Systems Research, OSNABRUECK, Germany
[2]Federal Research Centre for cultivated plants (JKI), BRAUNSCHWEIG, Germany
[3]Institute of Environmental Research, DORTMUND, Germany
In the last years, the relation between the use of antibiotics in animal production and the environmental occurrence of antibiotic resistance genes (ARG) has received growing interest. The implication of using manure from pigs treated with the sulfonamide antibiotic sulfadiazine (SDZ) as fertilizer for arable fields and pastures was investigated in a recent study (Heuer *et al*, SBB 2008). SDZ was administered as $^{14}C$-labeled compound to pigs to investigate the fate of the drug and its metabolites and the antibiotic effect on resistance genes in manure and manure-amended soil. In soil, the extractable amounts of the compounds decreased to less than 1 mg $kg^{-1}$ within 11 days after manure amendment. The abundances of SDZ resistance genes *sul1* and *sul2* were determined by qPCR relative to 16S rRNA genes in total DNA. With manure, high amounts of *sul1* and *sul2* were introduced into the soil, which were reduced by more than 10 times within 24 days. Thereafter, *sul1* was stable in soil, while *sul2* further decreased between day 60 and day 165. A mathematical model was developed that could well explain the time course of *sul* gene abundance by considering the cost of sul genes, horizontal gene transfer, and selection of resistant populations in the presence of SDZ. Modelling revealed a selective effect of SDZ on *sul2* even at low concentrations down to 0.15 mg $kg^{-1}$ soil.
This study showed that an increase of ARG levels in the environment can be a direct consequence of current practice in animal production. The simultaneous application of ARG and antibiotics leads to a prolonged persistence of ARG in soil. The risk for ecosystems posed by ARG may be rather low, because the accumulation of resistance genes in the environmental reflects an adaptation of microbial communities to selective pressure. Adaptation of microbial communities lead to stabilized soil functions. Examples for an adaptation of e.g. ammonium oxidation in soil as key step in nitrogen turnover are known (Schauss *et al*, Env.Microb. 2009). For human health, however, increasing frequencies of ARG in the environment lead to a higher exposure towards ARG via raw foods or farmers with known consequences for health and economics. Application volumes of antibiotics in animal production should be reduced by downsizing stocking rates or immediate separation of single sick animals instead of preventive antibiotic treatments of complete livestocks. This would possibly reduce the selection of ARG in the environment.

**WE 088**
**The genome of an extensively drug-resistant bacterium isolated from a wastewater treatment plant receiving effluent from antibiotic manufacturing**
A Johnning[1], E Kristiansson[1], YS Shouche[2], E Moore[1], DGJ Larsson[1]
[1]University of Gothenburg, GOTHENBURG, Sweden
[2]Pune University, PUNE, India
Antibiotics save millions of lives every year and are crucial for fighting disease worldwide. How-

ever, the heavy usage also leads to antibiotic resistance - one of the most important challenges for the health care sector. As bacteria can move between environments, and resistance genes often are transferred horizontally between species, it is important to protect also the environmental bacteria from excess antibiotic exposure. We have sequenced the genome of a multiresistant strain of *Ochrobactrum intermedium*, a common environmental bacterium and opportunistic pathogen. This particular strain was isolated inside a treatment plant in India receiving waste water from 90 bulk drug manufactures and was found to be resistant to 36 of 39 tested antibiotics. Massively parallel pyrosequencing (454 sequencing) of its genome resulted in an average sixteen-fold coverage. Comparative genomics were used to analyze the genome of the resistant strain in relation to the already sequenced reference strain (*O. intermedium* LMG 3301). The analysis revealed structural differences between the strains including both larger deletions and insertions. Several point mutations were also detected in coding sequences as well as in ribosomal RNA. We identified twelve resistance genes in the isolate, compared to two in the reference strain. The quinolone target enzymes DNA gyrase and topoisomerase IV showed nine amino acid changes in the protein sequences for the isolate, one of which is known to cause quinolone resistance in *Escherichia coli*. There is also a considerable number of reads that do not map onto the reference genome, suggesting that the isolate has acquired large regions of novel genetic material. The results presented here demonstrate the power of second generation sequencing technology as well as the need for sustainable management of antibiotic waste.

### WE 089

**Survival and leaching of Tetracycline resistant bacteria and fecal indicators from manure in field scale experiments.**

B Bech[1], L Fredslund[1], J Jeanne[1], A Forslund[2], M Amin[3], S Pedersen[3], M Lægdsmand[3], P Olsen[3], A Dalsgaard[2], CS Jacobsen[1]
[1]GEUS, COPENHAGEN, Denmark
[2]University of Copenhagen, COPENHAGEN, Denmark
[3]University of Århus, AARHUS, Denmark

The spreading of manure on agricultural land is an economic and practical solution for improving soil quality; however, animal manure frequently contains zoonotic pathogenic bacteria, such as certain Eschericia coli, Salmonella spp. and Campylobacter spp. The present experiment was conducted as a large multidisciplinary project. Pig manure with a natural content of Tetracycline resistant bacteria and fecal indicator organisms was followed in soil columns and a field scale experiment.

In the field experiment pig manure was injected into agricultural soil. The distribution and survival of natural occurring indicator bacteria around a manure slurry slit in the soil was followed. During a period of two months, sections of soils with different distance to the manure string were assayed to obtain information on survival and spread of bacteriophage, faecal indicators (Enterococci, Bacterioides, E. coli) and Tetracycline resistant bacteria. The die-off of the different organisms was quantified showing an extended survival close to the manure string. Genomic DNA from 400 Tetracycline resistant bacteria was isolated and their phylogenetic relationship was established using BOX PCR showing that the main Tetracycline resistant bacterial species is E. coli.

Drainage water from the field sites were collected weekly from one year prior to manure application, where no Tetracycline resistant bacteria were detected. For a period of 11 months following the first manure application, drainage water was sampled proportional to the flow and collected weekly. Selected storm events were intensively monitored by the collection of subsamples for every 2 mm of drainage runoff, using a refrigerated ISCO sampler. Drainage samples were tested for Tetracyckline resistant bacteria and fecal indicators. The highest concentration was found in the first drainage sample following manure application; however a fast decrease in cell numbers in the following drainage samples was seen. For the Tetracyckline resistant bacteria concentrations up to approximately 100 CFU $ml^{-1}$ was detected.

In conclusion, the survival and environmental spread of indicator organisms show that the upper soil and drainage water are impacted by the microorganisms natural originating from pig manure under natural conditions.

### WE 090

**Relationship between geochemistry and antibiotic resistance in Scottish soils**

CW Knapp[1], SM Mccluskey[1], BK Singh[2], CD Campbell[3], G Hudson[3], DW Graham[4]
[1]University of Strathclyde, GLASGOW, United Kingdom
[2]University of Western Sydney, PENRITH, Australia
[3]The Macaulay Land Use Research Institute, ABERDEEN, United Kingdom
[4]Newcastle University, NEWCASTLE UPON TYNE, United Kingdom

Links exist between heavy-metal and antibiotic resistance. Basically, these genes can either be found on same transferrable genetic elements (co-resistance) or a single gene confers resistance to both chemicals (cross-resistance). Therefore, the selection of one trait tends to confer resistance for the other. Most evidence exists in clinical samples (e.g., dental amalgams), but little evidence exists in the environment. Is it possible for background metal levels in the natural environment to promote the presence of resistance genes? Here, we examined the relationship between antibiotic resistance and certain geochemical conditions in Scottish soils, and we found that antibiotic-resistance gene abundance directly correlated with Cu, Zn and clay levels. The study suggests that geochemical conditions can impact the potential for resistance among soil micro-organisms. The extensive survey of soils done here, over wide range of geologic conditions, will help inform risk assessors understand background environmental conditions, which is essential to help drive policy and decision-making to protect agricultural and human health.

## EP03 - Emerging per- and poly-fluorinated compounds: Source identification, environmental fate, and remediation strategies

### WE 093

**Physicochemical properties of poly- and perfluorinated alkyl substances (PFAS) calculated using COSMOtherm®**

Z Wang[1], M Macleod[2], IT Cousins[2], M Scheringer[1], K Hungerbühler[1]
[1]Swiss Federal Institute of Technology, ZURICH, Switzerland
[2]Department of Applied Environmental Science (ITM), Stockholm University, STOCKHOLM, Sweden

Many man-made poly- and perfluorinated alkyl substances (PFAS) have been detected in the environment and human food, but there is still incomplete understanding of how they cycle and transform in the environment. To address this knowledge gap, environmental fate models have been applied to analyze the sources and distribution of some PFAS. However, lack of physicochemical data that are required as input data for the models has limited the focus of model studies to C8-C13 PFCAs and PFOS, and a limited number of their precursor compounds. Experimental determination of properties of PFAS is challenging and there are many compounds of potential interest. Therefore, computational methods are an attractive alternative for estimating properties of PFAS. A quantum chemistry-based software, COSMOtherm®, was applied to calculate properties for some PFAS in a previous study by Arp et al. [1]. In this work, we evaluate the performance of COSMOtherm® and extend its application to a much larger set of PFAS, including the most widely used perfluoroalkyl acids, their precursors and some important intermediates that have been identified in degradation studies. We evaluated the performance of the method using fluorotelomer alcohols as model chemicals, since measurement data exist. For these compounds, property data calculated by COSMOtherm® agree within one order of magnitude with the experimental data. We additionally applied the method to other PFAS for which no or very few data exist. Specifically, we calculated octanol-air, air-water and octanol-water partition coefficients (*Koa*, *Kaw* and *Kow*) for homologous series of sulfonic and sulfinic acids, phosphonic and phosphinic acids, olefins, iodides, phosphate esters, sulfonamides/-ethanols, and saturated and unsaturated aldehydes with poly- and perfluorinated chain lengths from 4-14 carbons. Consistency checks between different properties were made to assess the quality of empirical and modeled property data. The result of the calculations described here are a set of physicochemical property data that provide insights into structure-property relationships for PFAS. Within the same group, both *Kaw* and *Kow* increase with increasing fluorinated chain length, whereas for the same fluorinated chain length, the polarity of the functional group contributes significantly to the partitioning; e.g. *Kaw* decreases with increasing polarity of the functional group.

### WE 094

**Analysis of 18 perfluorinated compounds in blood by on-line turbo flow-LC-MS/MS**

M Llorca[1], F Pérez[1], M Farré[1], S Agramunt[2], M Kogevinas[2], D Barceló[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]CREAL, IMIM Hospital del Mar, BARCELONA, Spain

Perfluorinated compounds (PFCs) have been manufactured since 40s due to their thermal, chemical and biological stability. The PFCs are persistent and bioaccumulative due their affinity to proteins. The aim of the present work has been: I)to develop an on-line methodology turboflow extraction to analyze 18 PFCs in biological samples; II)to assess the presence of PFCs in 30 serum samples.

150µl serum sample was taken and introduced into PP eppendorf with 150µl Acetonitrile, shaked 1 min and centrifugated at 4000rpm, 10min, in order to precipitate the proteins from samples.100µl of supernatant was introduced into PP insert vial. The extraction and separtation was carried out in a Thermo Scientific Aria TLX-2 system utilizing TurboFlow. Different extraction columns were tested during optimization. The final methodology include two extraction columns in tandem: Cyclone and C18 XL. The injection volume was 20µl at turbulent flow of 1.5ml/min water pH 3.4. The loop elution (250µl) was performed with water pH 3.4:methanol (20:80). Separation was carried out in a LC-column Hypersil GOLD PFP (50x3) and an extra-column was used after LC pumps in order to remove the contamination from the pumps. Triple mass spectrometer for analysis, equipped with a Turbo Ion Spray source (negative mode) and single reaction monitoring.

Lamp blood was used as a blank material during optimization process. Method limits of detection were established between 18-1114ng/L. The CCα error and CCβ error were calculated according ISO 11843 (CCα = 39 to 2030ng/L and CCβ = 53 to 2690ng/L). Recoveries were established between 50 - 169%.

The developed method was applied to 30 serum samples. The levels of PFCs were between 0.09 and 26.99 µg/L. The highest ones corresponded to perfluoropentanoic acid and perfluorohexanesulfonate (PFHxS). One of the most ubiquitous patten was observed for ion perfluorooctanesulfonate.

### WE 095

**Fully automated analytical method for the determination of perfluorinated compounds accumulation in human hair**

F Perez[1], MC Llorca[1], MU Farré[1], DC Barceló[1], DC Barceló[2]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]Catalan Institute for Water Research (ICRA), GIRONA,, Spain

Perfluorinated compounds (PFCs) are ubiquitous contaminants in humans and animals worldwide [1]. Furthermore, concern has increased about the toxicity of these compounds. In addition, different studies have shown that PFCs affects the lipid metabolism, disturbs the immunity system, can cause liver cancer and can be a cause of human infertility [2]. Therefore, monitoring human exposure to PFCs is important.

In the present work a high-throughput method for measuring trace levels of 21 PFCs in human hair have been developed. The method consists of an ultrasonic extraction with acetonitrile, followed by an on-line clean-up step utilizing the TurboFlow[TRADEMARK] technology coupled to liquid chromatography-tandem mass spectrometry (LC-MS/MS). The method is sensitive, with LOD between 0.025 and 1 ng/g of hair, involves minimal sample preparation, and it is suitable for large epidemiologic studies to assess human exposure to PFCs. This approach involves the use of two extraction columns in tandem: Cyclone and C18 XL. The injection volume was 20 µl. The influent solvent consisted in water pH 3.4 at turbulent flow of 1.5 ml/min, 20 s. An extra clean-up step with water at 0.5 ml/min, 10 s, was included. The loop elution (250 µl) was performed with (water pH 3.4 : methanol (20:80)) and followed by (water at pH 3.4 : methanol (70:30)) at flow of 0.2 ml/min, 2 min. Separation was carried out in a LC-column Hypersil GOLD PFP (50 x 3) (Thermo Scientific). Chromatographic mobile phases were (A) aqueous ammonium acetate 20 mM, and (B) MeOH, and the total run time was16 min. Thermo Scientific TSQVantage mass spectrometer, coupled to TLX-2, was used for analytical purposes, equipped with a Turbo Ion Spray source operated in the negative mode and working in SRM. The analytical method was validated using fortiufied blank hair samples. The method showed high recoveries rates in the range from 60 to130%, and good reproducibility and repeatability were also shown. The applicability of the method was tested with 20 real samples of hair.

### WE 096

**Liquid chromatography-tandem mass spectrometry analysis of perfluorooctane sulfonate and perfluorooctanoic acid in fish fillet samples**

V Paiano, E Fattore, A Carrà, C Generoso, R Fanelli, R Bagnati
"Mario Negri" Institute for Pharmacological Research, MILAN, Italy

Perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) are two environmental contaminants, characterized by a fully fluorinated hydrophobic chain and an hydrophilic head.

Their specific properties, especially high chemical and thermal stability and low surface free energy, make these chemicals unique for their ability to repel both water and oils, and useful in several applications, such as surface treatments for coatings, clothes, carpets, packaging products, cookwares, and food contact papers. As a result of their widespread use, they are globally distribuited and detected in environmental and biological samples. Moreover, they are extremely persistent, bioaccumulative and of toxicological concern because they have been shown to be carcinogenic in experimental animals.
In this study we present a new and fast analytical method to quantify these compounds in the edible part of fish samples. The method, based on isotope dilution with 13C labeled internal standards, uses a simple liquid extraction by sonication, followed by a direct determination using liquid chromatography - tandem mass spectrometry and avoids a solid phase extraction step (SPE), resulting in a lower sample contamination by extraction solvents and in a shortening of the analysis time. The linearity of the instrumental response was good, since the average regression coefficients of the calibration curves were always close to 1. The repeatability, expressed as average coefficient of variation, was 14% and 20% (inter-day) and 8% and 19% (intra-day) for PFOS and PFOA, respectively. The method was applied to samples of homogenized fillets of wild fish from Mediterranean Sea. Most of the samples showed low or contamination below limit of detection values (LOD = 0.04 ng/g), which was the same for both the analytes. The highest concentrations of PFOS (5.96 ng/g f.w.) and PFOA (1.89 ng/g f.w.) were found in an anchovy (Engraulis Encrasicolus) and in a norway lobster (Nephrops Norvegicus), respectively.
The developed analytical methodology can be used as a tool to monitor and to assess human exposure to perfluorinated compounds through sea food consumption, which seems to be one of the main routes of exposure to these pollutants for human population.

**WE 097**
**Different quantification methods to calculate PFC concentrations in biota samples**
J Rubarth[1], A Dreyer[2], JW Einax[3], R Ebinghaus[1]
[1]Helmholtz-Zentrum Geesthacht, GEESTHACHT, Germany
[2]Eurofins GfA, Air Monitoring, HAMBURG, Germany
[3]Friedrich Schiller University of Jena, JENA, Germany
In this study we investigated the applicability of different quantification methods to calculate the concentrations of twelve perfluorinated compounds (PFCs) in biota samples. Four perfluorinated sulfonates (PFSAs), seven perfluorinated carboxylates (PFCAs), and perfluorooctane sulfonamide (PFOSA) were analysed using HPLC-ESI-MS/MS. Four liver samples of red-throated divers were prepared and analysed by an optimised and validated extraction and clean-up method. Biota samples were quantified by standard addition using two spiking levels. These calculated PFC concentrations were assumed to be 'correct'. Accuracy and precision of the standard addition method were verified before. Additionally, a calibration in solvent and a calibration in reference matrix (turkey liver) were used for quantification of PFC concentrations in the liver samples of the red-throated divers. All PFC concentrations were calculated by the external calibration approach as well as the internal calibration approach using mass-labelled standards. Results obtained by the different quantification methods were compared and evaluated for their applicability to calculate PFCs in biota extracts on the basis of influence on ionisation or relative recovery rates of native substances, i.e. the ratio of the native substance's recovery to the recovery of the mass-labelled counterpart. Using the t-test accuracies of all calculated PFC concentrations were verified and compared. Detailed results will be presented on the poster.

**WE 098**
**Occurrence of perfluorinated surfactants in the Korean water system and human exposure**
SK Kim[1], YL Kho[2], M Shoeib[3], KS Kim[4]
[1]School of Earth and Environmental Sciences (BK-21), Seoul National University, SEOUL, South-Korea
[2]School of Human and Environmental Sciences, Eulji University, SEOUL, South-Korea
[3]Environment Canada, Science and Technology Branch, TORONTO, Canada
[4]Center for Chemical Safety Management, Chonbuk National University, JEONJU, South-Korea
Perfluorinated surfactants (PFSs) are an emerging pollutants globally detected in human. Their human exposure and uptake mechanisms are unclear. To elucidate the relationship of ambient water PFSs with human exposure, we investigated tap water and the river/stream water in eight main Korean city basins. The tap water examined reflected the contamination pattern and levels in their corresponding source waters. Tap water from the two cities along the Nakdong River contained more than 10-fold higher perfluorooctanoate (PFOA) (13-33 ng L-1) than those of other cities. For Korean adults, the mean daily intake of PFOA and perfluorooctanesulfonate (PFOS) via tap water was estimated to be 5.03 ng kg-1 d-1 and 10.8 ng kg-1 d-1, respectively. However, these intake rates of PFOA and PFOS accounted for only 2.4% and 0.2% respectively of the total daily intake estimated from reported serum concentrations, indicating the existence of other more important exposure pathways.

**WE 099**
**Distribution and sources of polyfluoralkyl substances (PFASs) in the river Po (north of Italy)**
S Valsecchi, M Rusconi, L Visinoni, S Polesello
Water Research Institute- CNR, BRUGHERIO (MB), Italy
The river Po (north of Italy), the major Italian river which flows in the Adriatic Sea, was recognized as the dominant source of PFOA in the Europe. Preliminary studies on the PFASs in the river Po and in its major tributaries underlined the presence, in the Po rivers watershed, of point and diffuse sources of PFASs. The origin of PFOA was related to the presence of a point industrial emission in the Tanaro/Bormida watershed but available data were scarce and sporadic.
In this study sampling campaigns of the surface waters of river Po, collected downstream its main tributaries, were carried out in order to identify emission sources of PFASs in the Po watershed and to calculate PFASs annual discharges into the Adriatic Sea.
Analysis of perfluorinated carboxylates (from C5 to C10) and perfluorinated sulphonates (C4 and C8) were achieved by HPLC with ion trap mass spectrometry detection. Recovery for PFASs was, for all analytes, above 70% at µg/L levels. Limit of quantification (LOQ) ranged from 40 to 140 pg injected.
Concentration levels at the mouth of the river Po are comparable to the levels of densely populated and PFAS heavily impacted areas of northern Europe. PFOA and PFBS are the main compounds (47±39 e 65±51 ng/L respectively) contributing with about 30% (1.4 t/y) and about 40 %, (1.9 t/y) respectively, to the total PFAS load (4.5 t/y) discharged into the Adriatic Sea.
In general PFOS concentrations in the riverine water samples are low (5±2 ng/L) compared to riverine concentrations reported in previous studies and might be a result of the decreasing usage of PFOS and concurrent reduction of its emissions into the aqueous environment. Though the industrial source in the Tanaro/Bormida watershed was confirmed as an important source of PFOA (0.6 t/a; 50% of the total discharge), other diffuse or industrial sources of this compound are present in the Po watershed.
The river Adda, a Po tributary which drained one of most densely and industrialized region of the north of Italy, was identified as an important emission source of PFPeA e PFHxA for the Po watershed. The PFPeA and of PFHxA Adda fluxes were estimated to be about 82% (13 mg/s) and 65% (7.8 mg/s) of PFPeA and of PFHxA fluxes at basin closure of the river Po. Unlike PFBS e PFOS, it was not possible to identify emission point sources but their origin is probably related to urban sources since their fluxes correlates rather well with river basin population.

**Perfluorinated compounds: from urban wastewater to the river**
L Pasquini[1], T Gorner[2], JF Munoz[3], MN Pons[4], V Boiteux[3], P de Donato[2]
[1]Laboratoire Environnement et Minéralurgie, VANDOEUVRE LÈS NANCY, France
[2]LEM, VANDOEUVRE LÈS NANCY, France
[3]ANSES, NANCY, France
[4]LRGP, NANCY, France
Our everyday life is a source of environmental pollution through domestic wastewater. The wastewater treatment plants (WWTPs) have been conceived to biologically eliminate pollutants, such as organic matter or nitrogen. However, the used treatments are not effective for the elimination of many compounds that have been increasingly appearing in our everyday use for several decades: e.g. pharmaceuticals, biocides present in body care products or non-adhesive surfacing of frying pans.
This study aimed at assessing the concentration of two perfluorinated compounds (PFCs), perfluorooctanoic acid (PFOA) and perfluorooctan sulfonate (PFOS) in the wastewater of an urban area. We have followed the wastewater issued from a residential area on the one hand and from a mixed area (administrations, hospital, houses, etc.) on the other hand, both at the inlet of the WWTP (300 000 eq. inh.), which collects the wastewater from different municipalities, and at the WWTP's outlet.
The samples' aqueous phase was extracted by solid phase extraction (SPE) and the extract was analyzed by UPLC/MS/MS. The PFCs concentrations measured in the residential and mixed area were similar: PFOA was around 6-8 ng/L and PFOS around 4-8 ng/L. The concentrations measured at the inlet and at the outlet of the WWTP were identical: 10 ng/L for PFOA and 25 ng/L for PFOS. This showed that the biological treatment did not eliminate these compounds. The daily mass flow of PFCs to the river was of around 600 mg/d of PFOA and 1600 mg/d of PFOS.

**WE 101**
**Contribution of wastewaters to PFCs contamination in ambient river waters of South Korea**
SK Kim[1], KD Zoh[2], YL Kho[3], JK Im[2], YM Kang[2], SY Jung[2]
[1]School of Earth and Environmental Sciences (BK-21), Seoul National University, SEOUL, South-Korea
[2]School of Public Health, Seoul National Unviersity, SEOUL, South-Korea
[3]School of Human and Environmental Sciences, Eulji University, SEOUL, South-Korea
We selected and analyzed water from the outlet of wastewater and/or along an upstream-downstream transect of the outlet, to elucidate the contribution of industrial/municipal wastewaters to PFCs contamination in ambient river water. Waters were collected from 31 sites of eight water bodies receiving varying wastewater from LCD, semi-conduct, fabrication factories, two local airports, and municipal wastewater treatment plants. Total PFC concentration (sum of C6-C13 PFCAs and C4-C8 PFASs) ranged from 6.3 to 1,160 ng/L with a median of 30.4 ng/L. Dominant compounds were PFHxA (median = 5.8 ng/L), PFOA (median = 5.7 ng/L), and PFOS (median = 6.3 ng/L) in most waters. In comparison of waters along the longitudinal transect, the waters did not show an increase in PFC concentration after than before receiving wastewaters. This indicates that the contribution of wastewaters could not be significant enough to exceed water dilution effect in Korean waters if excluding some exceptions.

**WE 102**
**Ombotrophic peatbogs as natural archives to investigate the historical deposition of polyfluorinated compounds (PFCs)**
A Dreyer[1], S Thüns[2], T Kirchgeorg[3], M Radke[2]
[1]Eurofins GfA, HAMBURG, Germany
[2]University of Bayreuth, BAYREUTH, Germany
[3]HelmholtzZentrum Geesthacht, GEESTHACHT, Germany
As they get their pollution from the atmosphere only, ombotrophic peatbogs have been identified as suitable natural archives for the investigation of historical depositions of persistent organic pollutants such as polycyclic aromatic hydrocarbons, polychlorinated biphenyls or polybrominated diphenylethers. In order to find out if ombotrophic peatlands are also suitable natural archives for the reconstruction of atmospheric PFC pollution, two peat cores were taken in fall 2009 at Mer Bleue Bog, an undistrurbed ombotrophic bog close to Ottawa, Canada. For analysis, cores were cut into 5 cm segments. Dating of the peat segments was performed at a separate core using the 210Pb method. The peat cores roughly covered the past 100 years. Peat samples were extracted using a modified QuEChERS method and analysed for 25 PFCs comprising perfluoroalkyl carboxylates, perfluoroalkyl sulfonates as well as several neutral PFCs by HPLC-MS/MS. Analyses were performed in duplicates. By this approach, intra-core and inter-core variations could be determined. Of 25 PFCs, 15 were detected in the ombotrophic peatland. Perfluorooctane sulfonate (PFOS), perfluorooctanoate (PFOA) and perfluorobutanoate (PFBA) dominated the PFC profile with total depositions (entire core) of 10.4 +/- 2.5 $\mu g/m^2$, 7.4 +/- 0.7 $\mu g/m^2$ and 38.3 +/- 9 $\mu g/m^2$, respectively. The extremely high value for PFBA remained unclear. Whereas intra-core variations of PFC deposition rates were low, inter-core variations were not. Compared to the temporal trend of PFC production, chronological sequence of PFC deposition was shifted towards deeper, i.e. older peat segments. These temporal trends will be presented on the poster and indicate that PFCs migrate downwards to a certain extend or that there were problems with the peat dating. In conclusion, analyses of peat cores as natural archive for PFC pollution may help reconstructing the overall atmospheric input. Their suitability to provide authentic and reliable temporal trend data has to be evaluated carefully.

**WE 103**
**Perfluorinated compounds in ice core samples from the Alps**
TK Kirchgeorg[1], J Gabrieli[2], A Dreyer[3], Z Xie[1], M Schwikowski[4], C Barbante[2], C Boutron[5], R Ebinghaus[1]
[1]Helmholtz-Zentrum Geesthacht, GEESTHACHT, Germany

[4]Paul Scherrer Institute,Laboratory of Radiochemistry and Environmental Chemistry, VILLIGEN, Switzerland
[5]Laboratory of Glaciology and Geophysics of the Environment, Joseph Fourier Uni., GRENOBLE, France

Since 1950, per- and polyfluorinated compounds (PFCs) have been used in several industrial and consumer products due to their unique properties. Neutral PFCs are semi-volatile and are globally transported through the atmosphere. Remote areas, such as high alpine mountains, can be contaminated with PFCs by wet and/or dry atmospheric deposition. High altitude sites are usually not influenced by direct sources of PFCs and receive these contaminants by atmospheric deposition, only.

The aim of the present study was to investigate the occurrence and temporal variations of perfluorinated compounds in an high mountain area of the Alps. Furthermore, annual deposition rates and fluxes of PFCs to the high alpine environment were estimated. For this purpose, a 10 m shallow ice core was drilled at Colle Gnifetti (4452 m above sea level, Italy, Swiss) and was dated using the delta18O method. Overall, the ice core covered a period from 1996 to 2008. The ice core was cut according to annual and/or seasonal layers prior to the PFC analyses. Each ice segment was extracted using solid phase extraction and were separated and detected by HPLC-ESI-MS/MS. The target analytes included 17 PFCs (perfluorinated carboxylates (PFCAs) and perfluorinated sulfonates (PFSAs)).

We will present the results of PFC contamination from Colle Gniffetti. Concentrations, vertical distribution and deposition rates of PFCs were determined in the different ice core layers. The results will be compared to previous findings of PFCs in a shallow firn core from Mount Ortler (2004 - 2009, 3852 m a.s.l., Italy). There, 12 of 17 PFCs were detected with ∑PFC concentrations between 1 ng L-1 to 5.8 ng L-1. Most frequently observed individual PFCs were PFBA (0.3 - 1.7 ng $L^{-1}$), PFNA (0.1 - 2.1 ng $L^{-1}$) and PFOA (0.1 - 0.9 ng $L^{-1}$). Increasing concentrations from 2004 to 2009 were only demonstrated for PFBA (0.3 to 1.4 ng $L^{-1}$).

**WE 104**

**Mass balance analysis of fluorinated compounds in wet precipitation**

Y Kwok[1], E Yamazaki[2], S Taniyasu[2], MB Murphy[1], N Yamashita[2], KS Lam[1]
[1]City University of Hong Kong, HONG KONG, Hongkong
[2]National Institute of Advanced Industrial Science and Technology, IBARAKI, Japan

Thousands of tons of organic and inorganic fluoride are emitted to the atmosphere by various sources including releases from industrial processes, domestic applications and power plants. Per- and polyfluorinated compounds (PFCs) are organic fluoride chemicals that have received worldwide attention due to their environmental persistence. The ubiquitous distribution of PFCs has been documented globally in the atmosphere and in wet precipitation. However, there is currently a lack of robust analytical methods that can be applied to determine levels of all of the PFCs. In this study, mass balance analysis involving the determination of total fluorine (TF), inorganic fluorine (IF) and extractable organic fluorine (EOF) using combustion ion chromatography (CIC-F) was carried out to gain a comprehensive understanding of the fate of both known and unknown PFCs in wet precipitation.

Concentrations of TF and IF were measured in rain (n=50), snow (n=14) and ice core samples (n=6). EOF was extracted from several rain (n=10) and snow samples (n=6) using solid phase extraction (SPE) procedures. Concentration of 19 known individual PFCs were also determined by liquid chromatography-tandem mass spectrometry (LC-MS/MS). The contribution of EOF and IF to TF for different kinds of wet precipitation samples will be discussed. Interestingly, a high percentage of non-extractable organic fluorine was found in precipitation samples, in contrast to what was observed in seawater. This may due to the forms of fluoride present in the atmosphere and water-fluoride tends to bind to particulates in the atmosphere and exist as organic fluoride, while it dissolves in water and ionizes. Known PFCs were found to contribute around 0.0005% to EOF, suggesting the need to identify the unknown fluorinated chemicals present in the precipitation samples. Finally, geographical distribution of TF and IF among several locations can be compared, and source determination can be carried out by using the ratio of known PFCs to TF to provide more information on the fate and transport of PFCs in the atmospheric environment.

**WE 105**

**Long-term environmental fate of perfluorinated compounds after accidental release at Toronto Airport**

X Zhang[1], E Awad[2], SP Bhavsar[2], S Petro[2], PW Crozier[2], EJ Reiner[2], SA Mabury[1], R Fletcher[2], SA Tittlemier[3], E Braekevelt[3]
[1]University of Toronto, TORONTO, Canada
[2]Ontario Ministry of the Environment, TORONTO, Canada
[3]Health Canada, OTTAWA, Canada

Concerns about perfluorinated compounds (PFCs) have been raised during the past 15 years due to their persistent, bioaccumulative and toxic characteristics. Although perfluorooctane sulfonic acid, its salts and perfluorooctane sulfonyl fluoride were listed in Annex B of the Stockholm Convention in 2009 to restrict their worldwide uses, very few studies have simultaneously measured PFCs in various environmental media as well as assessed their long-term fate in aquatic systems. Since application of perfluorooctane sulfonate (PFOS) based aqueous firefighting foam (AFFF) can be a major source of PFOS to nearby aquatic systems, we monitored PFCs in water, sediment, fish tissue and liver in an upstream-downstream transect of Spring and Etobicoke Creeks near Toronto airport over the 10 years following an accidental release of 22000 L of PFC-containing AFFF in 2000. In 2005, another incident involving fire at the Toronto airport resulted in a release of 48000 L AFFF, which was likely different in composition compared to the earlier release.

The results indicate that PFOS is the predominant PFC in all four media. PFOS concentrations were approximately 10 times higher near the airport than the other sites in the water sampled in 2003 and 2009; however, PFOS was lower in 2006 than the other years at this. This could be a result of dilution due to precipitation prior to the sampling date. PFOS level in water measured by another study ~5 months after the spill in 2000 at a sampling site ~5 km downstream were over 5 times higher than our measurements in the 2003 at a site close to the sampling site of the other study. Unlike traditional neutral POPs with a high affinity for sediment, most PFCs could not be detected in the sediments. However, PFOS concentrations and detection rate in sediments were highest near the airport than other sites. No significant spatial trend could be observed for PFCs in fish tissue and liver since the exposures are not necessarily confined in one segment of the creek. Comparing the profile of PFCs in fish and water, higher Bioconcentration Factors for the long-chain PFCs were observed. Assuming no site specific loading of PFCs to the creek occurred since the import of PFC-containing AFFF to Canada ceased in 2002 and the regulation on existing stocks proposed in 2006, the elevated level of PFOS at the site with the spill 10 years ago raises concern about its persistence in aquatic system and/or contribution of secondary sources.

**WE 106**

**Determination of perfluorinated compounds in various consumer products**

J Becanova, J Klanova
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Perfluorinated compounds (PFCs) are a subject of increasing environmental concern. PFCs are used in many industrial and consumer products, such as polymers and surfactants, because of their unique and useful properties (stability, chemical resistance and generally low reactivity). The presence of residual unbound fluorotelomer alcohols and perfluoroalkyl sulfonamido ethanols was confirmed in technical fluorinated materials. Moreover, other perfluorinated compounds (PFOA and other PFCAs) may be present in various consumer products because of their usage in production of fluoropolymers. Monitoring of above mentioned perfluorinated compounds is crucial for identification of indoor environment contamination. An assessment of PFCs contamination of various consumer products was a target of the study presented here.

**WE 107**

**Sources of Perfluoroalkyl substances present in groundwater and drinking water**

C Eschauzier[1], I van Driezum[2], K Raat[1], P Stuyfzand[2], P de Voogt[1]
[1]KWR watercycle research institute, NIEUWEGEIN, The Netherlands
[2]VU, AMSTERDAM, The Netherlands

Several PFASs (perfluoroalkyl substances) appear to have persistent, bioaccumulative and toxic (PBT) properties. They have been found to be present in the low ng/L concentrations in drinking water. Water is the beverage consumed in the largest quantity on a daily base and therefore can be a significant dietary exposure pathway of PFCs to human beings. Because in many countries the majority of drinking water is abstracted from groundwater, PFASs in groundwater could be a possible source of contamination to drinking water. This especially because the treatment of groundwater dedicated for drinking water is often marginal compared to surface water treatment. This study explores the presence of PFAS in groundwater contaminated by landfill leachate. Two groundwater abstraction sites in the Netherlands with a landfill in the area of the water abstraction were sampled and analyzed for 18 different PFASs. Total concentrations in groundwater in one location ranged from a maximum of 5459 ng/L in the groundwater travelling towards the abstraction wells to a minimum concentration of 2.4 ng/L. In finished drinking water made from this groundwater a Σ PFASs concentration of 7 ng/L was observed. Patterns of PFASs indicated that the major source of the PFASs was the landfill leachate. However, other locations sampled within the groundwater abstraction area showed a different finger print indicating that different sources might be involved. Mechanisms determining the observed patterns were explored. Dominating compounds were perfluorooctanoic acid (PFOA) and perfluorobutanoic acid (PFBA). This study is part of the EU-sponsored PERFOOD project which aims at assessing the sources of and exposure to PFCs in the European diet.

**WE 108**

**Impact of treatment processes on the occurrence of perfluoroalkyl acids in the drinking water production chain**

C Eschauzier[1], E Beerendonk[1], P Scholte-Veenendaal[2], P de Voogt[1]
[1]KWR watercycle research institute, NIEUWEGEIN, The Netherlands
[2]Waternet, AMSTERDAM, The Netherlands

Perfluoroalkyl substances (PFASs) have been detected in drinking water at concentrations typically in the low ng/L range, with occasionally higher concentrations (lower µg/L level) in some contaminated areas. These findings suggest that PFASs are not or poorly removed during drinking water treatment. The behavior of polyfluoralkyl substances (PFASs) from raw source water to finished drinking water was assessed by taking samples from influent and effluent of the several treatment steps used in a drinking water production chain. This consisted of intake, coagulation, rapid sand filtration, dune passage, aeration, rapid sand filtration, ozonation, pellet softening, granular activated carbon (GAC) filtration, slow sand filtration and finished water. In the source water taken in at the Lek canal (a confluent of the Rhine), the most abundant PFAS were PFBA (Pefluorobutanoic acid) 52 ng/L, PFBS (Perfluorobutane Sulfonate) 42 ng/L, PFOS (perfluorooctane sulfonate) 10 ng/L and PFOA (perfluorooctanoic acid) 5.1 ng/L. During treatment longer chained PFAS such as PFNA and PFOS were readily removed by the GAC treatment step and their GAC effluent concentrations were <LOQ. However, more polar shorter chain PFAS (especially PFBA and PFBS) were not removed by GAC and their concentrations remained constant through treatment. A decreasing removal capacity was observed with increasing carbon life time. The finished water contained 26 and 19 ng/L of PFBA and PFBS. Other PFAS were present in concentrations below 4.2 ng/L. The concentrations observed are no reason for concern for human health whatsoever as margins to existing guidelines are sufficiently large

**WE 109**

**Uptake of perfluorinated alkyl substances by hydroponically grown lettuce**

ST Felizeter[1], PdV de Voogt[2]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]KWR Water Cycle Research Institute, NIEUWEGEIN, The Netherlands

Perfluorinated alkyl substances (PFAS) are bioaccumulative persistent, organic pollutants (POPs). They can be detected ubiquitously in the environment and they may pose a risk to human health due to accumulation in the food chain. The occurrence of PFAS in animals, such as fish, birds and mammals including humans is fairly well documented, but little can be found in the literature about crops or plants in general. However, humans are possibly exposed to PFAS through consumption of vegetables and other plant-related food items.

Plants appear to accumulate PFAS differently, as has become apparent from published data on PFAS concentrations in crops, e.g., potatoes or cereals. The objective of this study was to increase the understanding of the accumulation process of PFAS in crops.

In a first experiment lettuce was grown hydroponically in a greenhouse with a contaminated nutrient solution to make sure the offered PFAS were completely bioavailable. The lettuces were exposed to a set of 13 perfluorinated carboxylic acids and 4 perfluorinated sulphonates in four different concentrations to assess the difference in behavior between PFAS and concentration dependencies. Furthermore, the uptake of PFAS during the growth period of lettuce was investigated in a 4-5 days interval in a second experiment.

Because of the high water solubility of the compounds, we assumed that the PFAS will be taken up by the root system of the plants and will be distributed through the water system. Hence it can be assumed that evaporation plays an important role in the uptake, therefore bioaccumulation hypothetically takes place especially in the leaves of the plants. To confirm this hypothesis correla-

tions of the PFAS uptake with the water uptake were examined.
The contribution presents the results of the greenhouse experiments.

**WE 110**

**Uptake and depuration of PFOS in liver and muscle tissue of bluegill sunfish under environmentally relevant conditions**

SF Nakayama[1], AD Delinsky[1], MJ Strynar[1], MM Painter[2], TG Loes[2], ND Jahns[2], HL Schoenfuss[2], AB Lindstrom[1]
[1]U.S. Environmental Protection Agency, CINCINNATI, United States of America
[2]Saint Cloud State University, SAINT CLOUD, MN, United States of America

Previous studies have indicated that diet is one of the important routes of human exposure to perfluorinated compounds (PFCs), particularly perfluorooctane sulfonate (PFOS). Among food items, fish are frequently found to contain relatively high concentrations of PFOS and other long-chain PFCs. However, little is known about the uptake and depuration rates of PFOS in fish tissues under environmentally relevant condition, making it difficult to determine how fish are likely to be contaminated. In the current study, bluegill sunfish were placed in aquaria containing an environmentally relevant concentration of PFOS (50 ng/L) or in PFC-free well water for a period of 20 days followed by a 19 day depuration period. Control and exposed fish were sacrificed throughout the exposure and depuration periods. Fish fillets and livers were extracted by alkaline digestion and analyzed by LC-MS/MS. PFOS concentrations were found to slowly increase with time during the exposure and depuration periods for both control and exposed fish, suggesting that contaminated water is not the primary exposure route for bluegills. Instead, the analysis of the brine shrimp fed to control and exposed fish indicated that this dietary exposure was more likely to have lead to the small cumulative increase of PFOS concentrations observed.

**WE 111**

**Perfluorooctanoic acid toxicity in zebrafish (Danio rerio)**

M Ulhaq, G Carlsson, S Örn, L Norrgren
Swedish University of Agricultural Sciences, UPPSALA, Sweden

Perfluorooctanoic acid (PFOA) is a common surfactant with wide use, and has been detected as a contaminant in soil, air, water and biota. Previous studies have shown that PFOA has detrimental effects on different life stages in zebrafish (*Danio rerio*).
We have evaluated the effects of PFOA toxicity covering different life stages of zebrafish through three tests that were based on OECD guidelines. In the Fish Embryo toxicity (FET) test, fertilized embryos were used to calculate effective concentrations (LOEC and NOEC) based on early life stage lethal and sub-lethal endpoints. Based on the FET test, a Fish Sexual Development Test (FSDT) was conducted and effects on vitellogenin (VTG), body and liver somatic indices and gonad histopathology including sex ratios were evaluated. A reproduction test (Fish Screening Assay: FSA) was also performed where effects on reproductive parameters like spawning, fecundity and fertilization rate were evaluated, as well as effects on histopathology, liver enzyme activity VTG-levels and gene expression levels in the adult fish.

## ET08 - Environmental OMICS: a global answer to environmental questions

**Macro algae, Ecklonia cava - Ecotoxicogenomic approach for environmental stress responses**

S Woo, S Yum
Korea Ocean Research & Development Institute, GEOJE-SI, South-Korea

Environmental stress dramatically induces stress responsiveness in an organism and it affects the related genes expressions. The marine forest consisted of the kelp (macro algae) is identical to the ground forest and is worthy of spawning place as well as shelter for various marine organisms. Also they are very important for marine resources and environment-economic values. This study aimed to screen the differentially expressed genes induced by marine environmental changes at genomic level and to prove those gene expressions represent the individual organism's health as well as real environment. The targeted seaweed is Ecklonia cava known as dominant, plentiful and easily collected in Korean coastal regions. First of all, the RNA extraction method was established E. cava before screening of differentially expressed genes by environmental differences and the DNA sequences of several stress responsive genes were found. Massive screening of the differentially expressed genes by environmental changes was attempted by the construction of E. cava cDNA library. As a result, approximately 2700 genes were collected from the standard library and 11 oxidative stress responsive genes were cloned. Now we are comparing the gene expression profiling of E.cava collected in non-contaminated and contaminated sites in polluted areas and investigating that profiling differences could respond to the health status in the real environment.

**WE 115**

**Transcriptomic analysis of Japanese medaka exposed to mixtures of sex steroids**

K Kadota, SMM Mizukami-Murata
Japan Pulp and Paper Research Institute, Inc., TSUKUBA, Japan

In this study, the effects of mixtures were evaluated for an estrogen and androgen. Larval Japanese medaka, Olyzias laptipes, within 12h post-hatch, were exposed to mixtures of 17β-estradiol (E2) and 17β-trenbolone (TB). Chronic experiments showed that estrogenic and androgenic effects appeared to cancel each other at low concentration of mixture (30ng/L of E2 and 20ng/L of TB), resulting in no reproductive impairment. At high concentration of mixture (100ng/L of E2 and TB), reproductive activities were severely damaged for both sexes, although sex reversal did not occur. Gene profiling of medaka was performed using oligonucleotide-based DNA microarray containing 36,398 probes (Agilent Technologies). The gene expression profiles obtained for the mixtures were in agreement with biological experiments and histological analyses. Our study demonstrates that the exposure experiments of binary mixtures would be helpful to provide more insight into the mechanism of endocrine disruption compared with single exposure experiments.

**WE 116**

**Transcriptional responses of Enchytraeus albidus (Oligochaeta) to metal exposure: effects of zinc and cadmium**

SC Novais[1], T Vandenbrouck[2], AMVM Soares[1], W de Coen[3], MJB Amorim[1]
[1]Cesam & University of Aveiro, AVEIRO, Portugal
[2]Apeiron-Team NV, Pluyseghemstraat 69, 2550 KONTICH, Belgium
[3]University of Antwerp, Department of Biology - E.B.T., GROENENBORGERLAAN 171-U.7., B-2020 ANTW, Belgium

Enchytraeus albidus is an important and typical inhabitant of a wide variety of soil types and fulfils vital functions such as improvement of the soil pore structure and indirectly the degradation of organic matter. Traditionally, in soil Environmental Risk Assessment (ERA), several biological tests are commonly performed with E. albidus (ISO No 16387, 2003; OECD 202, 2004), providing information about effects on survival and reproduction. Such traditional test methods are important to predict realistic threshold values for policy makers and to screen the overall toxicity of polluted soils. Nevertheless, such bioassays are time-consuming and consider limited endpoints. It is commonly agreed that this information should be complemented with responses at lower levels to better understand the underlying response mechanisms but so far, very little is known about the effects induced by different toxicants on these organisms at the molecular level. Recently, substantial efforts have been made to further develop and enrich the existing microarray for this soil invertebrate species. In the present study, E. albidus were exposed during 2, 4 and 8 days to concentrations of zinc and cadmium known to cause 50 and 90% effects on their reproduction. The main goal of this study was to elucidate the early molecular responses and the toxic mechanisms of these metals in E. albidus with the use of transcriptomic analysis. The gene expression analysis was performed through hybridization of fluorescently labelled probes from the exposed and control organisms on the newly developed Custom Gene Expression Microarrays 8[GREEKX]15 k format (Agilent Technologies). Results show differently expressed genes involved in functions like transcription and translation, immune and stress response, protein metabolism, energy metabolism, development, cell structure and carbohydrate and fat metabolism. This study demonstrates that the determination of effects at different levels of biological organization allow a more in depth evaluation of the mechanisms of toxicity that may contribute to reproduction impairment by metals.

**WE 117**

**DNA-expression in roots of Oryza sativa exposed to sediments spiked with Ni - linking expression profiles to phenotype**

S Buchinger, J Wittholt, U Feiler, G Reifferscheid
Federal Institute of Hydrology, KOBLENZ, Germany

Sediments play an important role in the assessment of the environmental quality of a river because of several reasons. The matrix sediment is considered an ecosystem (benthos) with organisms reacting to particle bound pollution. The benthic habitat constitutes an integral and dynamic part of aquatic ecosystems, whose processes are important for the whole water body. Sediments can act as both, potential sinks but under other conditions as potential sources for many hazardous substances. Particle-bound contaminants are problematic due to their particular persistence and liability to bio-accumulation.
Taking this into account several methods for sediment contact tests with various species were developed in the recent years. Sediment contact assays have the advantage to cover various routes of exposure, namely direct exposure by particle contact as well as exposure via the sediment pore water. In the present study sediment contact tests with rice (*Oryza sativa*) were performed with Ni-spiked artificial sediments. *Oryza sativa* can be grown under emerse conditions and has - as a prerequisite for a comprehensive expression analysis - a sequenced genome.
The most sensitive end point for exposure to Ni was the root length; in addition to growth inhibition a different morphology of the root was observable. Roots of exposed plants were less branched and thicker compared to the unexposed control. In order to establish an endpoint with ecotoxicological relevance that is based on gene expression it is crucial to correlate expression data with an adverse phenotype - e.g. inhibition of root development. With this rationale sprouted seeds of *Oryza sativa* were exposed to different Ni-doses, i.e. $EC_0$ at 200 mg/kg and $EC_{50}$ at 600 mg/kg, with a subsequent analysis of the genome wide expression profile by DNA-arrays. The objective of the study is to determine if it is possible to discriminate between exposed / non-exposed samples but as well between affected (exposure at $EC_{50}$) and unaffected (control and exposure at $EC_0$) samples based on the gene expression data. If such a differentiation is possible, robust molecular markers should be identified the expression levels of which can be used as predictors for exposure and/or adverse effect. The successful correlation of molecular markers and adverse phenotypes in studies like the one presented here, is an essential prerequisite for the use of techniques like expression profiling in the field of regulation in the future.

**WE 118**

**Transcriptional responses of exposure to oil, mercury and CO2 in the marine zooplankton Calanus finmarchicus**

KE Tollefsen[1], KJ Macrae[1], D Altin[2], SA Pedersen[3], BH Hansen[4]
[1]Norwegian Institute for Water Research (NIVA), OSLO, Norway
[2]Bio Trix, TRONDHEIM, Norway
[3]Department of Biology, Norwegian University of Science and Technology (NTNU), TRONDHEIM, Norway
[4]SINTEF Materials and Chemistry, Marine Environmental Technology, TRONDHEIM, Norway

Calanus finmarchicus is one of the most common marine zooplankton in parts of the Norwegian-, the North- and the Barents Seas. C. finmarchicus is a pelagic species continuously exposed to the surrounding water, and would inevitably be exposed to pollutants originating from anthropogenic activities and changes in environmental factors. The biological effects of these stressors may be manifested at various levels (e.g. biochemical, behavioral and functional effects), although it is often assumed that alterations at the molecular (transcriptome) level occur prior to more adverse endpoints and therefore may serve as a early-warning biological marker (biomarker).
The main aim of this work was to develop a custom oligonucleotide microarray (oligoarrray) for C. finmarchicus and utilize this tool for assessing transcriptional effects of multiple stressors originating from different pollution sources. The Calanus oligoarray were constructed of contigs and singletons obtained from the pre-processing, clustering and assembly of 11k NCBI Expressed Sequence Tags (ESTs). Resulting contigs and singletons were subjected to blasting and annotation, sequence and probe redundancy reduction, and 6 k presumably non-redundant sequences were subjected to 60-mer probe production for inclusion on a 15k Agilent custom oligoarray. The performance of the Calanus oligoarray was evaluated with RNA from C. finmarchicus exposed to sublethal concentrations of CO2, inorganic Hg and the water soluble fraction (WSF) of a North Sea crude oil for 48h (10_C). The data obtained from analysis were normalized and filtered, followed by statistical analysis and identification of differentially expressed genes that were further subjected to analysis of functional enrichment analysis.
The results from the studies show that exposure to the different stressors gave rise to substantially different transcriptional patterns which were characterised by different Gene ontology functions. The Calanus oligoarray is a promising new tool in our genomic toolbox linking exposures to low concentrations of anthropogenic pollutants with an early biomarker response in the important marine organism Calanus finmarchicus.

**WE 119**

**Gene expression profiling in the Model Yeast Saccharomyces cerevisiae to characterize and**

**compare the toxicity of six pesticides and identify biomarkers of toxicity**

N Gil[1], AC Gonçalves[1], CA Viegas[1], JD Becker[2]
[1]Instituto Superior Técnico, LISBOA, Portugal
[2]Instituto Gulbenkian de Ciência, OEIRAS, Portugal

Short-term bioassays using non-animal eukaryotic models are required for the preliminary screening of the toxicity of chemicals and to early-warn potential toxic effects of xenobiotics in whole environmental samples. The yeast Saccharomyces cerevisiae is a useful experimental model of the eukaryotic cell; it is widely distributed, easy to cultivate, and has a vast amount of genomic knowledge and resources available. This work aims to identify molecular biomarkers in the yeast model that may be useful for assessing and diagnosing pesticide toxicity, and to get insights over mechanistic aspects of the yeast responses to pesticide-stress. Affymetrix GeneChip Yeast Genome 2.0 arrays were used to examine modifications occurring in the transcriptome of an exponential population of cells due to exposure to the 20%-inhibitory concentration (IC20) of each of four herbicides (alachlor, s-metolachlor, diuron and MCPA-methyl ester), the insecticide carbofuran and the fungicide pyrimethanil. The total number of genes with expression significantly altered by the herbicides varied between 350 and 750 (<12% of whole genome), while 1072 (~20% of genome) were responsive to the insecticide carbofuran; interestingly, most of the latter (~85%) seem to be carbofuran-specific. To try to understand correlations between gene expression profiles and chemical structure/mode of action, differences in the profiles of the six different pesticides are being further analysed based on clustering approaches. For each pesticide under study, the differentially expressed genes are also being categorized into overrepresented functional classes, predicted metabolic pathways and interaction networks within the encoded proteins. Search for proteins from diverse higher eukaryotes (e.g. relevant as representatives of ecosystems inhabitants or models in ecotoxicological studies) that are homologous to yeast proteins encoded by the differentially expressed genes is also in course. The modifications in the expression of a number of selected genes that may be relevant as biomarkers of pesticides toxicity is being further examined by quantitative RT-PCR. Significantly, the magnitude of the expression change in pesticide-stressed cells appears to increase in a concentration-dependent manner and to show a good correlation with pesticides growth inhibitory effects.

**WE 120**

**Transcriptomic approach to assess the effects of two Active Pharmaceutical Ingredients (APIs) in Mytillus galloprovincialis**

VL Maria[1], CO Oliveri[2], AN Negri[2], AV Viarengo[2], FD Dondero[2], MJB Bebianno[2]
[1]Algarve University&CIMA, FARO, Portugal
[2]University of Piemonte Orientale "Amedeo Avogadro" /Faculty of Sciences M.F.N., ALESSANDRIA, Italy

DNA region or gene specific oligonucleotides immobilization in ordered matrix allows attaining DNA microarrays. Recently, these DNA microarrays have been applied in relevant aquatic organisms exposed to diverse contaminant levels. However, there is no knowledge of any work reporting changes on mussels, M. galloprovincialis to nonsteroidal anti-inflammatory drugs at molecular/gene level.

Ibuprofen is commonly used as analgesic/antipyretic and diclofenac to treat rheumatic diseases and inflammations of the musculoskeletal. Their physic-chemical characteristics namely polarity, non-volatile low biodegradability favor their persistence in the aquatic ecosystems.

The main aim of this study was to assess the gene expression profiles using a 1.7 K cDNA microarray (Mytarray V1.1) in the digestive gland of mussels exposed to environmental realistic concentrations of ibuprofen and diclofenac (250 ng/L) during short-term exposure.

Total RNA (10 μg) from individual mussels (either drug exposed or not exposed ones) was reverse-transcribed using M-MuLV RNase Hðð reverse transcriptase primed by an anchored oligo-dT and in the presence of a modified dNTP mixture including amino-allyl dUTP. Fluorescence labeled nucleic acids probes were prepared by further coupling with the fluorescent Cy3 or Cy5 dyes. Tester and control cDNA labelled probes (20 pmoles each) were used for dual color competitive hybridization in a "dye-swap" experimental design. Microarrays were scanned at high resolution with an Agilent scanner and raw fluorescence intensities extracted with the Genepix 6.0 software. Further processing and statistical analysis of microarray were performed using the R-package Linear Mode for Microarray Analysis (LIMMA) implemented through a web user interface (TD_Hand).

This preliminary study demonstrated that both APIs induced significant alterations in gene transcription patterns of the exposed mussels. Ibuprofen exposure induced a significant expression of 33 (Benjamini and Hochberg adj_p < 0.05, N=4) genes which were mostly down-regulated. Furthermore, 29 differentially expressed genes were reported for the effects of diclofenac. About 40% of differentially expressed genes were shared between treatments, possibly indicating a common mode of action.

**WE 121**

**Dithiocarbamates induce craniofacial abnormalities and downregulate sox9a during zebrafish development**

J Legler[1], A Boxtel[2], P Cenijn[2], B Pieterse[3], J Kamstra[2]
[1]VU University Amsterdam, AMSTERDAM, The Netherlands
[2]VU University, AMSTERDAM, The Netherlands
[3]Bio Detection Systems, AMSTERDAM, The Netherlands

Dithiocarbamates (DTCs) have a wide variety of applications in diverse fields ranging from agriculture to medicine. DTCs are teratogenic to vertebrates but the mechanisms by which they exert these effects are poorly understood. Here we show that low nanomolar exposure to three DTCs, tetraethylthiuram (thiram), tetramethylthiuram (disulfiram) and sodium metam (metam), leads to craniofacial abnormalities in developing zebrafish embryos that are reminiscent of DTC induced bone and cartilage abnormalities found in higher vertebrates. In order to better understand the molecular events underlying DTC teratogenesis, we exposed embryonic zebrafish (PAC2) cells to thiram and disulfiram and measured changes in gene expression with microarrays. We found differential expression of 166 genes that were specific for exposure to DTCs and identified a network of genes related to connective tissue development and function. Additionally, we found eight downregulated genes related to transforming growth factor β-1 (TGF-β1) signaling, including an essential transcription factor for zebrafish craniofacial development; SRY-box containing gene 9a (sox9a). Finally, we show that sox9a expression is perturbed in the ceratobranchial arches in DTC exposed developing zebrafish suggesting that this is an important event in the development of DTC induced craniofacial abnormalities. Together, we provide evidence for a novel teratogenic endpoint and a molecular basis for a better understanding of DTC induced teratogenesis in vertebrates.

**WE 122**

**A proteomic study in zebra mussels (D. polymorpha) exposed to benzo(a)pyrene: role played by gender and exposure concentrations**

C Riva, A Binelli, F Rusconi, G Colombo, A Pedriali, R Zippel, A Provini
University of Milan, MILAN, Italy

Despite the fact that zebra mussel (*Dreissena polymorpha*) is considered a reference model for freshwater ecosystems, the investigation of proteomic approach in this organism has not been deeply investigated. This work represents the first attempt to verify the suitability of the proteomic approach also in this biological model. This aim was realized by evaluating the changes in protein expression profiles in gills of *D. polymorpha* specimens after an in vivo exposure (7 days) to benzo(α)pyrene (B[α]P). In order to provide a more in-depth evaluation of this approach, we investigated the role played by gender in proteome response: to this end, we evaluated the changes in protein expression analysing separately male and female mussels. Moreover, we choose to test the effects played by two different concentrations of B[α]P (0.1 and 2 μg L-1) in order to evaluate possible dose-dependent changes in the proteome. We identified proteins changed in response to the B[α]P exposure by MALDI-TOF/TOF mass spectrometry. Finally, B[α]P bioaccumulation in mussels soft tissues was also assessed to ensure a real effect of the selected chemical. On the whole, we found a total of 28 proteins differentially expressed. The most significant identified altered proteins are related to oxidative stress, signal transduction, cellular structure and generic metabolism. Although gill tissue was expected to be less prone to respond in a sex specific manner, males and females responded differently to exposure, because B[α]P affects different proteins in the two genders, with the exception of only two proteins. Surprisingly, the comparative analysis of protein data sets showed no proteins varying commonly between both experimental conditions. The present report shows not only the utility of proteomic techniques to study differences in protein expression in the freshwater mussel *D. polymorpha*, but above all that the interpretation of data set from this approach should be carefully checked. For instance, the role played by gender on protein modulation and the responses generated by different toxicant concentrations surely need to be deeply investigated. Finally, our preliminary results confirm the need of increasing the number of proteomic studies in invertebrates to allow a rise of their representation in databases and the successfully identification of the most relevant proteins.

**WE 123**

**Ecotoxicoproteomics tests on Daphnia pulex : preliminary steps**

M Borgatta, PW Waridel, TB Buclin, NC Chèvre
Université de Lausanne, LAUSANNE, Switzerland

Drugs administered in humans are eliminated through the excreta in either intact or metabolized form leading pharmaceuticals and their derivatives to reach sewage treatment plant. Several drugs are able to induce genetic and cell cycle changes and the current burgeoning of new therapeutic agents with original mechanisms of action call for a comprehensive assessment of their potential effects on the aquatic fauna and flora. It is therefore crucial to find out robust biomarkers to identify early noxious effects of these compounds. We assume that proteomics approach will allow us to identify at the protein level such biomarkers, which then may be used to assess the risk of drugs and their metabolites for aquatic life.

Toxicoproteomics is a field of science that seeks to understand changes, at the protein level, in cells or organisms exposed to toxins such as pollutants or drugs. Nowadays, toxicoproteomics can be used in environmental toxicology to find early ecotoxicological markers at the protein level; this field is called ecotoxicoproteomics. In this study, proteomics analyses were performed on waterflea Daphnia pulex. The sample preparation (i.e. daphnid homogenisation, cell lysis, protein extraction and fractionation) was optimized in order to dramatically reduce the amount of daphnia tissue needed. Three different procedures for homogenization and cell lysis were thus tested: (a) ceramic mortar; (b) ultra-sonic extraction; (c) FastPrep system. Preliminary results are presented here as a proof-of-principle of the developed method. The goal is to find out the best procedure for a relevant and reproducible protein extraction.

**WE 124**

**Convergent and specific responses of the flounder Platichthys flesus to different stress: a proteomic approach**

C Galland, C Dupuy, I Calves, L Quiniou, M Auffret, J Laroche, V Pichereau
Laboratoire des Sciences de l'environnement marin, PLOUZANÉ, France

The flounder Platichthys flesus spends the earlier years of its life in estuarine environments, along the European East Atlantic coasts. Estuarine environments are strongly subjected to anthropogenic stress factors such as hypoxia linked to eutrophication, chemical pollution especially in industrial area, or thermal stress in the context of global warming.

This study aims at understanding the molecular mechanisms allowing flounder to adapt to different stress factors and multi-stress conditions, and to determine whether a local adaptation to a specific stress could modify the ability of the individuals to cope with other stress.

Flounders were fished in different estuaries, one located in the southern limit of this species (the Mondego - Portugal), the others being chemically polluted (the Seine - France), or displaying hypoxia events (the Vilaine - France) or considered as a control area (the Canche-France). Some farm flounders were also raised in the laboratory under contaminated conditions (PAHs and PCBs cocktail at a concentration representing 10 times the concentration found in the Seine). They were then subjected to a second stress (thermal or hypoxic) to study the way they can cope with the multiple stress; thus, a proteomic approach by 2-dimensional electrophoresis has been performed on these animals. This allowed us to identify differentially expressed proteins by MALDI TOF-TOF mass spectrometry. Our main objective will be here to explore the molecular responses of a marine fish to single versus multiple stress, looking for specific versus convergent pathways.

**WE 125**

**Effects of heavy metal contamination on the expression of immune- and stress- response genes in the Sydney rock oyster, Saccostrea glomerata**

DA Taylor, E Thompson, S Nair, D Raftos
Macquarie University, NORTH RYDE, Australia

Environmental contamination by chemical pollutants is a serious threat to the biological sustainability of coastal ecosystems worldwide. Our current understanding of the biological effects of chemical pollution in these ecosystems is poor. Extensive chemical maps of pollution exist, but there is little corresponding biological effects data. New, more sensitive biomonitoring methods are needed to provide an early warning of biological harm that can assist in the management of sensitive marine environments and prevent permanent damage.

The current study tested the expression of immune- and stress- response genes after exposure to heavy metal contamination in Sydney Rock oysters (Saccostrea glomerata). Target genes (HSP70, HSP90, Metallothionein, Superoxide dismutase, Defensin and Ferritin) were selected from

previous studies that investigated the effects of contaminants on immune- and stress- responses in marine molluscs. Quantitative (real time) PCR analyses of gene expression showed that laboratory exposures to different metals (cadmium, copper, lead and zinc; 100μg/l) elicited different gene expression profiles. The expression of defensin, an antimicrobial peptide, was up-regulated in response to lead exposure, but was down-regulated in the presence of zinc. The bacteriostatic, metal-binding protein, ferritin, was up-regulated by exposure to cadmium, copper and lead, but not by zinc. Heat-shock protein 90 (a generic stress-response protein), ficolin (a lectin involved in host defense against pathogens), and the metal-binding protein, metallothionein, were up-regulated in response to all four metals. Conversely, superoxide dismutase (an antioxidant enzyme involved in phagolysosmal defence) was down-regulated by exposure to all four metals.
These results suggest that metal exposure may have complex, differential effects on the immune- and stress- responses of oysters and can potentially provide a mechanism for identifying the specific stressors responsible for changes in gene expression.
The environmental significance of this research will be assessed using oysters transplanted to a polluted estuarine environment so that their expression profiles can be analysed in the same way.

**WE 126**

**Molecular Biomarkers of exposure in marine diatom Thalassiosira pseudonana upon exposure to polycyclic aromatic hydrocarbons (PAHs): from in vitro to field studies**

RCN Carvalho Negrão[1], AB Burchardt[1], FS Sena[1], GM Mariani[1], AM Mueller[1], SKB Bopp[2], GU Umlauf[1], TL Lettieri[1]
[1]EU JRC/Institute for Environment and Sustainability, ISPRA, Italy
[2]EFSA-European Food Safety Authority, PARMA, Italy

Marine diatoms have a key role in the global carbon fixation and therefore in the ecosystem. Diatoms are unicellular, eukaryotic algae that inhabit marine and fresh waters worldwide and are responsible for about 40% of the total carbon fixation in oceans [1]. We used Thalassiosira pseudonana as a model organism to assess the effects of exposure to environmental pollutants at the gene expression level. Diatoms were exposed to polycyclic aromatic hydrocarbons mixture (PAH) from surface sediments collected at a highly PAH contaminated area of the Mediterranean Sea (Genoa, Italy), due to intense industrial and harbor activities. The gene expression data for exposure to the sediment-derived PAH mixture was compared with gene expression data for in vitro exposure to specific PAH compounds.
Genes involved in stress response, silica uptake, and metabolism were regulated both upon exposure to the sediment-derived PAH mixture and to the single component. Complementary monitoring of silica in the diatom cultures provide further evidence of a reduced cellular uptake of silica as an end-point for benzo[a]pyrene (BaP) exposure that could be linked with the reduced gene and protein expression of the silicon transporter protein. However some genes showed differences in regulation indicating that mixtures of structurally related chemical compounds can elicit a slightly different gene expression response compared to that of a single component [2]. Furthermore, based on the specific pathways affected by PAH exposure, some selected genes (silicon transporter and silaffin 3) involved in silica uptake and metabolism could be suitable molecular biomarkers of exposure to PAHs. This study aims to confirm the suitability of these genes as molecular biomarkers of phytoplankton species exposed to PAHs in contaminated aquatic environments. It also seeks to uncover molecular differences between the modes of action of complex PAH mixtures and the highly carcinogenic BaP as an isolated compound [2].

**The use of molecular responses of crayfish Procambarus clarkii as biomarkers of cadmium and uranium contamination**

S al Kaddissi[1], O Simon[1], A Legeay[2], P Gonzalez[2], C Camilleri[1], I Cavalie[1], S Frelon[1], R Gilbin[1]
[1]IRSN/LRE, SAINT PAUL LEZ DURANCE, France
[2]CNRS, ARCACHON, France

Uranium's (U) and cadmium's (Cd) distribution in ecosystems is currently increasing due to anthropogenic activities. Therefore, knowledge in describing the potential impact of these metals on ecosystem components is essential so that proper decisions can be made to protect the environment. Our study aims first to better understand the impact of U and Cd on the molecular level of crayfish Procambarus clarkii by studying modifications in gene expressions after an acute and chronic exposure, then link these changes to the bioaccumulation. Second, this work aims to identify relevant biomarkers of Cd and U contamination depending upon the type of exposure (chronic/acute). Groups of crayfish were exposed to 0 (controls), 0.05, 0.5, 5, and 10 mg/L of Cd and others with 0.3, 0.6, 4 and 8 mg/L of U for 10 days, whereas different groups were exposed to 0(controls), 40 μg/L of U or 10 μg/L of Cd for 60 days. The expression of genes involved in response to oxidative stress (sod(Mn), mt), in heavy metal detoxification (mt) and mitochondrial metabolism (cox1, atp6) were studied in the gills and the digestive glands of crayfish using real-time RT-PCR. 12S gene expression was used as an indicator of the amount of mitochondria in the cell. mt and atp6 genes had to be cloned and sequenced. Gene expressions were altered after short exposure duration and seemed to be sensitive tools to evaluate an early metals toxicity. Data suggest that the expression of mitochondrial genes and genes involved in oxidative stress responses are modified in presence of U and Cd in the gills and the digestive glands of crayfish in both experiments. However, the correlation between the expression of most studied genes and metals bioaccumulation were different in both experiments showing that the type of exposure influences molecular responses. Results proved that mt gene expression is a useful biomarker of Cd contamination no matter the type of exposure. This work also confirms the need of a mutliple biomarker approach.

**WE 128**

**Combined Cu-temperature effects in the Mediterranean mussel Mytilus galloprovincialis: gene transcription profiling associated to physiological responses**

A Negri, C Oliveri, M Bellone, L Boatti, A Dagnino, S Sforzini, I Saggese, A Viarengo, D Dondero
University of Piemonte Orientale, ALESSANDRIA, Italy

Little is known about the combined effects of heat with pollutants in tissues of marine organisms such as mussels. To get more clues on potential interactions, we carried out short term exposure (4 d) of *Mytilus galloprovincialis* specimens in natural sea water added with increasing amount of copper (10-40 microg/L) across a temperature gradient (16°C-24°C). Core lysosomal biomarkers responses, i.e. lysosomal membrane stability, neutral lipid and lipofuscin content, were examined in the digestive tissue along with transcriptomic profiling in the same organ and in gills.
At molecular level, a clear response to heat and unfolded proteins took place in the digestive gland of mussels exposed to the highest temperature (75 differentially expressed genes found, 5 hsp genes belonging to 3 different classes identified;moderated t-test,$p<0.005$,$N=4$).Gene expression profiles in tissues of animals exposed to 40 μg Cu across the temperature gradient, however, showed different patters respect to those obtained for the effects of temperature alone. A of bell shaped response with maximum effects -in terms of differentially expressed gene number- was observed at 20°C, and, indeed, in these tissues, the expression signature associated to heat response appeared to be suppressed.
The genuine response to Cu in digestive gland (23 genes, moderated t-test, p value < 0.005, N=4) encompassed some mitochondrial and extracellular matrix genes, the latter possibly indicating a response to inflammation. However no specific stress response genes, such as MT or oxidative stress related sequences, could be identified.
At physiological levels, biomarkers showed significant lysosomal alterations only at the highest copper concentration; moreover few differences could be ascribed to the temperature gradient per se.
In conclusion, our data demonstrated that the interference of temperature with copper did not produce effects at organismic level, such as mortality. Differences on biomarkers responses to copper were negligible across the temperature gradient, confirming the the ability of mussels to adapt to a changing environment and their role as robust biological indicators. Molecular analysis depicted a clear temperature dependent response and also the ability of Cu to affect such process. To get more clues on such molecular interactions, the effects on other tissues such as gills, where copper is preferentially accumulated during short term exposures, will be investigated.

**WE 129**

**Using metabolomics to identify class-specific changes in Chironomus tepperi larvae exposed to metal and non-metal contaminants**

SM Long[1], JR Sheedy[2], DL Tull[2], AA Hoffmann[1], VJ Pettigrove[1]
[1]CAPIM, The University of Melbourne, MELBOURNE, Australia
[2]Metabolomics Australia, Bio21 Institute, The University of Melbourne, MELBOURNE, Australia

Metabolomics can be defined as the analysis of the complement of small molecules associated with metabolism. Metabolic profiles can be used to investigate the underlying biochemical response of an organism following exposure to chemical or non-chemical stressors. The aim of the first experiment was to establish whether metabolomics techniques (Nuclear Magnetic Resonance spectroscopy (NMR)) could measure the metabolic profile of third instar *Chironomus tepperi* larvae. Results showed that a suite of metabolites in *C. tepperi* larvae could be measured, such as pyruvate, valine and histidine, from a number of biochemical pathways. A second study was conducted to investigate whether metal-specific changes in the metabolic profile of *C. tepperi* larvae could be identified following exposure to metal and non-metal contaminants. Third instar *C. tepperi* larvae were exposed to two sub-lethal aqueous concentrations of zinc chloride, copper sulphate and ammonium chloride for 24 hours. Larvae were sampled after 2 and 24 hours exposure. These exposures were repeated three times to ensure there was enough tissue for the analyses (based on results from the pilot study). There were three replicates per treatment, per time period. Controls (artificial water) were sampled at 2 and 24 hours exposure and at the start of the experiment. Changes in the metabolite profile following exposure to metals and non-metals are linked to the different mechanisms of toxicity of these chemicals. The value of this technique for identifying pollution impacts on aquatic ecosystems and understanding the mechanistic basis of pollution responses will be discussed.

**WE 130**

**Using the genotoxicity biomarker micronuclei piscine in Bathygobius soporator (Valenciennes, 1873) (Teleostei, gobiidae) in the coast of Salvador (Ba), Brazil**

TP Galindo
University of Aveiro, AVEIRO, Portugal

The aim of this study was to use the genotoxicity biomarker through micronucleus test in Bathygobius soporator in an urban coast environment. Herein we evaluated the metals Cr, Cd, Mn, Pb, Hg, Zn and 16 polycyclic aromatic hydrocarbons in the sediments. The dissolved oxygen, the pH and tide-pools temperature were measured as well. Micronucleus analyses were carried out on peripheral blood erythrocytes of Bathygobius soporator. There were significant differences ($p<0,05$) in the frequencies of micronclei betwen the negative and positive controls and the treatments (ANOVA one-way). Significant correlation was observed ($r = -0,743$, $p = -0,023$) between average frequency of micronucleus and the first axis of principal components analyses (PCA), which explained most of data variation (70,56%). We concluded that were a correlation between the micronucleus frequency and metals. The technique was effective in demonstrating cellular changes in B. soporator, that together with the correlation indicate stress conditions for the fish.

## ET12 - Metals and metalloids in the environment: adaptation, bioavailability and speciation

**WE 134**

**Cadmium adsorption in soils employed for pasture and sugarcane plantation with and without vinasse application from Northwest of São Paulo State, Brazil**

C Bisinoti, B Moreira, LC de Oliveira, V de Abreu, D Scaliante, FMS Ferrarese, F Manzini, MA Plicas
Universidade Estadual Paulista "Julio de Mesquita Filho", IBILCE, DQCA, SÃO JOSÉ DO RIO PRETO, Brazil

The northwest area of São Paulo's state (Brazil) has been presenting an expansion of the sugarcane culture in the last years (responsible by 18% of Brazilian ethanol production), where the vinasse application has been a practice common. Vinasse is a subproduct (wastewater) of sugarcane industry. Cadmium has been a metal present in some investigation in environment compartments in this region. Adsorption plays a key role in the remediation areas studies, since each soil has his own adsorption capacity. Thus, the main objective of this study was determine adsorption capacity for cadmium (II) in three different soil uses (natural soil, argissol and soil from sugarcane plantation with and without vinasse application), as well as the effect of pH and ionic strength on metals adsorption capacity. For this, soils samples were collected and homogenized employed official methods. The parameters pH (H2O, CaCl2), organic matter content, potential acidity, content of $Ca^{+2,}$ $Mg^{+2}$, $Al^{+3}$, $Na^{+}$, $K^{+}$, cation exchange capacity-CEC, particle size and Cd total contents were quantified in each soil samples. Soil cadmium (II) adsorptions capacity were obtained by batch experiments with metal concentration ranging from 0 to 200 mg $L^{-1}$ for Cd.

Langmuir and Freundlich isotherms models were employed to obtained cadmium adsorption. It was observed that the Langmuir model fit better than Freundlich to the metal cadmium (II). The increasing of pH showed a positive correlation to the adsorption, while the ionic strength showed a negative correlation to the adsorption. Sorption maximum capacities of cadmium (II) per gram of soil found were 2.5 mg/g; 0.7 mg/g and 2.5 mg/g respectively for natural, with and without vinasse soil. It can be concluded that vinasse application decrease soil adsorption capacity turning other environmental compartment more susceptible to pollution. Acknowledgments: FAPESP and CAPES.

**WE 135**

**Characterization of soil trace metal availability : DGT and kinetic extraction vs. conventional sequential scheme**

N Manouchehri[1], ML Nguyen Thi[1], S Besancon[1], LA Lê[2], A Bermond[1]
[1]AgroParisTech, PARIS, France
[2]Institut of Chemistry, HANOI, Vietnam

Numerous approaches are proposed in the literature about the mobility and bioavailability of soil trace metals (TMs). The conventional approach, principally based on the measurement of the metal fraction extracted from the soil solid phase using single or sequential extraction schemes, is carried out at equilibrium where kinetics aspects are generally not considered, while the soil media is a dynamic environmental system. For this reason, some authors have attempted to study the kinetic aspects of TMs transfer. The most frequently used kinetic methods correspond to kinetic fractionation by single extractive schemes and Diffusive Gradient in Thin layer (DGT) technique.
However, both equilibrium and kinetic approaches have been subject to some criticisms like as the operational character and the reliability of each methods to predict the bioavailable fractions. Furthermore, the extractive schemes and DGT techniques are scarcely compared in the literature. In this paper, a comparative study is proposed for estimating the potential availability of Pb and Cd in three polluted urban and industrial sites of old Hanoi in Vietnam. A modified BCR sequential extraction scheme, a kinetic single extraction scheme (EDTA) and DGT technique were used. The kinetic behaviour of of Cd and Pb desorption in soil/EDTA systems were compared with metal concentrations extracted within different steps of BCR scheme and those transferred from the soil solid phase to the resin sink in DGT probes. Kinetic parameters like as kinetic constants rate of desorption were employed to assess the potential availability of each metal. Different kinetic trends have been observed for Pb and Cd.

**Selective binding of target heavy metals using imprinting technique**

E Kasymova, EM Khudaibergenova, RP Koroleva, ShJ Jorobekova, KA Kydralieva
Institute of Chemistry & Chem. Technology, BISHKEK, Kyrgyzstan

The principle of "adjustment"of humic-based polymeric complexes by the substrate (template) on the stage of their synthesis or formation of three-dimensional structure has been used for selective binding of the heavy metals and radio-nuclides from migration cycles. The point is in the recognition and binding of ions of those metals, which were used as template ions in the synthesis of macro-complex. The principle of the Molecularly Imprinted Polymer (MIP) production is the formation of HA complexes with the corresponding cations of metals and the subsequent cross-linking of their chains, that allows to fix the conformations of the molecules favourable for the binding of these ions. It will result (after the removal of template ions) in the growth of sorption capacity and the speed and selectivity of sorption on the MIPs. Previously such approach was used for the selective binding of strontium ions in the regions contaminated as a consequence of Chernobyl disaster, adjusted polymeric sorbents on the basis of co-polymers of diacrylate strontium with sterol, methylmetacrylate, acrylic acid and cross-linking agent - dimethacryl ether ethylene glycol, etc. (1).
A specific MIPs for targeted Cu (II), Ni and Co metals have been designed and prepared for each metal of interest. MIPs used as a selective sensing material integrated in a sensoric system. Batch equilibrium studies using imprinted and non-imprinted polymer solutions were conducted to determine metal-binding capacities. As a result, such co-polymers possess significant speed of sorption (the balance is set up in several minutes) and sorption capacity (0.5-3.0 mg-eq. M/g). Imprinted sorbents showed increased binding to metals compared to non-imprinted. Factor of the selectivity (ratio of number of sorpted "own"ion to the number of "foreign"ion) is to 1:20- 1:25.

**Measuring mercury speciation in multi-component solutions using Donnan membrane technique**

H Zhang[1], YM Luo[2], LP Weng[3], D Cao[1], F Yu[1]
[1]Chinese Academy for Environmental Planning, Ministry of Environment Protection, BEIJING, China
[2]Institute of Soil Science, Chinese Academy of Sciences, NANJING, China
[3]Department of Soil Quality, Wageningen University, WAGENINGEN, The Netherlands

The DMT method has the advantages of simultaneous measurement of different elements in a single sample and it has less disturbance and interference of the sample equilibrium than most other methods.Even though the Donnan membrane technique has been applied successfully to measure several free metal ions in the environmental system, it's has never been used for mercury species measurement yet. Therefore, we tested the application of DMT to mercury measurement in multi-component solutions which contain different mercury species as the dominating components. The results showed that mercury species in solutions containing different ligands can be measured by a dynamic DMT approach at various pH values and ion strengths with a high agreement between calculated and measured mercury species. However, the most important factor which restricts the applicability of DMT to mercury species measurement is mercury adsorption to the cation exchange membrane in the form of Hg2+, HgOH+ and Hg(OH)2. This restriction can be partly solved by shortening sampling time and adding ligands to the acceptor side which complex strongly with mercury.
It was found that when 0.01 M CaCl2 was used as background solution, HgCl2, HgCl3- were main contributors to the flux of Hg transport through the cation exchange membrane. The rate-limiting step of Hg transport from donor side to acceptor side is Hg diffusion in the membrane. There is strong chemical adsorption of Hg in the membrane besides electrostatic adsorption of Hg, which plays as an important role restricting the applicability of DMT on Hg species measurement. The chemical adsorption of Hg can be reduced by shorten the sampling time and Hg species in the donor side can be calculated using the dynamic DMT method. 0.002 mol L-1 Ca(NO3)2 was also tried as background solution in which Hg2+ or Hg(OH)20 were dominative Hg species depending on solution pH. A much stronger Hg sorption phenomenon was observed compared with HgCl2-CaCl2 solution. The Hg loss in the donor side was more than 50% because of strong chemical Hg adsorption on the cation exchange membrane. A retardation factor was introduced to account for this retardation of Hg in membrane, but it could only help to solve this problem in some degree.

**WE 138**

**Effect of copper exposure on the activity of Na+/K+-ATPase in Eisenia foetida coelomocytes**

S Latronico, A Calisi, R Caricato, MG Lionetto, T Schettino
Università del Salento, LECCE, Italy

Na+/K+-ATPase is an ubiquitous plasma membrane pump playing a fundamental role in the intracellular ionic homeostasis. Its sensitivity to pollutant exposure was previously demonstrated in several aquatic organisms. A previous work on the earthworm Eisenia fetida (Calisi et al., Ecotoxicol. Environ. Saf., 72: 1369-1377, 2009) demonstrated copper sulphate exposure to induce a dramatic cells swelling in coelomocytes. The aim of the present work was to test the hypothesis of the possible impairment of E. fetida coelomocyte Na+-K+-ATPase by copper exposure in either in vitro or in vivo conditions.
First, the presence of a specific Na+-K+-ATPase activity was demonstrated in the coelomatic fluid of E. foetida, using the spectrofotometric method of Bartlett ( J. Biol. Chem., 234: 466-468, 1959). Then, the coelomatic fluid was in vitro exposed to copper sulphate (1 _M), or ouabain (0.2 mM) (specific inhibitor of Na+-K+-ATPase), or ouabain plus copper sulphate (0.2 mM + 1 _M) respectively, for a time interval of 5 hours. A significant increase of coelomocyte size was observed in the three experimental conditions. After 5 hours of exposure the effect of copper sulphate on cell welling was quite similar to the effect induced by ouabain or by the mixture of ouabain and Cu2+, suggesting that the in vitro inhibition of Na+-K+-ATPase is able to induce cell swelling in earthworm coelomocytes.
Thereafter, specimens of E. foetida were exposed to CuSO4 1 μM utilizing the standard acute toxicity test "Filter paper test"for 48 hours. A significant ($P<0.05$) increase of coelomocytes dimension was observed in exposed organism with respect to the control group paralleled by a significant ($P<0.05$) inhibition of Na+/K+-ATPase activity.
In conclusion, the results demonstrated that the Na+-K+-ATPase of E. fetida celomocites is inhibited by the exposure to Cu2+. This, in turn, is able to induce impairment of intracellular ionic homeostasis and cell swelling. Due to the important immunological role of ceolomocytes which mediate many of the innate immune responses in earthworms, the observed copper inhibition of colomocyte Na+-K+-ATPase activity and the following cellular swelling may increase the susceptibility of animals to diseases and reduce their survival capability. Moreover, results suggest that the pollutant-induced Na+-K+-ATPase inhibition in earthworm coelomic fluid can represent a non destructive biomarker of effect which may be directly linked to organism health.

**WE 139**

**Complexation of nickel by natural ligands and influence on Ni biovailability in aquatic ecosystems - kinetic considerations**

E Uher, A Mayenaquiby, C Gourlay-France
Cemagref, ANTONY, France

Among the priority pollutants that need to be monitored according to the European Union Water Framework Directive, relatively few studies about nickel fate and effect in freshwater ecosystems are available. The main reason is that the complexation kinetics of Ni is known to be slow, in contrast to those of other metals like Cu and Cd. Consequently we expect that speciation and bioavailability models for Ni require specific studies that take into account exchange kinetics and not only equilibrium status in the environment.
We propose here to present a case of study of the bioavailability of Ni, studied by the mean of Fontinalis Antypiretica. These aquatic mosses were chosen because of their resistance, but also their fast accumulation of metals, allowing working at low level of contamination. Moreover, previous successful studies on Cu have been conducted with them, showing that more than inorganic copper was available for the mosses (Ferreira et al, ET&C, 2008).
The Diffusive Gradient in Thin film technique (DGT) proposed by Davison and Zhang (1994) was chosen as speciation tool. DGT collects inorganic species and a variable part of metal complexes formed with organic ligands. Previous studies highlighted that DGT is suitable for monitoring bioavailability of Cu and Cd when we compare the fraction sampled by DGT and by aquatic organisms (Fontinalis Antypiretica and Daphnia magna).
The bioaccumulation experiments were conducted at environmentally realistic concentrations of Ni (5 to 15 μg.L-1) in natural water. We varied the speciation by adding different type of ligands (EDTA, humic acids, natural organic matter). Bioaccumulation kinetics was monitored from Ni concentration decrease in water. A preliminary study let us verify that Ni decrease corresponded to Ni bioaccumulation in mosses. After a 5d-exposure, bioaccumulated Ni in mosses was measured too. . .
Two behaviours were highlighted in our results depending on the composition of water: without organic ligands, a simple first-order decrease of Ni in the mineral medium, whereas in experiments with organic matter, Ni concentrations in water exhibited a plateau after a first decrease and then a second step decrease.The plateau might be due to the slow dissociation of organic complexes as bioaccumulation in mosses modifies Ni speciation in water.

**WE 140**

**Relationship between metals bioavailability and ecotoxicity in Catalan (Spain) river waters**

MI López[1], N Roig[1], J Sierra[2], M Mari[1], M Schuhmacher[1], JL Domingo[1]
[1]Universitat Rovira i Virgili, TARRAGONA, Spain
[2]Universitat de Barcelona, BARCELONA, Spain

It is well known that the toxicity associated to heavy metals is not directly caused by the total amount of metal, but only by its bioavailable form, being this closely linked with the fraction of free metal. The main objective of this study was to assess the toxicity of metals in Catalan (Spain) river waters and to correlate it to several parameters which may have a certain influence on metals bioavailability. For this purpose, the concentrations of 8 potentially toxic elements (As, Cd, Cr, Mn, Ni, Pb, V, and Zn) were analyzed in freshwater and filtered water samples from 11 Catalan river sections. Diffusive Gradient in Thin-Films (DGTs) passive samplers were also used to estimate the bioavailable fraction. Acid extracts of DGTs were used to assess the acute toxicity by using the photo-luminescent bacteria Vibrio fischeri (Microtox®). The knowledge of the tendency of metals to remain in the filterable fraction, adsorbed into suspended material or into DGT devices provides was used to acquire useful information for the prediction of metal speciation in waters. Furthermore, the Mineql+ software, a chemical equilibrium modeling system, was applied to check the consistency of experimental data. The evaluation of metal concentrations with competitive factors, such as water hardness or dissolved organic matter, mostly explained the amount of free ion metals responsible for toxicity. In general terms, toxicity levels in Catalan rivers were found to be relatively low, excepting for 2 sites presenting an important industrialization. On the other hand, the oxidation state of the elements in natural conditions was confirmed to be a critical aspect when assessing toxicity in fluvial ecosystems. The integration of modeling (chemical software) and monitoring (passive methods) seems to be crucial to understand the hazard of aquatic compartments for the river ecological status.

**WE 141**

**In situ validation of chronic biotic ligand models of Cu, Ni and Zn with caged Daphnia magna**

J Verschoor[1], PM Vink[2], G Vijver[1], R de Snoo[1]
[1]Leiden University, LEIDEN, The Netherlands
[2]Deltares, UTRECHT, The Netherlands

Twelve brooks covering a range of metal contaminations (PEC/NEC from <1 to 80) were selected for validation of chronic biotic ligand models of Cu, Ni and Zn in a complex outdoor multi-contaminant environment. The sites were located in the Dommel catchment in The Netherlands, which is historically contaminated with metals due to the activities of zinc smelters. Data of other organic and anorganic contaminants and general water quality parameters were also taken into account. The effects of pesticides and other organic contaminants were of minor importance, since sites were located in semi-natural areas, dominated by forest and heathland alternated with pastures and maize culture.

Four cages on each site with 20 juveniles of Daphia magna were exposed to natural outdoor conditions for three weeks. Survival and reproduction of Daphnids were determined after three weeks. Contents of Cu, Ni, Zn as well as Co, Cd, Se, Ca, Mg, Na, Fe and Mn were determined with HR-ICP-MS. The level of expected metal risks is reduced by application of the biotic ligand models. The level of observed effects on Daphnia reproduction corresponded well with the effects predicted by the added risk of metals (corrected for bioavailability). The explained variance further improved by taking into account the pH, DOC, $PO_4$, and $O_2$. Results of this experiment including accumulation data will be presented on the poster.

**WE 142**

**Models characterizing the nickel bioaccumulation in Gammarus pulex and influence of water cationic composition**

JD Lebrun[1], M Perret[1], E Uher[1], MH Tusseau-Vuillemin[2], C Gourlay-Francé[1]
[1]Cemagref, ANTONY, France
[2]IFREMER, ISSY-LES-MOULINEAUX, France

Nickel (Ni) is a common contaminant in freshwaters because of its industrial and domestic applications, with potential ecological consequences. Although chemical analyses allow to determine the total contamination levels in freshwaters, they do not give information on the bioavailability of the metal and consequently, on its toxicity and impact of environmental health. The biodynamic and saturation models characterizing the metal bioaccumulation offer promising perspectives to predict the metal bioavailability in freshwaters. However, the accumulation strategies have to be defined for each metal/organism couple in controlled conditions to construct these models.

This study aims at assessing the waterborne bioaccumulation of Ni and the influence of geochemical properties of water on this process in a crustaceous widely distributed in Europe, *Gammarus pulex*. In the laboratory, the organism was exposed to several concentrations of Ni (from 0.001 to 100 mg $L^{-1}$) in aquatic microcosms. Then, bioaccumulation of Ni was recorded in waters exhibiting various concentrations of three major ions (Na, Mg and Ca).

Our results showed that *G. pulex* was greatly tolerant to Ni ($LC50_{48h}$ = 477 mg $L^{-1}$). Time course experiments allowed to construct the biodynamic model by determining the uptake (*ku*) and elimination rate constants (*ke*). For the exposures above 1 mg $L^{-1}$, the metal uptake saturated. Thus, the maximal capacity of organism to accumulate the metal (*Bmax*) and the half-saturation constant (*K*) were determined to establish the saturation model. It was verified that the two models are comparable for the lowest exposures (< 0.1 mg $L^{-1}$), with *ku/ke = Bmax/K*. Furthermore, only an increase in the concentration of Ca decreased the bioaccumulation whereas Na and Mg had no effect until 80 mg $L^{-1}$.

This study reports for the first time the bioaccumulation of Ni in *G. pulex* and suggests that this crustaceous could be used as an integrative tool to quantify the Ni bioavailability in freshwaters. Taking into account the geochemical factors influencing the metal bioavailability allows to improve the prediction of bioaccumulation models.

**WE 143**

**Variability in Cd uptake by Pseudokirchneriella subcapitata among freshwaters containing dissolved organic matter with contrasting characteristics**

L Verheyen, F Degryse, E Smolders
KULeuven, HEVERLEE, Belgium

The Free Ion Activity Model (FIAM) predicts that the free ion is the preferred species for uptake from solutions with the same inorganic composition. It has been shown previously that FIAM not holds for the cadmium (Cd) uptake by the green algae Pseudokirchneriella subcapitata. The Cd uptake increased in the presence of inorganic (e.g. Cl-¬) at the same free Cd2+ activity. Here, we investigated the influence of natural dissolved organic matter (DOM) and synthetic organic ligands (e.g. NTA, EDTA) on the Cd uptake by green algae. Eighteen freshwater samples of natural, agricultural and urban areas were isolated by reverse osmosis. The waters were analysed for ionic composition, DOC concentration, SUVA and metal binding capacity. The Cd binding DOM properties per unit C varied tenfold among the different freshwater samples. The DOC concentration varied also a factor tenfold among waters. This suggested that both DOC quantity and DOC quality are equally important to predict Cd availability. We exposed algae for 4 days to different DOM samples and synthetic ligands at a constant free Cd2+ activity. The DOC concentration in the test medium was 25 mg C/l. In this design, we observed a higher Cd uptake in the presence of DOM/ synthetic ligands than in absence of complexes, in contrast with FIAM that predicts no change. As a result, Cd uptake by green algea increased with increasing metal binding capacity of the freshwater DOM samples.

**WE 144**

**Relevance of water chemistry to assess lethal and sublethal effects of metals using Daphnia magna**

FT Jesus[1], J Ranville[2], AJA Nogueira[1]
[1]CESAM & Department of Biology, Aveiro, Portugal, AVEIRO, Portugal
[2]Department of Chemistry, Colorado School of Mines, GOLDEN, CO, United States of America

The aquatic toxicity of metals is a current and widespread environmental problem. The toxicity of metals is known to be dependent on the water chemistry parameters (pillar of the Biotic Ligand Model). The majority of the existing works focus either on the acute or chronic toxicity of metals. However, few models, integrating water chemistry, address the toxicity of metals on feeding activity. The feeding activity constitutes a sensitive indicator of toxicity and is an ecologically relevant endpoint. Thus, in this work we studied the relative importance of hardness and alkalinity in the toxicity of copper and zinc to the feeding activity of *Daphnia magna*. Concomitantly, we studied the effects of both these water chemistry parameters on the acute lethal responses.

The establishment of functional relationships between water chemistry-metals and the feeding rates in *D. magna* is essential to provide a better and more realistic understanding of potential long-term effects of the metals on cladocerans under ecologically relevant conditions. Both hardness and alkalinity were found to influence the lethal and sublethal effects of metals, although the effect of the former was more relevant. Additionally, regression analysis showed that the toxicity of copper and zinc was well described by these water chemistry parameters.

**WE 145**

**Mitigating effects of humic substances in the polluted environments caused by chemical binding to ecotoxicants**

SP Lee, KA Kydralieva
Institute of Chemistry & Chem. Technology, BISHKEK, Kyrgyzstan

Humic substances (HS) are natural organic compounds comprising 50 to 90 % of the organic matter of peat, lignites, sapropels, as well as of the non-living organic matter of soil and water ecosystems. Being the products of stochastic synthesis, HS have elemental compositions that are non-stoichiometric, and structures, which are irregular and heterogeneous. The structural heterogeneity of HS may explain their resistance to biodegradation: the longevity of humics in soils is typically on the order of thousands of years. This is of particular practical relevance if objective is to develop soil/aquifer remediation technology predicated on a recalcitrant matrix derived from HS.

The complex structure provides a very diverse reactivity of HS. They are able of binding both heavy metals and organic xenobiotics. The most common metal binding occurs via carboxylic and phenolic oxygen, but nitrogen and sulfur also have a positive effect on metal binding. The various binding mechanisms between organic contaminants and HS include hydrogen bonding, van der Waals forces, ligand exchange, and charge transfer complexes representing weak binding energies and formation of covalent linkages representing chemically stable bonds.

The binding to HS causes a change in speciation of heavy metals and organic xenobiotics followed by a change in their toxicity and bioaccumulation.

The goal of the research was to develop detoxicants of integrated effect on the basis of humic substances and to conduct the feasibility studies on their production. 8 samples of parent humic materials have been isolated and about 30 humic-based de-toxicants have been synthesized. The experimental approaches undertaken to produce humic-based de-toxicants included enrichment with different groups (O-, OH-, CO-, hydrophobic groups). It has been demonstrated from both chemical characteristics and detoxifying ability point of view that all the produced de-toxicants possessed equal or higher detoxifying potential in relation to heavy metals or herbicides. Derivatives of humics have been studied at both express bioassay, laboratory vegetation experiments and field trials scales as well. All the experiments confirmed not only high detoxifying potential of those de-toxicants in relation to heavy metals but also their prolonged activity in the environment. Producing of the above de-toxicants at pilot plant scale demonstrated an opportunity to synthesize them at industrial scale.

**WE 146**

**Assessing fate and toxicity of copper from re-suspended sediments in rainbow trout (Oncorhynchus mykiss)**

J Kuckelkorn[1], M Brinkmann[1], S Hudjetz[1], C Cofalla[2], S Roger[2], L Erdinger[3], H Zimmer[4], S Buchinger[5], G Reifferscheid[5], H Schüttrumpf[2], H Hollert[1]
[1]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[2]RWTH Aachen, Institute of Hydraulic Engineering and Water Resources Management, AACHEN, Germany
[3]Heidelberg University, Department of Medical Microbiology and Hygiene, HEIDELBERG, Germany
[4]Heidelberg University Hospital, Main Laboratory, HEIDELBERG, Germany
[5]Federal Institute of Hydrology, KOBLENZ, Germany

Sediments can act as a sink as well as a source for environmental pollutants. One interesting field of recent scientific studies is to investigate possible ecotoxicological effects due to the uptake of resuspended particles and contaminants during flood events. In this work, juvenile rainbow trout (Oncorrhynchus mykiss) were exposed to resuspended natural sediments from Ehrenbreitstein (River Rhine) spiked with copper at a nominal concentration of 500 mg kg-1 dry weight. Furthermore a control test without spiking was used in this experiment. Samples of water, suspended particles, fish tissues and livers were taken at days 0, 1, 2, 3, 6, 8, and 12. The aims of this study are twofold. The first approach is to look into the distribution of copper between the compartments water, suspended particles an fish tissues using different methods of digestion (UV, microwave) and ICP-MS. Secondly biomarkers, i.e. measurement of lipid peroxidation, as an indicator for oxidative stress, and quantification of metallothionein using Western immunoblotting, as an indicator for metal exposure, were used. The presentation will include the results of the experiments, which are currently being conducted. The RWTH Aachen University Undergraduate Funds Programme provided funding for performing ICP-MS analyses at the University of Heidelberg by a personal travel grant to the first author.

**WE 147**

**Effect of DOC concentration and type on the bioavailability of copper in Lambro River (Italy)**

MT Palumbo, MM Mingazzini
Water Research Institute, CNR, BRUGHERIO, Italy

The interaction with physicochemical parameters, including pH, hardness, cationic competition and dissolved organic carbon (DOC), greatly affects the toxicity of metals to aquatic organisms in ambient water. Standard procedures for deriving environmental quality criteria are recognized inadequate, since toxicity data generated by tests set-up using standard media may be poorly representative for assessing metal toxicity in surface waters. The water-effect ratio (WER), based on the direct ecotoxicological evaluation of metal toxicity in site-water, is the only approach which measures the water-chemistry effect on metal toxicity at specific sites. Bioavailability adjustment using WER can thus help improving the development of mathematical models to predict the toxicity of dissolved metals in freshwater systems with different chemical composition.

Since important changes of the riverwater chemistry are expected up to downstream over the course of rivers draining highly anthropized areas, the aim of this work was to evaluate changes of metal toxicity over the River Lambro, which drains one of the most densely populated area of

Northern Italy. The experimental design was mainly focusing on the complexing properties of DOC, as differently affecting the toxic bioavailability of copper over the river-course.
The ecotoxicological WER procedure, involving the simultaneous evaluation of Cu toxicity in riversite-water and in standard-water, was set-up using the alga growth-inhibition test with Pseudokirchneriella subcapitata. Changes of Cu-toxicity were evaluated both in different river-flow, and over the river-course, up to downstream from the most urbanized area comprising the city of Milan. Following DOC enrichment, mainly originated from urban sewage, the protective effect of the organic-ligands was amplified in the lower part of the river. The experimental removal of organic ligands by SPE extraction of the downstream samples also proved the protective role of DOC in the control of Cu-bioavailability. Finally, changes of DOC type, at similar DOC concentration, have been suggested by the important enhancement of WERs measured in conditions of high river-flow, possibly involving the river-sediment release as an additional DOC-type source.
The obtained results highlight the importance of the WER-derived information to improve predictive models for metal bioavailability, suggesting to take account of the effect of DOC type, which is hardly predictable at present.

**WE 148**
**Spatial and temporal variation in bioavailability and species sensitivity of Cu, Ni and Zn in surface waters of The Netherlands**
J Verschoor[1], PM Vink[2], G Vijver[1], R de Snoo[1]
[1]Leiden University, LEIDEN, The Netherlands
[2]Deltares, UTRECHT, The Netherlands
Geographical and temporal variations in metal speciation were calculated and water-type specific sensitivities were derived for a range of aquatic species, using surveillance water chemistry data that cover almost all WFD-surface water types in The Netherlands. Biotic ligand models (BLMs) for Cu, Zn and Ni were used to extrapolate chronic NOECs determined in test media towards site-specific NOECs for 372 sites sampled repeatedly over 2007-2010. Site-specific species sensitivity distributions were constructed accounting for chemical speciation. The sensitivity of species as well as the predicted risks shifted among species over space and time, due to changes chemical speciation and biotic ligand binding. The sensitivity of individual species (NOECs) and of the ecosystem (HC5) for Cu, Ni and Zn showed a spatial variation up to two orders of magnitude. Seasonality of risks was shown, with an average ratio between lowest and highest risk of 1.3, 2.0 and 3.6 for Cu, Ni and Zn respectively. Maximum risks were predicted to occur in the winter months (peaking in February) and minimum risks in September. A risk assessment using space-time specific HC5-values of Cu and Zn resulted in a reduction of sites at risk, whereas for Ni the number of sites at risks increased.

**Delivering a practical methodology to account for metal (bio)availability in the Water Framework Directive - tools and techniques**
P van Sprang[1], P Simpson[2], D Haesaerts[3], G Merrington[2], C Schlekat[4], K Delbeke[5], F van Assche[3], F Verdonck[1]
[1]ARCHE, GENT, Belgium
[2]WCA, FARINGDON, United Kingdom
[3]IZA, BRUSSELS, Belgium
[4]NIPERA, RALEIGH-DURHAM, United States of America
[5]ECI, BRUSSELS, Belgium
Significant scientific progress has been made for assessing metals in surface waters. Recently, the current state of the science has been incorporated into the new EU Technical Guidance for deriving Environmental Quality Standards (EQS) under the European Water Framework Directive (WFD). The guidance supports the use of a tiered compliance assessment regime for metals that incorporates, notably, (bio)availability and recommends using Biotic Ligand Models (BLMs). This approach was recently supported by the EU Scientific Committee on Health and Environmental Risks (SCHER). However, the guidance does not provide practical tools to implement a bioavailability-based compliance regime (e.g. individual member state compliance assessment). To this end, simple screening tools based on full BLM calculations have been developed for several metals (e.g. Cu, Zn and Ni). The tools require the input of the following abiotic water parameters: Dissolved Organic Carbon, pH and Hardness/Calcium concentration. As such, they capture most of the variability in metal (bio)availability caused by the chemistry of a given water body. The tool can be fully automated in laboratory information management systems. Extension to other metals is anticipated. Screening tools, when used as part of a tiered approach, provide water managers with an opportunity to efficiently account for metal (bio)availability in a transparent way and deliver a robust metric of potential environmental risk. A website (www.bio-met.net) acting as a portal for all aspects of metal (bio)availability and its implementation, including the multi-metal tool for assessing bioavailability, will be demonstrated at this meeting and will be made publically available in the course 2011.

**WE 150**
**Spatial risk assessment of nickel in surface waters of Great Britain**
C Simpson[1], A Peters[1], L Surl[1], C Schlekat[2], E Rogevich[2]
[1]WCA environment, FARINGDON, United Kingdom
[2]NiPERA, DURHAM, United States of America
The potential risks due to nickel in surface waters can be assessed by comparing the local dissolved Ni concentration against a local water quality standard calculated using the Ni Biotic Ligand Model (NiBLM). Data for dissolved Ni exposure and the required input data for the NiBLM are often unavailable for the same location, so kriging, a spatial interpolation approach, was used to estimate data for unsampled locations. The approach reproduces general trends in the data, and interpolated local water quality standards identify areas of high and low Ni bioavailability, which are driven predominantly by local dissolved organic carbon concentrations. Interpolated exposure data identify areas of current and historic metalworking industries, former mining areas, and areas of high soil background concentrations of Ni, all of which contribute to elevated Ni exposures. The predicted risks due to nickel in surface waters also follow general trends, although predictions for specific sites are poor. This approach is useful for identifying areas where increased monitoring effort may be required, but is not sufficiently reliable for more detailed assessment purposes.

**WE 151**
**Water quality standards for silver in Dutch surface waters - a proposal in accordance with the Water Framework Directive**
CE Smit, R van Herwijnen, CTA Moermond
RIVM, BILTHOVEN, The Netherlands
Over the last years, the use of silver in consumer products has rapidly increased. Most of these applications are in the form of nano-silver, which is used as anti-microbial agent in many consumer products. This increased use is expected to lead to increased emissions of silver into the environment. The current water quality standard (QS) for silver in the Netherlands originates from 1999. In view of the expected increase in environmental concentrations, updated QSs for silver and nano-silver in surface water are needed. The number of aquatic ecotoxicity studies with nano-silver is still limited, but there are indications that silver ions determine the effect. Also for "non-nano"silver, dissolved ions are considered most relevant from an ecotoxicological point of view. Therefore, QSs for dissolved silver were derived in accordance with the methodology of the European Water Framework Directive (WFD). Public literature on aquatic ecotoxicity of silver was reviewed with respect to scientific reliability and relevance for this purpose. Only toxicity data which relate to dissolved silver were selected for QS-derivation. Most available studies are performed with silver nitrate, but also studies with other species like silver chloride and silver thiosulfate were reviewed. Following the requirements of the WFD, secondary poisoning of predatory birds and mammals was considered as well, since this could be a significant route of exposure. Human exposure through fish consumption is not considered relevant for the derivation of QSs, because human toxicological risk limits for silver are relatively high and this route is most likely not critical. For naturally occurring compounds like silver, QSs are expressed as maximum concentrations that may be added to the background level. Monitoring data are not available for Dutch surface waters, but literature data indicate that environmental concentrations can vary from 2 ng/L to 2 µg/L. This means that the background levels will have a significant influence when compliance to the new QSs needs to be evaluated.

[4]Leiden University, LEIDEN, The Netherlands
Current practice in chemical hazard ranking and toxic impact assessment estimates fate and toxicity assuming the chemical exists in dissolved and particulate phases and, for metals, that all dissolved species are equally bioavailable. This treatment of metals, similar to organic chemicals, introduces a significant error in their estimates of hazard ranking since metal bioavailability and ecotoxicity effects are related to truly dissolved phase and free metal ion within it, not the total dissolved phase. We previously addressed this concern by introducing a Bioavailability Factor (BF) to the calculation of Comparative Toxicity Potentials (CTPs) for hazard ranking of chemicals (Gandhi et al. 2010 ES&T). In this method, we showed that the aquatic ecotoxicity Effect Factor (EF) for metals are calculated using the Biotic Ligand Models (BLMs) to correct for water-type specific bioavailability to aquatic organisms. However, the method application is currently limited to cationic metals for which BLMs are available (e.g., Ag, Cu, Ni, and Zn). To address this issue, we extended the method of calculating CTPs by proposing the use of the modified Free Ion activity Model (FIAM) to replace BLMs for other metals. We first compare EFs and resulting CTPs for several distinct water-types around the world to show that the variations between the estimates from the two models are within the reasonable range for the purpose of hazard ranking and risk assessment. Our results stress that it is more important to select a generic freshwater archetype on which the analysis should be based than the type of ecotoxicity model itself. We then applied the extended method to calculate CTPs of metals like B, Cd, Co and Pb for which the BLMs are not publicly available yet. We present the variability in CTPs of these metals using the aquatic chemistry of several global freshwater systems.

**WE 153**
**Development of a methodology for the ecotoxicological analysis of air samples. Correlation with chemical pollutant levels.**
N Roig Montserrat[1], JS Sierra[1], MN Nadal[2], JR Rovira[3], MS Schuhmacher[3], JL Domingo[2]
[1]Universitat Rovira i Virgili, TARRAGONA, Spain
[2]Laboratory of Toxicology and Environmental Health, Universitat Rovira i Virgili, REUS, Spain
[3]Department of Chemical Engineering, ETSEQ, Universitat Rovira i Virgili, TARRAGONA, Spain
The human being is exposed to multiple environmental chemicals, rather than to specific agents. Pollutant mixtures may pose important adverse health effects, not only because of the effects of individual substances, but also as a result of the potential synergisms/antagonisms among them. Despite that, and because of the difficulties to assess the hazard potential of these mixtures, regulation measures to control the levels of pollutants are traditionally focused on determining the levels of contaminants individually. Air inhalation is known to be an important exposure pathway to some chemicals, such as heavy metals and polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs). In recent years, a number of surveillance programs have been performed in order to monitor the air quality in industrial (close to incineration and cement plants) and urban areas in Catalonia (Spain). Data on the concentrations of metals (As, Cd, Cr, Hg, Mn, Ni, Pb, Tl, U, and V), PCDD/Fs as well as particulate matter (PM10), obtained by means of high-volume active sampling devices, are available. However, an assessment of the exposure to air pollutants has not been carried out from an integral point of view; this is health risks have not been fully characterized from an integrative way. Microtox® bioassay utilizing Vibrio fischeri bioluminescence bacteria is a suitable method to evaluate the ecotoxicity of environmental samples. Although it has been largely used in aquatic and solid extract studies, its applicability in other environmental compartments has been merely occasional. The objective of the present study was to develop and validate a Microtox®-based ecotoxicological method to evaluate the air quality. To obtain a first approximation of air samples ecotoxicity, the light emission was measured when the organisms were exposed to the PM10 retained in Quartz Fibber Filters (QFF) from different areas of Catalonia. The suitability of combination different solvents with different polarity such as, ethanol, methanol, acetone, hexane, DMSO was firstly checked and compared with corresponding QFF acid extracts neutralized with NaOH. Furthermore, toxicity values were correlated with the levels of metals, PCDD/Fs and PM10.

**Challenges for the ecological assessment of organometallic substances under the Canadian Environmental Protection Act, 1999**
JP Gauthier, M Eggleton, J Hill
Environment Canada, GATINEAU, Canada
As part of Canada's commitment to address the ecological and human health risks associated

with chemicals in commerce by 2020, Environment Canada needs to assess the ecological risks of a variety of metal-containing substances. One important group of metal-containing substances are the organometallics. These are defined as substances that contain at least one metal atom that is covalently bound to a carbon atom or that has multiple bonds with oxygen, nitrogen, sulphur, or phosphorus atoms. Organometallic substances are often not well studied in the realm of ecotoxicology. They are chemically complex and often fall outside of the domain of applicability of current models. In addition, their extent of degradation and contribution to the environmental loadings, and influence on the speciation of the metal moieties are not well characterized and may be variable. Organometallics may therefore require nuanced and specific approaches for individual cases or subgroups. This poster presentation will outline important data gaps for scientific questions and possible approaches for grouping organometallic substances and assessing their ecological risks. New information and understanding of these substances would greatly benefit current and future ecological assessments in Canada and elsewhere. Environment Canada will continue to engage the international community, researchers, stakeholders and partners to refine the evaluation methodology for organometallic substances.

**WE 155**

**Empirical model of As bioavailability to earthworm, Eisenia fetida; approaches using geochemistry of soils**

BT Lee, KK Kim
Gwangju Institute of Science and Technology, GWANGJU, South-Korea

Arsenic contamination in soils has been issued because of the toxic properties of a number of its compounds. Earthworm has been kown to bioaccumulate As from soils and found to be highly elevated in As. It is generally known that the inorganic forms of As are more toxic than the organic forms and readily accumulate in living tissues due to their affinity for proteins, lipids, and other cellular components. Geochemistry of soil has been reported to affect metal accumulation in earthworms. Understanding the As accumulation in earthworms with regard to both kinetics and metabolisms can make it possible to determine the bioaccessibility (or environmental availability) of As in soils. The study was aimed to determine the effects of soil characteristics on As toxicity, accumulation and metabolisms in earthworms and derive the geochemical factors on As accumulation. Field soils which were contaminated with As were collected and pre-treated in the lab. The soils were characterized for several geochemistry of soils. Earthworms, Eisenia fetida, cultured in the lab were exposed to field soils for 70 days and worms were collected at appropriate time interval to measure As body burdens. One compartment model was applied to estimate uptake rates. Calculated uptake rates were correlated with various soil properties and empirical models were created to predict uptake rates. Sorbed As on soils were significantly correlated with uptake rates implying bioavailability could be estimated by As fraction in soils. Fe-oxide contents were the second predictor of uptake rates. Multivariate regression was also applied to calculated uptake rate constant with various soil properties and sulfate, Fe-oxide, and DOC in soils were the predictors of uptake rate constants. All predictors in the empirical models were highly important in As fate and transport in soils implying As transport in soils played a significant role in As bioavailability in soils.

**WE 156**

**Ecotoxicological assessment of catalytic heavy metals leaching from waste fuel cells**

N Ota, S Hidenobu, R Shoji
Tokyo National college of technology, HACHIOJI, Japan

Transportation relies on liquid fuels derived from fossil fuels with many associated environmental impact. Therefore, a lot of hopes are being placed on the future of fuel cells to replace today's batteries. However fuel cells are composed of separator (made from metals such as Fe), electrolytes (made of polymeric materials), electrodes (carbon), catalysts (metals such as Co, Ni). Leaching of Co, Ni, and other catalytic heavy metals from waste fuel cells poses possible environmental risk during dumping. This study will be very useful in us for making decisions on the type of fuel cells which should be used in the engineering of environmentally friendly batteries. The individual Co and Ni toxicity to the Daphnia magna (D. magna) and green alga Pseudokirchneriella subcapitata (P. subcapitata) were investigated. Acute 48h immobilization assays with juvenile D. magna (<24h old) were performed according to the OECD ecotoxicity test guideline 202. Acute 72 h growth inhibition assays with P. subcapitata were performed according to the OECD ecotoxicity test guideline 201. NiCoFe/C fuel cell catalyst was assessed for their leaching properties based on the Japanese Leaching test 13 (JLT13). The ecotoxic properties of the leachate obtained by leaching method was determined by the use of the freshwater crustacean D. magna. Toxicity of Co and Ni leached from the real fuel cells were also observed with D. magna and P. subcapitata. Our result indicates that the tested fuel cell catalyst was of the toxicity evel equal to that of D. magna used in our assay.

**WE 157**

**Assessment of some environmental pollutants in Beni-Sueif Governorate, Egypt**

K Abdou, KI Ibrahem, MS Housein
Faculty of Veterinary Medicine, BENI SUEF, Egypt

Concentrations of cadmium (Cd), lead (Pb), iron (Fe), manganese (Mn), zinc (Zn) and copper (Cu ) were measured in water, Ceratophillyum demersum (C. demersum) aquatic plant, and the muscle, gill, liver, blood and kidney of Claries lazera fish (C. lazera) collected from nine sampling stations (districts), Beni Suef, Elfashn, Beba, Somosta, Ehnasia, Elwasta and Naser, along El Ebrahimia canal and two districts located at the east bank of the Nile (Bayed El-Arab and Sanor) in the province of Beni Suef, Egypt during 2009-2010 using Solar Atomic Absorption spectrometer M6.The results reveal that the studied metals were detected in all the examined samples. In water, Pb had the highest concentration among the metals detected in Elfashn, Beba, Naser, Elwasta, Somosta, Bayed El-Arab and Sanor; Mn presented the highest concentration in Ehnasia, while Fe had the highest concentration in Beni Suef. The concentrations of Pb, Fe, and Mn were above the maximum permitted limits in all the districts. Cd concentration was above the permitted limit, except in Somosta and Naser, while Zn and Cu concentrations were below the permitted limits in the nine districts. The metal levels in water were compared with national and international water quality guidelines, and with the literature values reported for rivers and streams. Comparisons were made of the metal concentrations in water and aquatic plants with those in the catfish tissues obtained from water. The metal concentrations found in the C. demersum aquatic plant samples taken in the nine studied districts were distributed in this order; Mn > Zn > Cu >Pb >Fe > Cd. and were higher than the water. In fish, metals accumulated in the various examined tissues at several levels, but the metal concentrations in muscles (edible part) were below the metal levels in the other organs (nonedible) in the fish samples. The concentrations of Cd, Pb and Fe in fish tissues were above the international standard, while the concentrations of Mn, Zn and Cu were below this standard. The high concentrations of these metals in water, aquatic plants and fish in El Ebrahimia canal may be the result of both anthropogenic activities producing industrial, agricultural and domestic waste and accidental pollution incidents.

**WE 158**

**Bioavailability of trace metals in contaminated soils (Northern Portugal)**

PJC Favas
University of Trás-os-Montes e Alto Douro, VILA REAL, Portugal

A chemical sequential extraction of heavy metals (Fe, Mn, Cu, Zn, Pb, Cd, Sn, W, Bi, Ni, Cr, Mo, Co) and As in tailings and soils samples around a five W/Sn mines (Northern Portugal) was realized using a 7-steps fractionation procedure: (1) water-soluble; (2) exchangeable; (3) bound to Fe oxyhydroxides (easily reducible); (4) bound to Fe oxides (moderately reducible); (5) bound to organic matter and secondary Cu-sulfides; (6) bound to primary sulfides; (7) residual. The extracted element contents were measured by ICP-MS. Samples were also analysed for pH, electrical conductivity and organic matter.
The results allowed us to notice that: 1) The pH was the main factor for controlling the geochemical distribution of the studied elements. The tailing and soil samples were very acid, with an average pH of approximately 4.37. Some metal cations (Mn, Cd, Cu, Zn, Pb, Co, Cr, Ni) behave in a similar way, revealed important enrichments in the most bioavailable fractions (water-soluble and exchangeable fractions). In contrast, oxyanions as Mo and As show low mobility through adsorption to Fe(III) oxyhydroxides dissolved in the two reducible fractions. These results reflect the pH dependent adsorption on the clay minerals, Fe and Mn oxyhydroxides and the co-precipitation with these secondary minerals; 2) Residual fraction was the most important fraction for Sn, Mn, Cr and Zn. These results suggest that in these soils these elements are in a detrital, non available form; 3) Scavenging of mobilized elements (mainly Fe, Mn, Cu, Zn, Cd, Pb, W, Bi, Mo, Cr, Ni, Co and As) in secondary mineral phases and sulfides could be considered a temporary mechanism of metal retention. These metal fractions are susceptible of being set free depending on some changes of environmental conditions.

**WE 159**

**Monitoring data for trace elements in soil and their use in risk assessment: the GEMAS project**

K Oorts[1], K Delbeke[2], C Reimann[3], I Schoeters[4]
[1]ARCHE, GENT, Belgium
[2]European Copper Institute, BRUSSELS, Belgium
[3]Geological Survey of Norway, TRONDHEIM, Norway
[4]Rio Tinto, LONDON, United Kingdom

A sound risk assessment for trace elements in soil must preferentially take into account the variation in natural background concentration and the differences in bioavailability across soil types. Data availability for both aspects differs largely across different countries or regions, hampering a consistent approach on a large (e.g. continental) scale. The European REACH Regulation specifies that industry must prove that it can produce and use its substances safely and risks, due to the exposure to a substance during production and use at the local, regional and European scale, all need to be reliably assessed. The GEMAS (geochemical mapping of agricultural and grazing land soil) project provides good quality and comparable exposure data of metals in agricultural and grazing land soil; in addition soil properties known to influence the bioavailability and toxicity of metals (and other elements) were determined in soil at the European scale. The GEMAS project was carried out by the EuroGeoSurveys (EGS) Geochemistry Expert Group in cooperation with Eurometaux and the aim of this project was to produce harmonised data with respect to the spatial scale (sampling density), analytical methodology and land-use (comparable level of diffuse emissions). These data provide a strong basis for taking into account the spatial variability of both exposure (metal concentrations) and effect concentrations (considering bioavailability through variation in soil properties) in a risk assessment for metals in soils. The results of the GEMAS project further allow a harmonized country"ðspecific regional risk characterization and correction for the correlation between exposure and effect concentrations in the development of a generic risk assessment. The use of GEMAS data in a local and regional risk assessment of metals in soil will be discussed based on a case study for Cu.

**WE 160**

**Metals dynamic from ferti-irrigation in soils in the northwest region of the São Paulo state, Brazil**

FMS Ferrarese, C Bisinoti, B Moreira
UNiversidade Estadual Paulista "Júlio de Mesquita Filho"/IBILCE, SÃO JOSÉ DO RIO PRETO, Brazil

Brazil is the world leader in the sugarcane production, where the São Paulo state is responsible by 60% of the Brazilian production and the northwest area of the state contributes with 18% of this amount. For alcohol production from sugarcane two types of wastewater are generated, one of the alcohol distillation (vinasse) and another of the industry machines cleaning, from sugarcane washing, floor washing, among others. All these residues are employed for ferti-irrigation, being this practice accomplished following technical norm P4.231 of the São Paulo State Environmental Control Agency, which establishes guidelines for the wastewater soil application. Northwest area of São Paulo state possesses two aquifers (Bauru and Guarani) employed main by water supply. In this region there are 15 sugarcane agro industries, with an area of approximately 400.000 hectare with sugarcane plantation. This study conducts a study of the metal dynamics for the several environmental compartments of the northwest area from São Paulo state. During one hydrological year water samples (underground, surface and sugarcane agro industry wastewater) and soils (with and without vinasse application) were collected, preserved and conditioned following to standard methods recommendations. Total metal (Cd, Cr, Zn and Cu) in all these samples were quantified employing a Graphite Furnace Atomic Absorption Spectrometer (GFAAS, Varian Z-280) or a Flame Atomic Absorption Spectrometer (FAAS, Varian FS240). Values found of Cd, Cu, Cr, and Zn in the surface water samples were <0.05, 3.8, 2.6 and 4.4 ug/L, respectively. For underground water the values obtained were <0.05, 3.6, 5.4 and 2.7 ug/L, respectively for Cd, Cu, Cr and Zn. Wastewater from sugarcane agro industry presents high values of metal concentration (Cd, Cu, Cr, and Zn of the 0.1, 35, 27 and 115 mg/L, respectively). According to the technical norm 86.486 L are applied for each soil hectare. Then 0.001, 0.3, 0.3 and 1.1 mg/$m^2$ of the Cd; Cu; Cr and Zn, respectively, are disposals during the sugarcane harvest season. Adsorption capacity of the soil of the region is 2.5 mg/g and 1.2 mg/g for Cd and Cr, respectively. It can be concluded that ferti-irrigation contributes as a metal sources for several environmental compartments. Finally, we waited to create a vulnerability index for the soils, as well as to infer on which environmental compartments will be more susceptible to the contamination. Acknowledgments: FAPESP and CAPES.

**WE 161**

**Assessing the relationship between elimination and detoxification in fish and shellfish exposed to cadmium, copper, and zinc**

J Yun Ru[1], WY Wei-Yu[1], S Sher[2], CM Chung-Min[1]
[1]National Taiwan University, TAIPEI, Taiwan
[2]National Taiwan Normal University, TAIPEI, Taiwan

The purpose of this study was to estimate physiological traits related to Cd, Cu, and Zn bioaccumulation, compartmentalization, and susceptibility in fish and shellfish based on recent publish data. The subcellular partitioning was incorporated into metal influx threshold hypothesis to estimate the detoxification rate constant that is based on exposure concentration and elimination rate constant. Then elimination-detoxification relationships were constructed to predict the detoxification capacity by known elimination rate constants. Our results show negative relationship between elimination rate constant and % metal in metabolically detoxification pool for all aquatic species exposure to metals. Interestingly, a species-specific difference in relationship of detoxification rate constant and % metal in metabolically detoxification pool was found indicating a positive correlation for fish, and a negative correlation for shellfish. We found fish had higher bioaccumulation in metabolically active pool (MAP) when exposed to essential metals of Cu and Zn (~ 60 - 90 %), whereas ranged between 10 - 50 % accumulation for non-essential metal of Cd. A species-specific difference was also found in relationship between elimination rate constant and detoxification rate constant, indicating fish had negative relationship and shellfish had positive relationship. The combination of the biokinetics of metal accumulation with an understanding of the relationship between elimination and detoxified capacities can be applied for environmental risk assessment in the future study.

**WE 162**

**Applications of non-biting midge larvae (Chironomus riparius) for sediment toxicity testing - a critical assessment**

Z Rabova[1], K Hilscherová[1], R Kizek[2], J Kuta[1], K Brabec[1], R Triebskorn[3], L Bláha[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Mendel University, Faculty of Agronomy, BRNO, Czech Republic
[3]University of Tübingen, Faculty of Biology, Animal Physiological Ecology Departm, TUEBINGEN, Germany

The non-biting midge Chironomus riparius larvae are routinely used in subchronic (10-day) and chronic (lifecycle) sediment toxicity assessement tests. The chironomid response to stress caused by environmental contaminants may be affected by other factors like organic matter content, age of larvae or feeding regime. In our studies, we investigated the chironomid responses in 10-day and lifecycle experiments in both artificial sediments and natural sediments collected from several sampling campaigns in the Czech Republic. Further, variability in responses of test organisms originating from three distinct culture lines were evaluated. The chironomids showed high tolerance to contamination in the natural sediments and it was complicated to find a clear correlation patterns between the toxicity results and analytical data of sediment contaminants. Our results of 10-day tests further demonstrate the decrease in chironomid larvae sensitivity to toxicity with their posthatch age. The 2nd instar larvae were at least 100fold more sensitive than their 3rd-4th instar counterparts, and these differences must be carefully considered during experimental design. We also recorded a significant difference in the absolute values of larvae body length (sublethal growth endpoint) among individuals originating from different culture lines. In another experiment with cadmium contaminated artificial sediment, application of chironomids for bioaccumulation and biomarker assessment was demonstrated. Our results contribute to a critical evaluation of the sediment toxicity tests using chironomids. Various sources of variability have been described, and these should be carefully considered in the experimental design.

**WE 163**

**Derivation of sediment effect concentration and site specific evaluation of potential ecotoxicity of metals in Korean freshwater sediment**

JH Lee, CK Kim, TW Lee, KH Park
NeoEnbiz Co., BUCHOEN, South-Korea

This study was implemented with objective of assessing potential ecotoxicity of sediment-associated metals from Korean freshwater using sediment effect concentration (SEC10 and SEC50) showing the chemical concentrations that correspond to a 10% and 50% probability of observing sediment toxicity to Hyalella azteca. A total of 540 sediment samples from rivers in 13 cities and counties were collected in July and November 2007, and analyzed for three metals (As, Cr, Ni) and one conservative element (Li) for normalizing the bulk sediment metal data. The average concentration (range) of As, Cr, Ni and Li are 68.5 (<0.002-2268), 60.1 (2.8-450), 30.7 (<1.9-360), and 20.8 (4.3-56) mg/kg, respectively. There were significant linear relationships between three metals and Li in most of areas, except for some areas located near heavily industrialized areas. The percentage of sediment samples exceeding SEC10 and SEC50 were 22.8% and 6.7% for As, 32.3% and 6.9% for Cr, and 12.5% and 3.8% for Ni, respectively. However, site specific background levels for Cr and Ni in some areas were higher than SEC10. This result indicates that it is necessary for a new SEC to be derived from the site specific background metal concentration in sediment.

**WE 164**

**The effect of increased oxygen conditions on metal bioavailability, uptake and growth of Myriophyllum aquaticum.**

J Teuchies, M De Jonge, E de Deckere, P Meire, R Blust, L Bervoets
Antwerp University, WILRIJK, Belgium

Despite a gradual improvement of the surface water quality of many European waters, historically polluted sediments may still pose an environmental risk. Metals, precipitated with sulphides under anaerobic conditions, can become available when exposed to higher oxygen concentrations. In a 60 day lab experiment, metal availability to the aquatic plant *Myriophylum aquaticum* was compared between a low (40%) and a high (95%) oxygen level treatment. Sediment metal and AVS-SEM concentrations, surface water metal concentrations, plant root and above ground metal concentrations and metal availability with DGT membranes were measured at different depths during five sampling campaigns. A significant decrease in superficial AVS concentrations following surface water aeration was measured. An increase in Pb availability and release to the surface water can be expected. However, no significant higher Pb concentrations in surface water or above ground plant tissues were found in the 95% $O_2$ treatment. An AVS/SEM value higher then 1, even at the end of the experiment and adsorption to Fe- and Mn-hydroxides might be an explanation. *Myriophyllum sp*. are often used in sediment contact tests with growth as end point. Altering bioavailability by oxidation of anaerobic sediments by plant growth or aeration might be a potential risk fot the tests. The slow uptake compared to biosorption and small biomass of the plants makes this species not very suitable for phytoremidiation of contaminated organic rich sediments.

**WE 165**

**Comparing the performance of DGTs and SEM-AVS models of Ni bioavailability in lotic sediments**

DM Costello[1], GA Burton[1], CR Hammerschmidt[2], WK Taulbee[3]
[1]University of Michigan, ANN ARBOR, MI, United States of America
[2]Wright State University, DAYTON, OH, United States of America
[3]Great Lakes Environmental Center, COLUMBUS, OH, United States of America

For heavy metal contaminated sediments, diffusive gradients in thin films (DGTs) have been promoted as potential monitoring tools to measure metal bioavailability and thus predict adverse effects in biota. We conducted two manipulative field experiments using Ni-amended sediment to compared DGTs to the currently used acid volatile sulfide simultaneously extracted metal (AVS-SEM) models of bioavailability in their ability to predict changes in the colonizing benthic macroinvertebrate community. In total, we used 7 sediment types differing in AVS, organic carbon (OC), and Mn and Fe oxide concentration. Each sediment type was amended with Ni (concentrations ranged from control sediments with little Ni to potentially highly toxic Ni concentrations) and placed in baskets within a streamside mesocosm or flush with the stream bottom. Metal flux measured by DGTs correlated well to total Ni concentrations, but was not affected by AVS, OC, or Mn and Fe oxide concentration. The benthic macroinvertebrates responded to the sediment Ni with reduced abundance and diversity at higher Ni concentrations. The SEM-AVS bioavailability models outperformed the DGT-based models in predicting changes in the macroinvertebrate community. Neither the SEM-AVS nor DGT-based models of bioavailability accounted for the protective effects of Fe and Mn oxides, which greatly reduced the bioavailable Ni fraction at later sampling points. These results suggest that for lotic sediments with significant binding capacity (i.e., AVS, OC and Fe and Mn oxides), DGTs may not be the best tool for measuring Ni bioavailability.

**WE 166**

**Uptake and accumulation of sediment-bound heavy metals and effects on gene expression in zebrafish (Danio rerio) embryos**

R Redelstein[1], H Zielke[1], L Erdinger[2], H Zimmer[3], U Feiler[4], D Spira[4], S Wiseman[5], M Hecker[5], JP Giesy[5], TB Seiler[1], H Hollert[1]
[1]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[2]Department of Medical Microbiology and Hygiene, University of Heidelberg, HEIDELBERG, Germany
[3]Department of Internal Medicine I, University Hospital Heidelberg, HEIDELBERG, Germany
[4]German Federal Institute of Hydrology, KOBLENZ, Germany
[5]Toxicology Centre, University of Saskatchewan, SASKATOON, Canada

Predicting the bioavailability and effects of heavy metals in sediments is of major concern within sediment risk assessment. The present study investigated the bioavailability and bioaccumulation of heavy metals from spiked sediments in zebrafish (*Danio rerio*) embryos. In addition, effects on the transcript abundance of metallothioneins (MT1 and MT2) and the transcription factor MTF as molecular biomarkers of metal pollution were investigated. Furthermore, transcript abundances of the genes sod1, hsp70 and hsp90α1 as indicators of cellular stress as well as GST and CYP1A as markers of dioxin like compound exposure were examined.
Firstly, toxicity tests with heavy metal solutions and direct sediment contact tests on spiked sediments were carried out with *Danio rerio* embryos. For further experiments, zebrafish embryos were exposed to a natural and an artificial sediment, both spiked with cadmium, copper, nickel and zinc as single substances and as a mixture at concentrations between 150 and 3000 mg/kg. Following exposure, embryos were UV-acid-digested and metal concentrations were determined by means of ICP-MS. Changes in transcript abundance were investigated by Q-RT-PCR.
In the toxicity tests, the impact of heavy metals from sediments on zebrafish embryos, measured as $LC_{50}$ values, was up to $10^2$ times less compared to aqueous solutions. In the uptake-experiments, Danio rerio eggs accumulated heavy metals from spiked sediments in concentrations up to a few hundred times higher compared to the spiked concentrations. With a BAF of 275 ± 42, copper spiked to artificial sediment was accumulated at significantly greater rates than the other metals. The presence of a mixture of heavy metals reduced the uptake of individual metals. All heavy metals accumulated to a greater extent in embryos exposed to the artificial sediment compared to natural sediment exposure. This is likely due to greater contents of organic matter and bacterial activity which reduce bioavailability of metals spiked to the tested natural sediment. Conforming to this, artificial sediment spiked with zinc and the mixture of metals resulted in significantly greater transcript abundances of both MT1 and MT2 as well as hsp70 in zebrafish embryos compared to the control. MT1 showed up to 30 fold changes. Transcript abundance of hsp90α1 was significantly greater after exposure to the natural sediment spiked with cadmium and copper. Transcript abundances of other genes were not altered significantly.

**WE 167**

**Toxicity of nickel in freshwater sediments: sediment spiking methodology, sensitivity of invertebrate taxa, and influence of sediment characteristics on bioavailability**

JM Besser[1], WG Brumbaugh[1], CG Ingersoll[1], EC Rogevich[2], CE Schlekat[2]
[1]U.S. Geological Survey, COLUMBIA, MISSOURI, United States of America
[2]Nickel Producers Environmental Research Institute, DURHAM, NORTH CAROLINA, United States of America

The toxicity of nickel (Ni) in European freshwater sediments is being evaluated under EU Existing Substances and REACH regulations. We conducted toxicity studies with Ni-spiked sediments to evaluate the variation in the sensitivity of invertebrate taxa to Ni toxicity and variation in Ni bioavailability among sediment types. The studies consisted of three tasks: (1) develop methods for preparing Ni-spiked sediments; (2) characterize toxicity of Ni-spiked sediments to 8 species of benthic invertebrates; and (3) evaluate variation in Ni bioavailability among 8 Ni-spiked sediments.
A three-stage spiking and equilibration process resulted in stable partitioning of Ni between sediment and pore water and avoided high Ni concentrations in overlying water during toxicity tests. Chronic toxicity values for sediment Ni (e.g., 20% effect concentrations or EC20s) varied widely among invertebrate taxa. The most sensitive taxa were two amphipods (*Hyalella* and *Gammarus*) and a mayfly (*Hexagenia*), with lowest EC20s ranging from 221 mg/kg (*Hyalella*) to 572 mg/kg (*Gammarus*). Nickel EC20s for sensitive taxa varied up to 8-fold among the sediments tested. These differences in bioavailability corresponded to Ni distribution coefficients (Kd=sediment Ni/pore-water Ni) and to concentrations of sediment constituents (acid-volatile sulfide or AVS, organic carbon, iron, and manganese). Normalization of Ni concentrations to AVS substantially reduced variation in EC20s among sediments.

These results will be used in an Integrated Sediment Effects Assessment for Ni (see related presentation by Vangheluwe et al.), which will estimate probable no-effect concentrations for a 'reasonable worst case scenario' (i.e., low Ni-binding sediment) and develop bioavailability models based on sediment characteristics.

**WE 168**

**Acid-volatile sulfide and simultaneously extracted metals in sediments: results from an inter-laboratory comparison and recommendations for obtaining reproducible results**

WG Brumbaugh[1], JW Arms[1], EC Rogevich[2]
[1]US Geological Survey, COLUMBIA, United States of America
[2]Nickel Producers Environmental Research Association, DURHAM, NC, United States of America

Acid-volatile sulfide (AVS) can be an important factor in controlling the bioavailability of certain metals in sediments. However, there are concerns that measurements of AVS and the accompanying simultaneously extracted metals (SEM) are irreproducible among different laboratories. In support of a multi-component research program to determine nickel partitioning behavior and toxicity in sediments, we conducted an inter-laboratory comparison of acid-volatile sulfide and simultaneously extracted nickel (SEM_Ni) in spiked sediments. Five independent laboratories participated, but each was provided structured sample preparation and analytical guidelines to perform the measurements. The AVS and SEM_Ni measurements from this inter-laboratory study were in close agreement, indicating that reproducible results are obtainable among different laboratories. Results of the inter-laboratory comparison will be presented and the potential sources of variability will be discussed. In addition, quality control results that span nearly 20 years of SEM-AVS analyses conducted at the USGS Columbia Environmental Research Center will be presented. Finally, we offer specific recommendations for processing samples and for performing the SEM-AVS measurements.

**WE 169**

**Assessment of bioaccumulation of platinum group metals in a river system in close proximity to mining activities in South Africa**

V Somerset[1], C van der Horst[1], B Silwana[1], CR Williams[1], I Iwuoha[2]
[1]Council for Scientific and Industrial Research (CSIR), STELLENBOSCH, South Africa
[2]University of the Western Cape, BELLVILLE, South Africa

The emission of heavy and precious metals from mining, smelters and other industrial activities in the South African environment has been receiving considerable attention, due to the potential threat to human health and the environment. These metals have the potential to accumulate in sediment and biota, posing a serious threat to aquatic ecosystem health. It is further known that some of these elements are toxic to living organisms even at quite low concentrations, whereas others are biologically essential and natural constituents of the aquatic ecosystems and only become toxic at very high concentrations. Studies conducted on the toxicity of platinum group metals (PGMs), its environmental bioavailability and increased concentrations in biologically relevant media have indicated that environmental exposures to PGMs may indeed pose a health risk, especially at sublevel concentrations. The wide application and increasing use of palladium (Pd) in catalytic converters in motor vehicles and in some industrial processes, has seen increasing levels of Pd in the environment. Since Pd is toxic, the monitoring of this metal in surface waters, soil surfaces, plant and particular matter samples has been getting increasingly important. Research has further shown that aquatic macro-invertebrates form an integral part of the diet of freshwater fish and can be considered an important step in the aquatic food chain, playing an important role in the trophic transfer of pollutants, e.g. trace metals. The present study considered the bioaccumulation of trace metals such as cadmium (Cd), lead (Pb) and zinc (Zn), including precious metals such as platinum (Pt), palladium (Pd) and rhodium (Rh) in freshwater invertebrates. Preliminary results have shown that the metal concentrations were considerably higher in the sediment than in the water, whereas the benthic invertebrates showed differences in PGMs concentrations, taxon richness, number density and biodiversity for the different sampling sites evaluated in the Crocodile (West) Marico Water Management Area, North-West Province, South Africa.

**An integrated effects assessment of nickel in freshwater sediments**

LU Vangheluwe[1], I Vercaigne[1], J Besser[2], WG Brumbaugh[2], CG Ingersoll[2], GA Burton[3], E Rogevich[4], C Schlekat[4]
[1]ARCHE, GENT, Belgium
[2]U.S. Geological Survey, COLUMBIA MISSOURI, United States of America
[3]University of Michigan, MICHIGAN, United States of America
[4]Nickel Producers Environmental Research Association, DURHAM, NORTH CAROLINA, United States of America

A multi-component study was conducted to examine the effects of nickel bioavailability and toxicity of sediments in the laboratory and under field conditions. The goals of the study were to: 1) determine Predicted No Effects Concentrations (PNECs) for sediment-associated nickel (PNECsed) and 2) identify relationships between important sediment parameters and the toxicity of nickel to sediment-dwelling organisms. Using laboratory and field data from this testing initiative, an Integrated Sediment Effects Assessment was conducted to evaluate the use of laboratory generated toxicity thresholds (e.g., 5th Percentile Hazard Concentrations (HC5) and PNECs) in the regulatory context (e.g., REACH, Water Framework Directive) and to explore the possibility of incorporating sediment bioavailability models within the EU risk assessment framework. The Integrated Sediment Effects Assessment for nickel explored the following issues: 1) the derivation of a Reasonable Worst Case (RWC) HC5 sediment value of nickel for the freshwater environment; 2) the development of predictive models of bioavailability and toxicity of nickel in freshwater sediments; 3) the derivation of HC5 sediment values of nickel for the freshwater environment for different bioavailability scenarios; and, 4) the robustness of the HC5 estimate with regards to uncertainty in the sediment compartment. Laboratory toxicity data were obtained for 8 species of freshwater benthic invertebrates tested in 8 sediments with widely different Ni binding affinities. Field data were obtained for 5 of these sediments. Significant relationships between sediment parameters (namely AVS and related sediment phases such as iron and organic carbon) were observed with both laboratory and field endpoints. The relevance of this assessment to EU regulatory initiatives is discussed.

**WE 171**

**Multi-generation exposure of the midge Chironomus riparius to three model toxicants**

M Marinkovic, K de Bruijn, M Asselman, MJ Jonker, MHS Kraak, W Admiraal
University of Amsterdam, AMSTERDAM, The Netherlands

In polluted ecosystems some species disappear, while others are able to maintain viable populations. Chironomids are particularly successful in persisting in extremely polluted environments, but the mechanism allowing them to survive in such hostile environments remains still unclear. The aim of the present study was therefore to investigate how *Chironomus riparius* copes with prolonged exposure to pollution, i.e. by phenotypic plasticity or genetic adaptation. To this purpose a multi-generation experiment was performed where *C. riparius* populations were exposed for nine consecutive generations to sublethal concentrations of three model toxicants, i.e. the essential metal copper, the non-essential metal cadmium and the organometal tributyltin. For each compound two exposure scenarios were designed, one where the concentration remained constant and one where after the 6th generation the exposure concentration was drastically increased for three more generations. Total emergence and delay in emergence were monitored during each generation for all populations. To assess if adaptation had taken place, 14-day toxicity tests were conducted with the corresponding toxicant after the 6th and 9th generation. We observed that all exposed populations were equally affected by the toxicants and that even when the exposure concentrations were increased after the 6th generation, the populations persisted. No signs of increased tolerance were found for any of the exposed populations in the 14-day toxicity tests. Therefore, we conclude that *C. riparius* has the ability to withstand strong selection pressure of different toxicants without immediate extinction or adaptation due its phenotypic plasticity.

**WE 172**

**Can we expect genetic adaptation to metals at conventionally derived HC5 values?**

IM de Coninck, M Messiaen, CR Janssen, KAC de Schamphelaere
Ghent University, GENT, Belgium

Under sufficiently strong selective pressures natural populations can genetically adapt and evolve an enhanced stress tolerance. The evolution of tolerance to chemical stress may have important implications for current practices in ecological risk assessment considering, for instance, possible costs of tolerance or co-tolerance with respect to other stressors. We reviewed the relevant literature and constructed a database on genetic adaptation to Cd, Zn, Cu and Pb to invertebrates. Here, we will evaluate at which concentrations genetic adaptation to Cd has been detected in freshwater invertebrates. Studies on (i) genetic adaptation in natural populations in the field and (ii) selection experiments under laboratory circumstances were considered. To distinguish between acclimation and genetic adaptation, only studies in which exposures to Cd were performed with F1 populations, i.e. progeny from from parental populations which had been reared in clean conditions, were considered. Surprisingly, only few such data were available for Cd. Concentrations at which genetic adaptation was reported, were normalized to a water hardness of 50 mg-$L^{-1}$ and evaluated against conventionally derived effect values typically used in risk assessments, such as the HC5. For this study, a median HC5 value of 0.43 µg-$L^{-1}$ was calculated, using quality 1 and 2 NOEC values reported in the European Union final risk assessment report on Cd and CdO. Genetic adaptation in field populations of the dipterian *Chironomus riparius* was reported in a concentration range of 6.69 µg-$L^{-1}$ to 27.08 µg-$L^{-1}$, well above the HC5 value. Adaptation in evolution experiments under laboratory circumstances was detected for the dipterians *Chironomus plumosus* and *Culicoides furens* at 100 and 350 µg-$L^{-1}$, respectively. Different strains of the gastropod *Biomphalaria glabrata* evolved an increased Cd tolerance in the concentration range of 2.58 µg-$L^{-1}$ to 10.33 µg-$L^{-1}$. Finally, genetic adaptation in *Daphnia magna* populations was observed in the range of 6.68 µg-$L^{-1}$ to 24.6 µg-$L^{-1}$. In addition, a potential for genetic adaptation was predicted at 1.40 µg-$L^{-1}$ in 6 out of 11 natural populations of *D. magna*.
It is concluded that, until now, genetic adaptation has only been detected or predicted at concentrations at least 3 times higher than the derived HC5 value.

**WE 173**

**Sensitivity to cadmium of Carcinus maenas populations from two NW Portuguese estuaries with different levels of contamination**

SR Mesquita[1], S Fikirdesici[2], L Guilhermino[1], L Guimarães[1]
[1]Interdisciplinary Centre of Marine and Environmental Research, PORTO, Portugal
[2]Faculty of Science, Ankara University, Dept. Biology, ANKARA, Turkey

Aquatic invertebrate populations from chronically contaminated sites may adapt to pollutant-induced toxicity. Carcinus maenas is an ecologically important invertebrate of European estuarine and coastal systems, and a common inhabitant of the estuaries of rivers Lima and Minho (NW Portugal). The Lima estuary has a history of chemical inputs from untreated effluents of urban and industrial origin, including a paper mill, a harbour, and a shipyard, and is contaminated by metals including Cd, among other substances. The Minho estuary is low contaminated and has been used as a reference estuary in previous ecotoxicological studies. The sensitivity to Cd of these two crab populations was investigated by performing laboratory bioassays based on biomarkers involved in key physiological functions. Crabs were captured in the studied estuaries and transported to the laboratory where they underwent a 7-day acclimation period [salinity 15 ppm, temperature 16ºC, photoperiod 14:10 (L:D)]. Crabs from both populations were then individually exposed for seven days to Cd concentrations ranging from 1.31 to 2000µg/L. At the end of the assays, biomarkers linked to moulting [epidermis and hepatopancreas chitobiase activity (NAGase)], neuromuscular function [muscle cholinesterase activity (ChE)], energy metabolism [muscle lactate dehydrogenase (LDH), and NADP+-dependent isocitrate dehydrogenase (IDH) activities], oxidative stress [hepatopancreas activities of glutathione S-transferases ( GST), glutathione peroxidase (GPx) and glutathione reductase (GR), and the levels of total glutathione (TG)], and oxidative damage [lipid peroxidation (LPO), levels in the hepatopancreas] were determined. Altered biomarker responses were found following exposure to Cd, especially in crabs from the reference estuary. In particular, epidermal and hepatopancreas NAGase activity was significantly inhibited in exposed crabs from the Minho estuary, compared to controls, but not in those from Lima. The results suggest that crabs from Minho estuary are more vulnerable to Cd-induced moulting impairments than those from the Lima estuary. Moreover, the crab population from the Lima estuary appears to be less sensitive to Cd than the reference population, probably due to an adaptation induced by chronic exposure to metal contamination.

**WE 174**

**Multi-generational exposure of Folsomia candida to Cadmium: effects on survival, reproduction and growth**

CMS Pereira, SIL Gomes, SC Novais, AMVM Soares, MJB Amorim
CESAM &Dpt Biology, AVEIRO, Portugal

Environmental contamination can be of short duration but can also be historical or due to long term scenarios. Therefore, there has been growing concern about multigenerational exposure effects on organisms but, few studies are currently available on multi-generation experiments with soil invertebrates. In the present study, the effects of cadmium multigenerational exposure were studied in Folsomia candida. Cadmium was selected due to being a common contaminant worldwide due to human industrial activities. Organisms were exposed consecutively to two concentrations of Cd (EC50 and lower) spiked LUFA 2.2 soil, along ten generations so far. The

Collembolan test ISO guideline with adaptations was followed. Survival, reproduction and size were assessed. Results showed an increase in the number of juveniles and adults along generations, as well as size, but no major change in the EC50. At F6 generation the reproduction EC50 increased from 60mg Cd2+/kg to 82mg Cd2+/kg for the organisms consecutively exposed to 60mg Cd2+/Kg. The expression level of the metallothionein codifying gene is being analyzed using quantitative real time PCR to investigate possible explanations for the increase in organisms' performance.

**WE 175**

**Mercury, SETAC, and Global Change: Implications for the 2013 International Mercury Treatise**

S Bank[1], M Mozur[2], B Vigon[2]
[1]Harvard University, School of Public Health, BOSTON, United States of America
[2]Society of Environmental Toxicology and Chemistry (SETAC), PENSACOLA, FL, United States of America

Mercury deposition and contamination is widespread and well-documented and continues to be a public-health issue of concern for certain sectors of the global human population. In early 2013 the United Nations Environment Programme's (UNEP) internationally binding treaty on the control of mercury will be signed. Documentation of the pervasiveness of this contaminant is a first step toward understanding the potential environmental health and ecological implications of mercury pollution and will be critical to the success of the UNEP program. Identifying broad scale distribution patterns of mercury bioaccumulation can convey to regulators that certain ecosystems may be degraded and require development of policies and regulations that may reduce mercury emissions, and ultimately, improve air and water quality. A more synthesized, holistic, perspective on the mechanisms related to aquatic and terrestrial biogeochemistry linkages of fate, transport, and bioavailability of mercury in aquatic ecosystems will result from long term, multi-ecosystem monitoring programs coupled with process-oriented research questions. Here we identify UNEP partnership goals, key topics, and highlight recent and relevant scientific and mercury policy advances in the field. Additionally, we outline the necessary steps for advancing and developing SETAC's contributions to the partnership and discuss methods for identifying clear and measureable objectives.

**WE 176**

**Temporal increase in organic mercury in an endangered pelagic seabird assessed via century-old museum specimens**

E Vo[1], MS Bank[2], JP Shine[2], SV Edwards[3]
[1]University of California, Berkeley, BERKELEY, United States of America
[2]Harvard School of Public Health, BOSTON, United States of America
[3]Harvard University, CAMBRIDGE, United States of America

Methylmercury cycling in the Pacific Ocean has garnered significant attention in recent years, especially with regard to rising mercury emissions from Asia. Uncertainty exists over the extent to which mercury in biota may have resulted from increases in anthropogenic emissions over time. To address this, we assessed historical and recent mercury exposure in an endangered seabird, the Black-footed Albatross (Phoebastria nigripes), using feather samples from museum specimens spanning the past 130 years. We additionally analyzed stable isotopes of nitrogen (δ15N) and carbon (δ13C) to control for confounding factors such as temporal change in trophic structure or diet. A significantly higher proportion of post-1940 samples contained above deleterious threshold levels (~40,000 ng/g) of methylmercury (the bioaccumulated form of mercury) relative to pre-1940 samples, and mean concentrations were significantly higher in post-1990 than in pre-1990 samples. We also found higher levels of (presumably curator-mediated) inorganic mercury in older specimens of albatross as well as two non-pelagic species lacking historical sources of natural exposure, which suggests that future studies on bioaccumulation should employ methylmercury rather than total mercury analyses on all but recently collected museum specimens. Although complementary stable isotope data suggested no historic change in albatross trophic level, there was a significant change in δ13C signature over time. After controlling for confounding factors, time showed a significantly positive association with methylmercury exposure. Changes in methylmercury levels were consistent with historic global and recent regional increases in anthropogenic mercury production, and mercury toxicity may undermine current and future reproductive efforts in the species.

**WE 177**

**Heavy metal concentrations in internal tissues of striped dolphin (Stenella coeruleoalba) stranded on the coast of Murcia Region (SW Mediterranean)**

J García-Fernández[1], P Toledo[2], J Peñalver[3], A Alcaraz[3], AC Miñano[3], E Martínez-López[2]
[1]University of Murcia, MURCIA, Spain
[2]Department of Toxicology, University of Murcia, MURCIA, Spain
[3]Department of Agriculture and Water, Autonomous Community of Murcia Region, MURCIA, Spain

Many studies have been carried out concerning the monitoring of contaminants in cetaceans as an indicator of the pollution degree in marine environments. It is known heavy metals appear highly concentrated in top predators of the trophic networks such as seal, cetacean, tuna, swordfish and shark. In fact, cetaceans present several physiological particularities that cause the accumulation of these pollutants. They have great blubber that covers the whole body and effectively stored lipophilic compounds. In addition, it is necessary to add that these animals have a very low capacity to degrade some pollutants due to the lack of sebaceous and sweat glands, through which toxins are released, or gills to carry out an active exchange between blood and water. This work presents the results of a research about the levels of mercury (Hg), lead (Pb), cadmium (Cd) and arsenic (As) found in the liver, kidney and brain tissues of eleven striped dolphins (Stenella coeruleoalba) stranded on the coast of Murcia Region in 2009. In all tissues, mean concentration of mercury was highest followed by cadmium, lead and arsenic. The major accumulator tissue was the kidney (69.79 ± 34.96 µg g-1 dw (dry weight) Hg; 15.53 ± 7.81 µg g-1 dw Cd; 0.21 ± 0 µg g-1 dw Pb; 3.30 ± 2.65 µg g-1 dw As), except for mercury which reaches the greatest median levels in liver (720.3 ± 573.25 µg g-1 dw Hg; 3.76 ± 2.72 µg g-1 dw Cd; 0.18 ± 0.076 µg g-1 dw Pb; 3.11 ± 1.82 µg g-1 dw As). Moreover, there was a positive correlation between metals in liver, although only was significant in mercury and cadmium concentration (Rho=0.609, p=0.047), suggesting a similar metabolism pathway. On the other hand, a significant positive relationship was found between body length and mercury levels in liver and brain samples (Rho=0.691, p=0.019; Rho=0.857, p=0.014; respectively) and between body length and cadmium in liver (Rho=0.645, p=0.032). Our metal concentrations were similar than those described in tissues of striped dolphins from others Mediterranean areas and higher than those found in remote areas. However, Hg liver levels are considered in the limit of tolerance for mammalian hepatic tissues and Cd and Pb tissue levels are not associated with toxic effects. Thanks to MICIIN for funding (CGL2008-4318/BOS).

**WE 178**

**Fish otoliths as potential chronological biomarkers of environmental aquatic contamination by heavy metals**

AT Correia[1], R Capela[1], DM Silva[1], P Hamer[2], B Nunes[3]
[1]CIIMAR, PORTO, Portugal
[2]Victoria Department Industries, VICTORIA, Australia
[3]CESAM, AVEIRO, Portugal

The European eel, Anguilla anguilla, as a facultative catadromic species, presents a complex life cycle. This species habitat goes from salt to freshwater grounds, including also estuarine brackish areas. It usually crosses several habitats, potentially affected by anthropogenic activities. Human activities, like industry, harbour activity or mineral extraction, or nature itself, through particular geological formations, can contaminate aquatic systems with heavy metals. Additionally, the available studies about the potential use of the chronological properties of otoliths as indicator of aquatic contamination by metals are scarce. In this study we used 180 juveniles (yellow eels) of the European eel (A. anguilla) to test the uptake of three important metals (zinc, cadmium and copper) through the water into the otoliths. Simultaneously the otolith growth during the chronic exposure (28 days) was estimated using a fluorescent otolith dye (tetracycline), important to choose the electron beam diameter (ICPMS-LA) used for otolith metal concentrations assessment. Although our results suggest that the trace metal concentration in otoliths appear to increase from the lower to higher tested concentrations on water, the obtained differences are not statistically significant. Furthermore there were no significant relationship between the otolith elemental and water concentrations for all the experiments. Our data indicates that water trace metal concentration has no significant effect on incorporation of Cu, Cd and Zn in otoliths of A. Anguilla. However these preliminary results should be interpreted with caution, since the obtained data were highly variable, and probably much of this variation is related to poor analytical precision at such low concentrations as consequence of a small ablation spot size.

**WE 179**

**Ameliorative effect of Moringa oleifera, activated charcoal and charcoal on lead toxicity in wistar rats**

F Ernest[1], AT Peter[1], NO Ozele[2], TM Ahmed[3], MD Matae[4], IS Sunday[5]
[1]University of Buea, BUEA, Cameroon

[3]Medico-legal Department, CAIRO, Egypt
[4]Nkame Kumar University, ACCRA, Ghana
[5]Amadou Bello University, ZARIA, Nigeria

**Introduction**

Lead poisoning is one of the largest environmental problems. Conventional treatment of lead poisoning has been based on chelating agents which are relatively expensive for poor communities. In this present study, we evaluated the efficacy of Moringa oleifera aqueous leaf extract, activated charcoal and charcoal in treating lead induced toxicity in wister rats.

**Materials and Methods**

The rats were divided into 5 groups of 10 rats. An oral daily dosage of 1000 mg/kg body weight of lead acetate was administered to rats in 4 groups for 7 days. The positive control group received distilled water. After 7 days of lead acetate administration, 10 rats were sacrificed from a lead acetate group and control group. From day 8 to day 21, an oral daily dosage of 1000 mg/ kg body weight of M. oleifera, activated charcoal and charcoal were administered separately to 3 of the lead acetate treated groups while one of the groups was allowed untreated. On day 21, all the remaining rats were sacrificed. During and after the administration period, rats were examined for clinical signs, body weight changes, serum biochemistry, haematological parameters and histopathological lesions.

**Results and Discussion**

Lead acetate significantly decreases body weight, aspartate aminotransferase, alanine aminotransferase, and red blood cells count. Gamma glutamyl aminotransferase, mean corpuscular volume, mean corpuscular haemoglobin and mean corpuscular haemoglobin concentration were increased. Histopathology examination revealed damages in the liver, brain, muscle and kidneys. Activated charcoal and M. oleifera showed ameliorative effects in the haematology, serum biochemistry and histopathological analysis.

**Conclusion**

Our results suggest that M. oleifera aqueous leaf extract and activated charcoal can treat lead induced toxicities.

**Acknowledgment**: The authors thank the Africa Education Initiative Mystic, USA and the National Veterinary Research Institute Vom, Nigeria for funding the project.

## ET15 - New developments in aquatic macrophyte testing, higher tier risk assessment and ecotoxicology

**WE 182**

**Myriophyllum spicatum toxicity test: design and first results of an interlaboratory ring test using a sediment-free test system**

D Maletzki[1], CK Kussatz[1], MR Ratte[2], TR Ratte[3]
[1]Umweltbundesamt, BERLIN, Germany
[2]ToxRat Solutions GmbH, 52477 ALSDORF, Germany
[3]RWTH Aachen, 52074 AACHEN, Germany

Dicotyledonous macrophytes are not yet part of the initial risk assessment of plant protection products in the aquatic environment although they are an important part of the ecosystem. In this context alternative test methods with Myriophyllum sp. are under development.

The Ecotoxicological Laboratory of the German Federal Environment Agency has established a standardised sediment-free test system with the dicotyledonous water milfoil Myriophyllum spicatum using Andrew's medium with 3% sucrose following the ASTM Designation E 1913-04. A sediment-free single-phase system was chosen to get toxic threshold and effect concentrations being independent of the water-sediment-distribution of the test item. The only-water exposure of the testplants reduces time and efforts for analytics and facilitates modelling and interpretation of the results. Also, a direct comparison to results obtained with the monocotyledonous duckweed, Lemna spec. (OECD Guideline 221), is possible.

Twelve laboratories participated in an interlaboratory ring test organized by the German Federal Environment Agency from October 2010 to April 2011. The ring test aimed at 1) investigating

the practicability and reproducibility of the sediment-free test system, 2) identifying the most appropriate endpoints reflecting different modes of action of the test items, and 3) optimising and standardising the test method in order to obtain a sound test system for dicotyledonous macrophytes.
In so doing, three test items were investigated representing different modes of action: 3,5-dichlorophenol (pesticide with narcotic action, reference substance for OECD 201 and OECD 221), 2,4-dichlorophenoxyacetic acid (auxine herbicide, growth inhibitor) and isoproturon (photosynthesis inhibitor). Manifold response variables were measured such as fresh weight, dry weight, shoot length, number of whorls, number and length of lateral branches, number and length of roots. Test duration was 14 days, the plants were grown under sterile conditions, culture medium was replaced after 7 days. The temperature was adjusted to 23 + 2 °C and light intensity to 100-150 µE m-2s-1 under a light-dark cycle of 16:8 h.
To obtain statistically sound results with acceptable statistical power the test design prescribed 10 control replicates and eight treatments with five replicates, each. NOECs and EC50 values including 95% confidence limits were calculated.
First results of the interlaboratory ring test will be presented.

**WE 183**

**Measuring shoot length of submerged aquatic plants using graph analysis**

H Zweers[1], G Polder[2], TCM Brock[1], I Roessink[1], RPA Wijngaarden[1], HLE Hovens[3]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Biometris, Wageningen UR, WAGENINGEN, The Netherlands
[3]Eindhoven University of Technology, EINDHOVEN, The Netherlands

In aquatic risk assessment procedures for herbicides within the context of EU Regulation 1109/2009/EC, tests with rooted submerged macrophytes may be required. The ecotoxicological impact of herbicides in experimental studies can be observed by measuring concentration-response relationships for the endpoint total shoot length of submerged aquatic plants, such as Myriophyllum spicatum L. and Elodea canadensis , as recommended by the HARAP workshop. Using different spieces, concentrations of the target compound and replicates ,in experimental studies, gives a lot of samples. Manual measurement of the shoot lengths takes a lot of time. The traceability of the measurements is not possible because after measurements the samples will be destroyed by analyzing the dry matter content. An ImageJ application has been developed to measure the individual shoot length of the plants taken by a digital picture. After thresholding the picture, the binary image is transferred to a skeleton and the skeleton to a weighted graph using the ImageJ plug-in Analyze-Skeleton. The nodes in the graph are the junction pixels and the edges are the slab pixels. The weight of the edges corresponds with their length. In computer science, the FloydWarshall algorithm is a graph analysis algorithm for finding shortest paths in a weighted graph. A single execution of the algorithm will find the lengths (summed weights) of the shortest paths between all pairs of nodes. The longest length can be considered as a good estimation of the total length of the plant. The warshall algorithm was implemented in the Analyze-Skeleton plug-in and used to measure the length of a large number of plants of both specimens. The lengths measured this way were compared with manual measurements. The R2 was 0.94 for E. canadensis and 0.91 for M. spicatum. From those high R2 values we can conclude that the algorithm works very well. The proposed procedure is a cost-effective approach to study concentration-response relationships of herbicides (and other relevant pesticides) on shoot length growth of submerged rooted macrophytes, as required in the test procedures underlying EU Regulation 1109/2009/EC.

**WE 184**

**Ecotoxicity of herbicide Glyphosate used in tolerant transgenic soybean cultivation in Pampasic Region (Argentina) to aquatic macrophyte and microalgae**

ME Sáenz[1], WD di Marzio[1], JL Alberdi[2]
[1]CONICET/National University of Lujan, LUJAN, Argentina
[2]Ecotoxicology Research Program, Depart. Basic Scien,National University of Luján, LUJAN, Argentina

Increasing use of Glyphosate in Argentina is directly related to the increase of areas cultivated with a Glyphosate tolerant transgenic variety of soybean. That has raised concern about the effects of this herbicide in the local aquatic ecosystems, as is the most used herbicide. Beside the amount of herbicide used, in most cases aerial applications is preferred due to the vast areas to be treated. In these cases the herbicide is spread directly over de aquatic systems witch are inside or near the cultivation areas. The recovery and detection of early effects from the action of this pesticide is fundamental especially on primary producers, due to be an essential trophic level of any ecosystem, because it provides the basic energy for food webs in aquatic systems. The aquatic macrophytes Lemna minor (floating) and Vallisneria spiralis (rooted) as well as four species of green microalgae were used in this assessment. Different endpoints were use (biomass, growth, physiological and anatomic parameters, oxidative stress and lipoperoxidation biomarkers). Gliphosate produced hormesis in Lemna minor and Vallisneria spiralis within its Expected Environmental Concentration (EEC) of 1,7 and 2,88 mg Gly/L. The leaf area of the fronds of Lemna minor was modified as a response to a transfer of resources against the stress caused by the herbicide, also the colony architecture was modified as the stipe was observed more often and permanent. Glyphosate increased and altered de activity of oxidative stress enzyme and lipoperoxidation of both Lemna minor and Vallisneria spiralis in the range of its EEC. A stimulation of photosynthetic rate of green algae species was observed at EEC, resulting changes that would imply effects at algal community level regarding competitiveness. The differences between macrophyte species in aquatic systems on the stimulation of growth produced by the action of low concentrations of herbicide, would alter the ability of them towards competitions mechanisms, being ones more privileged than others. This fact over time could cause a change in species composition of plant communities. The action on reproduction of the different primary producers would also be a factor to consider regarding this competition. The morphological and enzymatic biomarkers related to oxidative stress could be used as indicators of incipient changes in aquatic primary producers provoked by this herbicide widely used in our country.

**'Comet' Assay in seeds of the emergent aquatic plant Bidens laevis L. exposed to the insecticide endosulfan**

DJ Perez[1], ML Menone[2], EL Camadro[3], EA Madrid[4]
[1]Lab. Ecotoxicología- UNMdP, MAR DEL PLATA, Argentina
[2]Lab Ecotoxicología-UNMdP-CONICET, MAR DEL PLATA, Argentina
[3]Lab Genética UNMdP-INTA Balcarce-CONICET, BALCARCE, Argentina
[4]IIB-UNMdP-CONICET, MAR DEL PLATA, Argentina

The increasing release of genotoxic chemicals into the environment is negatively affecting the ecosystems and the health of diverse organisms. Plant bioassays can be an integral part of test batteries used for the detection of genotoxic-carcinogenic environmental contamination of the aquatic environment. In fact, highly sensitive, time- and cost-effective plant models have been developed for the detection of toxic compounds arising from the use of pesticides. Plant response to mutagenic treatments can be considered on different levels of organization: the DNA molecule, the chromosome, and the genome up to the whole organism. In previous studies, we identified the emergent aquatic macrophyte Bidens laevis as a sensitive species able to show increased frequencies of chromosomal aberrations under exposure to endosulfan. However, for detecting genotoxicity at the molecular level, the "comet"assay is widely used. The goals of this work were, in seeds of Bidens laevis: 1) to find a suitable concentration of methyl methanesulfonate (MMS) to be used as positive control for the "comet"assay and 2) to study the potential clastogenic effect of endosulfan. A sample of seeds were exposed to 0; 10; 20; 100; 500 and 1000 mg/L MMS during 48 h (n=8) whereas another sample was exposed to 0; 0,02; 0,5; 5; 10; 50 and 100 ug/L endosulfan (n=10) at room temperature in the darkness; using a negative control and 20 mg/L MMS as positive control. The alkaline technique of the plant "comet"assay was used. At 10 and 20 mg/L MMS, normal germinative power was obtained while higher concentrations caused inhibition of germination and necrosis of the seed. Notwithstanding, a significant increase of the damage index (DI) with respect to the negative control was found at 20 mg/L MMS ($p<0.05$). Radicles from seeds exposed to endosulfan did not differ in their DI from the negative control at any concentration ($p>0.05$), indicating that this insecticide is aneugenic instead of clastogenic in B. laevis as we have previously demonstrated working with roots.

**WE 186**

**Are additional macrophyte tests necessary for a safe risk assessment of auxins and fatty acid synthesis inhibitors?**

J Schott[1], M Langer-Jaesrich[2], K Friede[3], S Mohr[1]
[1]The Federal Environment Agency, BERLIN, Germany
[2]Eberhard Karls Universität Tübingen, TÜBINGEN, Germany
[3]Freie Universität Berlin, BERLIN, Germany

In the current risk assessment the toxicity of herbicides on aquatic macrophytes is based on laboratory tests with the monocot *Lemna* (duckweed species). However, this floating macrophyte is not sensitive to auxins and fatty acid synthesis inhibitors. For that reason, an additional test with the submerged dicot *Myriophyllum* sp. has been proposed, which is known to be sensitive to auxins (Maltby et al. 2010). Furthermore and in contrast to *Myriophyllum* and *Lemna*, grasses like the emerse swamp species *Glyceria maxima* seem to respond negatively to fatty acid synthesis inhibitors.
Microcosm experiments were conducted to further elucidate these differences in sensitivity of the three macrophyte species. 18 microcosms were filled with sand and water, and established with *Landoltia* sp. (duckweed species), *G. maxima* and *M. spicatum*. Three microcosms served as controls. Five microcosms were dosed with five different concentrations of the herbicides fluroxypyr (auxin), clodinafop-propargyl (fatty acid synthesis inhibitor) and isoproturon (photosynthesis inhibitor), respectively. The experiment lasted 10 weeks from the middle of May to July. Besides endpoints such as fresh weight, shoot length, and number of leaves, pictures were taken to document and rate the growth deformities of *M. spicatum*.
It was confirmed, that there are huge differences in the sensitivity of the tested species towards the herbicides with different modes of actions. As expected, *M. spicatum* was most sensitive to fluroxypyr with fresh weight of roots (FWR) being the most sensitive endpoint. *Glyceria maxima* was strongly inhibited by clodinafop-propargyl ($EC_{50}$ total length of leaves, 3 weeks: 48,73 µg*L$^{-1}$, 95% CI 6,00µg*L$^{-1}$ to 395,37 µg*L$^{-1}$), while no negative effects were measured for *M. spicatum* and *Landoltia* sp.. Regarding isoproturon, the EC50 of *M. spicatum* after 8 weeks for FWR was 34, 96 µg*L$^{-1}$ (95% CI 15,14 µg*L$^{-1}$ to 80,72 µg*L$^{-1}$), which is similar to the $EC_{50}$ as reported in the literature for duckweed. However, dry weight of *Landoltia* sp. showed no dose-response relationship, but more sensitive endpoints have yet to be analyzed. Overall, the results support the suggestion of Maltby et al. (2010) to introduce additional macrophyte tests.

**Benthic macroinvertebrate community responses to metal leaching and ultraviolet radiation in high altitude Andean streams**

RA Loayza-Muro[1], R Elías-Letts[2], JK Marticorena-Ruíz[2], EJ Palomino[3], MHS Kraak[1], W Wim[1]
[1]University of Amsterdam, AMSTERDAM, The Netherlands
[2]Universidad Peruana Cayetano Heredia, LIMA, Peru
[3]Universidad de Ancash 'Santiago Antúnez de Mayolo', HUARAZ, Peru

High altitude Andean streams drain metal-rich bedrock and are subjected to particularly high ultraviolet-B (UV-B) radiation. The combination of these factors may create highly selective conditions that challenge the survival and persistence of biota. The aim of the present study was therefore to evaluate the effect of environmental drivers on benthic macroinvertebrate community composition in Andean streams in Peru. At the high altitude sites (4000 meters above sea level, m a.s.l.), UV-B radiation was more than two-fold higher than at lower sites (3000 m a.s.l.). At leaching sites metal concentrations in the water were up to 590 fold higher than at reference sites, with Cumulative Criterion Units predicting altered community composition. Principal Component Analysis of physical and chemical variables showed that the reference sites were influenced mostly by UV-B radiation and the polluted sites by metals. Canonical Correspondence Analysis indicated a strong influence of UV-B in structuring communities at reference sites, and of metals at polluted sites. Under the most extreme metal and UV-B conditions only mites and chironomids persisted, while under less extreme conditions a replacement of sensitive taxa by tolerant ones sustained a high faunal diversity. It is concluded that igneous rock leaching high up in the Andes together with the high UV-B radiation regime modulate benthic macroinvertebrate community composition.

**WE 190**

**Age and toxicant exposure modify the energy budget in Daphnia schodleri (Anomopoda: Daphniidae)**

F Martinez-Jeronimo, MA Arzate-Cardenas, R Ortiz-Butron
National School of Biological Sciences, I. P. N., MEXICO CITY, Mexico

Daphnia schodleri is a cladoceran which belongs to D. pulicaria complex and its wide distribution includes Mexico. This is an important organism because its ecology and possible use as experimental model due to its relatively large size. Recent studies have been focused on searching and linking biomarkers, such as enzymatic pathways, with high ecological relevance organization levels. Nevertheless, some of them do not offer a general overview of toxic effects, as it has been referred to the organisms´ energy content, which could be modified during toxicants exposure and promote changes in their fitness and decreasing its reproductive performance, besides energy reserves could be consumed in order to deal with the energetic requirements for detoxification. With the aim of assess how age specific requirements are modified by a toxicant, seven age groups (0, 3, 5, 7, 14, 21 and 28 d) were exposed during 24 h to sublethal concentrations of hexavalent chromium in two experimental designs: a) 6.4 and 32 μg $L^{-1}$; and b) two fractions (1/5 and 1/25) of previously determined $LC_{50}$ for every age group. After exposure, three energy reserve macromolecules were quantified (proteins, carbohydrates and lipids), and obtained results transformed into energetic equivalents using their respective energy of combustion (mcal daphnid-1). Results in the first experimental design showed that organisms younger than 7 days consumed higher amounts of their energy budget than older. In the second design, several changes were recorded in all age groups, with higher differences in organisms at both extremes of their life cycle. Although Cr (VI) concentrations for 7-14 day old daphnids were higher than for the rest, their caloric content did not decrease at the same level than other ages. Whereas enhanced tolerance to chromium was observed in the middle age organisms, according to their higher $LC_{50}$ values, major energetic requirements were found in organisms at both sides of this cladoceran life cycle, which mean higher susceptibility to toxicant exposure. If stress conditions persist, their normal growth rate and reproductive behavior could be modified. Thereafter, their population structure in contaminated environments may be altered.

**WE 191**

**Anthropogenic organic contaminants in water, sediments and benthic organisms in the mangrove-fringed Segara Anakan Lagoon, Java, Indonesia**

L Dsikowitzky[1], I Nordhaus[1], P Khrycheva[2], Y Sivatharshan[2], E Yuwono[3], T Jennerjahn[1], J Schwarzbauer[4]
[1]Leibniz Centre for Tropical Marine Ecology, BREMEN, Germany
[2]University of Bremen, BREMEN, Germany
[3]Universitas Jenderal Soedirman, PURWOKERTO, Indonesia
[4]RWTH Aachen University, AACHEN, Germany

Segara Anakan in Central Java, Indonesia, is a mangrove-fringed coastal lagoon with a high diversity of macrobenthic invertebrates. The ecosystem provides vital services to the local population whilst simultaneously it is increasingly affected by anthropogenic activities. Organic pollution of the lagoon is expected to originate from municipal sewage, shipping traffic and from Indonesia's largest oil refinery, releasing effluents into the lagoon.
In order to characterize chemical contamination, water, sediments, mangrove invertebrates and fish were sampled at 5 stations of varying distance to the oil refinery, including peanut worms (Phascolosoma arcuatum), clams (Polymesoda erosa), oysters (Crassostrea sp.), snails (Telescopium telescopium), crabs (Neoepisesarma versicolor) and mullets (Mugil cephalus). Non-target GC/MS screening analysis was performed on concentrated extracts of all samples.
Most of the 51 identified contaminants in both abiotic and biotic samples belonged to the class of polycyclic aromatic hydrocarbons (PAHs). The characteristics of the PAH assemblages pointed to emissions from the oil refinery or oil spills as the main source of contamination. PAHs mainly consisted of alkylated PAHs which are more abundant in crude oil and more persistent in the environment than the better-known parent PAHs. Highest total PAH concentrations were 42 μg/l in water and 122 mg/kg dry weight in sediment. Apart from petrochemicals, other contaminants e.g. from municipal sewage or agriculture had a patchy distribution and were detected in only a few samples, which presumably is caused by the lagoon's hydrodynamics or by low input levels. Organic contaminants were detected in all tissue samples. Different benthic species from the same stations stored different numbers of contaminants depending on their microhabitat and their feeding mode. The number of contaminants in T. telescopium decreased with increasing distance to the oil refinery suggesting that it is a potential sentinel species for sediment pollution. This study clearly showed high contaminant concentrations in the vicinity of the oil refinery and presence of contaminants in all investigated aquatic organisms. The health risk for benthic organisms, fish and humans remains to be determined. In particular, environmental fate and toxicity of alkylated PAHs which did not receive much attention in the past require further investigation.

**WE 192**

**The use of mysids and copepods bioassays to assess the environmental status of a tropical estuary**

J Nilin, AQ Silva, LF Pitombeira, LV Costa-Lotufo, M Bergo Davanso
Universidade Federal do Ceara, FORTALEZA, Brazil

The dynamics of contaminants in sediments is a complex and poor explored phenomenon, in which the availability to benthic communities is quite difficult to estimate. In this context, toxicity bioassays have been applied worldwide to contribute to the assessment and monitoring of sediment quality, once they provide information on how the living systems respond to the influence of contaminants. In this view, the purpose of this work was to assess the toxicity of sediment collected at Ceará River at northeast of Brazil, using bioassays with the mysid *Mysisdopsis juniae* and the copepod *Nitokra* sp. Two campaigns were conducted (November/10; February/11), and sediments were collected from the exposed estuarine banks, during low tides at three sampling stations in the Ceará River. Mysid tests were carried out in polypropylene vessels (4 replicates/sample), with approximately 200 ml of sediment and 700 ml of filtered seawater 24 hours prior to adding the mysids (n= 5 juveniles ≤ 24h old). The chambers were kept under gentle aeration during ten days, and then the surviving mysids had the length and dry weight measured. Copepod toxicity tests were performed in chambers (4 replicates/sample) prepared 24 hours before exposure of ovigerous females (n=10) with nearly 2 g of homogenized sediment and 5 ml of seawater. The containers were kept without aeration for 10 days. After exposure, a solution of formalin 10 % and the vital dye Rose bengal were added in order to preserve and identify the animals, that were classified in adults and young individuals (copepodits and nauplii), and counted to evaluate the reproduction. It is important emphasize that there are a few sediment bioassays standardized with tropical species and this study will contribute to improve biomonitoring programs in tropical coastal areas.

**WE 193**

**Biomarkers responses in Crassostrea rhizophorae (Bivalvia: Ostreidae) in a tropical estuary collected in the dry and rainy seasons**

J Nilin[1], AQ Silva[1], S Loureiro[2], AMVM Soares[2], LV Costa-Lotufo[1]
[1]Universidade Federal do Ceara, FORTALEZA, Brazil
[2]CESAM,Department of Biology University of Aveiro, AVEIRO, Portugal

Estuaries are very important ecosystems, which present high biological productivity and economical value, associated to intensive human activities that can have a negative impact on the environmental health. In this view the aim of this study was to evaluate the responses of biomarkers in *Crassostrea rhizophorae* collected at Ceará River at northeast of Brazil, during the dry and rainy seasons. The Ceará River Basin is one of the three major water sources of the Metropolitan Region of Fortaleza, Ceará State. As an urban river, it receives domestic and industrial effluents, but the impacts of such discharges were not properly investigated. Oysters were collected at three sites along the estuary in November/10 and February/11, dry and rainy seasons, respectively. Tissues were dissected and frozen until analyzes of acetylcholinesterase, carboxylesterase, glutathione-S-transferase, catalase, lipid peroxidation, energy reserves and condition index. Tropical areas are stressed by constant range of high temperatures throughout all year even during the rainy season. Some studies have shown that this period contribute to increase the toxicity in waterbodies by the leaching of superficial residues, along with domestic and industrial sewages that are drained to the estuary, carrying contaminants and a great organic load.

**WE 194**

**Genotoxic effects of the herbicide Roundup Transorb® and its active ingredient glyphosate on a Neotropical fish species**

BR Martinez, C Moreno, H Sofia
Universidade Estadual de Londrina, LONDRINA, Brazil

In Brazil, glyphosate-based herbicides are the most often utilized and high concentrations of glyphosate have already been detected in water near to intense cultivation areas in southern Brazil. Despite its extensive use, little is known about the genotoxic effects of this herbicide to Neotropical fish species. Roundup Transorb® (RT), an example of an herbicide that uses glyphosate as the active principle, is classified as harmful to the environment and the main differential of this product is its rapid translocation allowed by the surfactant used in this formulation. In this work, genotoxic effects of glyphosate and RT in erythrocytes of *Prochilodus lineatus* were evaluated in vivo tests (6, 24 and 96 h) using the Comet Assay. Juvenile fish were exposed, for 6, 24 and 96 h, to 1 mg.$L^{-1}$ and 5 mg.$L^{-1}$ of glyphosate or RT, or only to clean water (negative control or NC). Fish of the positive control group (PC) were injected with cyclophosphamide (40mg.$kg^{-1}$). After each experimental period blood cells solution were resuspended in agarose (low melting point), placed on slides, submersed on a lyse solution, subjected to electrophoresis, neutralized, fixed in ethanol, stained with GelRed and analyzed under a fluorescence microscope. DNA damage was visually scored by the length of DNA migration in four classes (0: undamaged; 1: minimum damage; 2: medium damage; 3: maximum damage) and each comet assigned a value of 0 to 3 and the total score varied from 0 to 300. The results showed that the score of DNA damage (mean ± SE, n = 6) in the erythrocytes of fish exposed to glyphosate was significantly higher than CN after 6 h (NC: 18.8 ± 4.8, 1 mg.$L^{-1}$: 33.8 ± 6.6 and 5 mg.$L^{-1}$: 43 ± 2.6; PC: 74.6 ± 24.0) and 96 h (NC: 35 ± 2.0, 1 mg.$L^{-1}$: 60.8 ± 7.4 and 5 mg.$L^{-1}$: 65.1 ± 6.0, PC: 79.5 ± 2.1). After 24 h exposure to glyphosate significant difference were not found (NC: 20 ± 4, 1 mg.$L^{-1}$: 33 ± 7 and 5 mg.$L^{-1}$: 27 ± 6; PC: 88.5 ± 1.8). Moreover, the scores of DNA damage found after RT exposure were higher than the NC after 24 h (NC: 26.6 ± 2.0, 1 mg.$L^{-1}$: 59.8 ± 7.4 and 5 mg.$L^{-1}$: 94.1 ± 4.1, PC: 88.5 ± 1.8) and 96 h (NC: 33.6 ± 2.0, 1 mg.$L^{-1}$: 52.1 ± 3.3 and 5 mg.$L^{-1}$: 69.1 ± 7.0; PC: 79.5 ± 2.1). These results show that both glyphosate and the formulate herbicide RT can produce DNA damage on red blood cells of P. lineatus, contradicting the idea that the active principle is less genotoxic than the formulate product.

**WE 195**

**Biochemical and genotoxic effects of natural blooms of cyanobacteria and Microcystis aeruginosa, containing microcystin, on the freshwater fish Prochilodus lineatus**

BR Martinez, C Zambrozi
Universidade Estadual de Londrina, LONDRINA, Brazil

Microcystin is a toxic substance released by cyanobacteria, among which stands out *Microcystis aeruginosa* (MA). In the natural environment, blooms of cyanobacteria (FC) where MA is present alone will rarely happen. Normally, we can find in cyanobacteria blooms different cyanotoxins and substances that together to microcystins may increase or decrease the effects of this toxin on the aquatic organisms. In this study we evaluate whether microcystin-LR (MC-LR), present in lyophilized FC and MA, is able interfere on detoxification enzymes (glutathione S-transferase-GST) and on antioxidant defenses (superoxide dismutase-SOD, catalase-CAT, glutathione peroxidase-GPx and reduced glutathione, GSH) and cause DNA damage. Juveniles of *Prochilodus lineatus* were exposed to solutions containing 1 mg.$L^{-1}$ of lyophilized FC or MA or only water (control) for 24 and 96 h. After exposure, aliquots of water were collected for quantification of MC-LR and the fish were anesthetized for blood sampling, and then killed to remove the gills and liver. Biochemical analyses were run in gills and liver samples and the comet assay (CA) was performed using red blood cells. The analysis of water containing FC and MA showed 0.9 μg.L-1 MC-LR. When compared to controls, fish exposed to FC for 24 h showed a significant increase on liver SOD, and after MA exposure there was an increase on SOD, CAT and GPx in the gills and GST, CAT and GSH in the liver. After 96 h exposure, the exposure to FC lead to an activation of SOD and GPx in gills and GSH in the liver, while after MA exposure, there was an inhibition of GSH in gills and CAT in liver. DNA damage was detected only after 96 h exposure to MA. In summary, these results show that after 96 h exposure to MA there was inhibition of antioxidant defenses leading to oxidative stress and DNA damage of erythrocytes. Thus, it appears that exposure to lyophilized MA was more toxic to the P. lineatus than the exposure to lyophilized FC, although the two materials have the same concentration of MC-LR. This variation is a sign that, in addition to MC-LR, there are other cyanotoxins and/or other substances in lyophilized FC that inhibited the effect of MC-LR on the fish species studied in this work.

## HM03 - Integrated long term monitoring as a tool for the global assessment of POPs

**WE 198**

**Determination and risk of POPs in forest soils of Taurus Mountains**

C Turgut[1], BM Mazmanci[2], LA Atatanir[1], MM Mazmanci[2], SM Mermer[1], MU Usluy[1], HB Henkelmann[3], KS Schramm[3]
[1]Adnan Menderes University, AYDIN, Turkey
[2]Mersin University, MERSIN, Turkey
[3]Helmholtz Zentrum Munchen, MUNCHEN, Germany

Persistent organic pollutants (POPs) are global concern due to their ubiquitous presence and toxicity. These substances can be transported long-range and have been dispersed world-wide. The United Nations Environmental Programme(UNEP) initiated work on the Stockholm Convention on POP's with the intension of reducing and ultimately eliminating these pollutants. Forest and their soils are important sink for POP's in the environment. For example , the study area , Taurus mountains in Turkey, are geographical and meteorological traps for atmospheric pollutants and organic forest soil is an important sink for pollutants deposited on needless and leaves during their lifespan, so the sampling locations for forest soils were selected up to 1881 m height above the sea level and the samples were collected, extracted and analysed. The concentration of polychlorinated dibenzo-p-dioxin(PCDDs), dibenzofuran(PCDFs), caplanar-biphenyls(PCBs), hexachlorocyclohexanes(HCH), dichlorodiphenyltrichloroethanes(DDT) and organochlorine pesticides. The concentration of PCDD in soils were detected slightly lower for in comparison than European studies. The level of PCB was higher than PCDD and PCDF but the TEQ values were similar. The DDT concentration was observed really high because of the heavily agriculture and may effect from neighbour countries.

**WE 199**

**The determination and source of DDT pollution in Turkish soils**

C Turgut[1], TJC Cutright[2], LA Atatanir[1], SM Mermer[1], MU Usluy[1]
[1]Adnan Menderes University, AYDIN, Turkey
[2]The University of Akron, AKRON, United States of America

The concentration and impact of DDT on the environment was expected to decrease after its ban in the mid 1980's. Unfortunately, DDT contamination via its presence as an impurity in dicofol has led to a new source of contamination. This is particularly true especially in cotton production in Soke Plain, Turkey, where difocol-based pesticides are being used. The aim of this research was to investigate the extent and source of DDT contamination in cotton soils.
Soke Plain soil samples were collected from 0-30 cm, 30-60 cm, and 60-90 cm depth and analyzed by GC/MS/MS. o,p'-DDT and p, p'-DDE were detected at 16.2% and 17.6% of the sites in the 0-30 cm depth of soils. In the 20-60 cm, p, p'-DDT (14.9%), o, p'-DDE (8.1%) and p, p'-DDE (2.7 %) were found in soil samples and p, p'-DDT was the most prevalent with 9.5% of the sampling sites.
The dominant source of DDT particularly in the 60-90 cm depth was due to historic use of DDT. The presence of p, p-DDE, o, p-DDE and p,p-DDT in the topsoil was attributed to recent dicofol applications.

**WE 200**

**Chemical assessment of organoclorine pesticides and polychloro biphenyls residues in sediment and pomatoschistus microps tissues from Ria de Aveiro, Portugal**

JR Gadelha[1], JR Rendón von Osten[2], SN Abreu[1], FM Morgado[1], AMVM Soares[1]
[1]University of Aveiro, AVEIRO, Portugal
[2]Centro EPOMEX: Universidad Autónoma de Campeche. Av. Augustin Melgar y Juan de l, CAMPECHE, Mexico

In the European Union (EU) about 3000 different substances are used in human medicine such as analgesics and antiinflammatory drugs, contraceptives, antibiotics, beta-blockers, lipid regulators, neuroactive compounds and many others. Also a large number of pharmaceuticals are used in veterinary medicine, among them antibiotics and anti-inflammatory chemicals. In the last few years, knowledge about the marine and coastal environmental occurrence of pharmaceuticals and other pollutants has increased to a large extent due to new analytical techniques able to determine polar compounds at trace quantities. The assessment of endocrine disrupting activity in complex environmental mixtures requires application of integrative procedures combining chemical analysis and specific bioassays. This approach was focused on health and environmentally relevant compounds and based on the toxicity identification and bioaccumulation evaluation, to find a correlation between organochlorinated compounds and chlorobiophenyls congener concentrations in sediments and fish tissues of Ria de Aveiro The fish species Pomatoschistus microps was chosen because they might possibly be effective pollution indicators. They are very common and live in marine transitional and coastal environments which are continually exposed to garbage dumping, untreated sewage inflow, land and river runoff, atmospheric fallout from heavy traffic and various small-scale industries. In this work we observed the potential of fishes to provide valuable new insights into ecotoxicological effects and to make the functional link between environmental effects and human health level disturbances. Data for bioaccumulation on fishes were obtained in Portuguese coastal ecosystem Results indicated the involvement of this species in the bioaccumulation of a large spectrum of POPs, primary organochlorine contaminants such as PCBs, DDTs, and other pesticides, as well as exposure to metals and metal-containing organics such as methylmercury and organotins, with concentrations varying between 0.131-4.508 µg/g dry weights.

**WE 201**

**Differential accumulation of metals and changes in Cholinesterases and d15N levels in the sea Anemone Anemonia sulcata (Cnidaria) as a function of aquaculture effluent gradient exposition**

JR Gadelha[1], AR Asensio[2], I Gonzales[3], JR Aboal[3], A Carballeira[3], LR Vieira[4], L Guilhermino[4], SN Abreu[1], JR Rendón von Osten[5], FM Morgado[1], AMVM Soares[1]
[1]University of Aveiro, AVEIRO, Portugal

[3]Faculdade de Biologia, Universidade de Santiago de Compostela. Espanha, SANTIAGO DE COMPOSTELA, Spain
[4]University of Porto: CIIMAR & ICBAS - CIIMAR - Centro Interdisciplinar de Inves, PORTO, Spain
[5]Centro EPOMEX: Universidad Autónoma de Campeche. Av. Augustin Melgar y Juan de l, CAMPECHE, Mexico

Aquaculture technically is a process akin to the fermentation process where it has to be seeded and it also produces an effluent discharge, which must be regarded as a potential pollutant. Pollution, destruction of sensitive coastal habitats, threats to aquatic biodiversity and significant socioeconomic costs are the more important aquaculture impacts on environment and can involve health risks. The assessment of aquaculture effluents effects in complex environmental mixtures requires application of integrative procedures combining chemical analysis and specific bioassays. This approach was focused on health and environmentally relevant compounds, and based on the toxicity identification on water and sediments and bioaccumulation Information on aquaculture-related environmental impact was assessed using the stable nitrogen isotopic composition (δ15N) and metal analysis of benthic sessile sea anemone Anemonia sulcata tissues in the exposed areas compared to two unpolluted reference sites. A map of the δ15N values and metal bioaccumulation in organisms was created, which could be used for tracing the dispersion of 15N loading generated by aquaculture and sewage in the receiving environment, and their transfer into biota in the adjacent coastal ecosystem. The use of biomarkers to diagnose the contamination of ecosystems and the exposure of wild populations has several advantages relatively to other approaches. Biomarkers can be related to exposure to or toxic effects of environmental chemicals. Sea anemones known as non-selective suspension feeders, but hosting abundant bacterial populations, may have δ15N values lower than bioaculated metals, but still reflecting the overall enrichment of the environment in 15N due to the presence of enriched effluents from aquaculture discharges. The integration of the relevant results obtained are presented and discussed to address the central question of the work.

**WE 202**

**Talitrid amphipods as biomonitors of PCBs and PBDEs contamination of supralittoral of sandy shores**

A Cincinelli[1], T Martellini[1], G Ungherese[2], A Ugolini[2]
[1]University of Florence, SESTO FIORENTINO-FLORENCE, Italy
[2]Department of Evolutionary Biology, University of Florence, FLORENCE, Italy

Coastal areas are characterized by a great input of environmental contaminants that can reach these zones by land based sources (including wastes from industrial, urban and agriculture activities, aquaculture, tourism), from sea based sources (oil spills, oil exploration and production) as well as atmospheric depositions. The contaminants of main concern include persistent organic pollutants (POPs), oils, fertilizers, heavy metals and pathogens. Talitrid amphipods constitute one of the main animal components (in terms of biomass) of sandy beaches representing, moreover, a key species in the food web of these ecosystems. In the last two decades, many species of sandhoppers and beachfleas have been successfully employed as biomonitor of trace metals contamination. In fact, studies carried out along European sandy shores have shown the ability of one of the most common Mediterranean sandhopper species (*Talitrus saltator*) to accumulate many trace elements (e.g. Hg, Cu, Cd and Zn).
To date, no studies have been reported about POPs contamination of supralittoral of sandy shores and their presence in talitrid amphipods. In this study we analysed supralittoral amphipod *T. saltator* and sand samples collected from different coastal areas of Tuscany (Italy) looking for PBDEs and PCBs in order to verify if this species could represent a suitable biomonitor of POPs contamination of supralittoral of sandy shores. 20 PCBs and 9 PBDEs were identified in both sand and amphipods samples and their concentration in *T. saltator* was, for most part of PCBs and PBDEs congeners, higher than in the sand. Furthermore, results showed significant differences in bioaccumulation between amphipods form different localities. Therefore *T. saltator* could represent a promising biomonitor of PCBs and PBDEs contamination of the supralittoral band of sandy shores.

**WE 203**

**Global Aquatic Passive Sampling (AQUA-GAPS): using passive samplers to monitor POPs in the waters of the world**

R Lohmann[1], D Muir[2]
[1]University of Rhode Island, NARRAGANSETT, United States of America
[2]Environment Canada, BURLINGTON, Canada

We believe there are major benefits in starting global aquatic passive sampling (AQUA-GAPS) and propose the phased development of an AQUA-GAPS network of stations. The program could be started by initiating monitoring with PE samplers at key locations which are accessible and relatively well studied already e.g., the Great Lakes, US East coast, Baltic or North Seas, Mediterranean, and South China Sea. Investigators with access to ship time and buoys would be invited to participate to locate samplers and if capable, to also analyze them. Although analyzing samples at on central lab, as in GAPS would be desirable, we believe multiple labs could be involved so long as there was an interlaboratory quality assurance and training program. The list of POPs to be analyzed would be those readily analyzed by low resolution GC-mass spectrometry and for which analytical standards are readily available (the legacy chlorinated pesticides, lindane, endosulfan, selected PCB congeners, chlorobenzenes, tetra- and penta-BDEs). The program would also encourage deployment of different passive devices for comparison with PE samplers. Some of the Stockholm Convention regional and subregional centres for POPs that are located near deployment sites might want to be involved in their roles of capacity building and technology transfer. We seek volunteer investigators to help conduct the initial monitoring phase including the associated costs for passive sampler deployment and analysis.

**WE 204**

**Persistent organic pollutants and stable isotopes in vegetation from King George Island, Antarctica**

CVZ Cipro[1], GT Yogui[2], S Taniguchi[1], P Bustamante[3], JL Sericano[4], RC Montone[1]
[1]IOUSP, SÃO PAULO, Brazil
[2]Universidade Federal de Pernambuco, RECIFE, Brazil
[3]Université de La Rochelle, LA ROCHELLE, France
[4]Texas A&M University, COLLEGE STATION, United States of America

Vegetation samples from King George Island, Antarctica (62° 05' S, 058° 23' W) were collected in the austral summer of 2004-05. Lichens (*Usnea aurantiaco-atra* and *Usnea antarctica*), mosses (*Sanionia uncinata*, *Syntrichia princeps* and *Brachytecium* sp), and one angiosperm (*Colobanthus quitensis*) species were analyzed for persistent organic pollutants (PCBs, DDTs, HCHs, HCB, PBDEs, mirex, aldrin, dieldrin, endrin and chlordane-related compounds) as well as $\delta^{13}C$ and $\delta^{15}N$ stable isotopes. The following contaminants were found above the method detection limit (MDL): HCB (0.14 to 1.06 ng $g^{-1}$ dry weight), HCHs (< MDL to 1.20 ng $g^{-1}$ dw), DDTs (< MDL to 1.73 ng $g^{-1}$ dw), PCBs (7.76 to 18.6 ng $g^{-1}$ dw) and PBDEs (146 to 811 pg $g^{-1}$ dw). In all cases, levels in mosses were higher than in lichens , suggesting similar biogeochemical processes involved, mainly due to chemical similarity and long range transport characteristics. Carbon stable isotope ratios ($\delta^{13}C$) showed clearly different ranges for lichens (-21.13 to -18.43"ð) and mosses (-25.99 to -21.64). The only angiosperm species investigated exhibited $^{13}C$ signature within the moss range. A large range of $\delta^{15}N$ was found (-7.67 to 20.75"ð) and seemed to be related to nitrogen uptake from different animal-derived sources. Pearson's correlation showed significant results between some historically linked contaminant groups and suggested the influence of the origin of both nitrogen and pollutants, notably taking secondary sources (animal derived nitrogen) in consideration.

**WE 205**

**Specific effects of air contaminants from passive sampling campaign in Africa**

J Novak[1], A Ersekova[1], JP Giesy[2], J Klanova[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Dept. Biomed. Veterin. Sciences and Toxicol. Centre, University of Saskatchewan, SASKATOON, Canada

Polluted air has been associated mainly with lung and hearth diseases until recently. Recent studies indicate that the air pollutants could act also as endocrine disruptors (ED). Evaluation of this type of effects cannot be based only on data form chemical analyses. That shows the importance of incorporation of specific bioassays into evaluation part of the air pollution monitoring programs. The utility of these methods in monitoring of atmospheric pollution levels has been shown previously. In this work, we show usage of passive sampling in evaluation of specific biological effects in vitro. Passive air sampling presents an interesting alternative to relatively expensive active sampling. It allows relatively long-term sample collection even in areas without developed infrastructure. Samples in this study came from localities all over African continent. The localities were chosen to describe background level of pollution as well as some hot spots. The sample extracts were assessed for priority chemical pollutants and specific effects using in vitro bioassays with reporter genes linked with aryl hydrocarbon receptor (AhR) and estrogen receptor, the receptors that are traditionally linked with ED. The results have confirmed that the endocrine disruptive potential of the air samples could be closely related to type of pollution and that endocrine disruptive effects seem to be connected both with particulate and gas fraction of the air. This research was supported by GACR P503/10/P249 and CETOCOEN (CZ.1.05/2.1.00/01.0001).

**Sampling rates when measuring gas phase POPs air concentration with passive air samplers.**

E Alonso, A de la Torre, P Sanz, MA Martinez
CIEMAT, MADRID, Spain

The Stockholm Convention was adopted globally in 2004 for reducing or eliminating the release of Persistent Organic Pollutants (POPs) since the exposure to these chemicals supposes a risk for human and environmental health. As essential part of this Convention is the Global Monitoring Plan which aims to control and evaluate its effectiveness. Air has been selected in this Plan for assessing spatial trends and the regional and global transport of POPs. For this purpose Passive Air Samplers (PASs) with polyurethane foam (PUF) disks as sorbent media has being used. PASs are advantageous against high-volume air samplers (HVSs) because of their low cost, simple construction, and electricity-free operation. However, high uncertainties over PASs sampling rate (R) have been addressed for these devices. Sampling rates are calculated by the quantification of loss of depuration compounds added to the PUF disk prior to deployment. Several calibration studies have calculated these rates for gas phase POPs, reporting a typically value of ~ 3 to5 m3/day. Nevertheless, sampling rates out of this range have been observed. This variation has been mainly attributed to diverse climatic or environmental conditions such as wind speed or temperature. To evaluate the potential influence of temperature on sampling rates, a literature review was performed. A total of 288 site-specific R were collected from scientific studies conducted worldwide and calculated under a wide range of temperatures (from -27 to 36ºC). The study of this database showed that approximately 66% of data were within the range of 3 to 5 m3/day, while the rest of the data (34%) were located outside it. This revealed the need to calculate specific sampling rates when using PASs for monitoring gas phase POPs. Statistical analysis was performed to evaluate correlations in the database. A weak relationship was obtained between temperature and R ($p<0.01$; $r = -0.24$). This result indicates that estimations of sampling rates from temperature are not trustworthy and suggests that other parameters like wind effects should be considered.

**WE 207**

**Monitoring the continental and intercontinental background of persistent organic pollutants in Africa**

G Lammel[1], P Dobrovolný[2], A Dvorska[1], K Chromá[2], R Brázdil[2], K Hošková[1], I Holoubek[1], J Hošek[3]
[1]Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Institute of Geography, Masaryk University, BRNO, Czech Republic
[3]Academy of Sciences of the Czech Republic, PRAGUE, Czech Republic

To facilitate the evaluation of the effectiveness of the Stockholm Convention on Persistent Organic Pollutants (POPs), long-term monitoring of these substances in the environment is required. As Africa is one of the least studied regions and almost no data on POPs exist here, an effective monitoring network has been designed. The results of a pilot passive air sampling programme in January - July 2008 conducted at 26 stations in 15 countries and meteorological and climatological data from the 1961-2007 period were used to apply objective criteria for the selection of a small but sufficient number of stations for the long-term monitoring network.
The character of the sampling sites (urban, industrial, rural, background) was determined by discussing the sampling results and diagnostic ratios of polycyclic aromatic hydrocarbons were checked, too. The stations for the long-term monitoring network were selected from the list of the pilot phase sampling sites according to the following criteria: (i) absence of source influence and adequate geographic distribution, (ii) suitability to address long-range transport (avoidance of unsuitable local meteorological features) and (iii) long-term stability of air flow.
Nine stations remained after applying criteria (i) and (ii): Tunis, Khartoum (Sudan), Tombouctou (Mali), Sheda (Nigeria), Mt. Kenya, Asala (Ethiopia), Lusaka (Zambia), Reduit (Mauritius) and Molopo (SAF). With minor exemptions, the advection during the pilot sampling phase in 2008 was found to be typical for recent climate a these sites.The analysis of air flow patterns indicated a low variability between years, however, on-going changes in air flow were indicated.
The functionality of the monitoring network is not threatened by on-going long-term changes of the advection to the selected stations, as these do affect the coverage of target areas only to a minimal extent. The network does not cover several regions, e.g. the densely populated areas of Southern Cameroon, parts of the Abessinian plateau and most of the Great Lakes area. Also, the outflows of western and south-western Europe were considered important to be covered by the future monitoring network. Therefore, a monitoring station at the Canary Islands was added to the network, which now consists of this additional station and a slightly changed (due to practical reasons) list of the proposed stations. Regular long-term monitoring started in the beginning of 2010.

**WE 208**

**Are the Mt. Qomolangma regions in Himalayas (Nepal) really remote areas for persistent organic pollutant contamination?**

L Guzzella, G Poma, C Roscioli
CNR-IRSA, BRUGHERIO, Italy

The transport and fate of these semi/volatile persistent toxic substances (PTS) in remote areas has received increasing attention during the past decade. PAHs, polybromodiphenyl ethers (PBDEs) and organochlorine compounds (OC, as DDT, hexachlorobenzene - HCB, hexachlorocyclohexanes - HCHs and PCBs) were measured in water and sediment samples from several high altitude mountain lakes and in soil samples collected in 2007 near the same lakes and along the ascent in Sagarmatha National Park, located in Nepal and included in the Himalaya ridge. The study represents the first published research in the Nepal Himalayn region.
Results showed that HCH levels in all the matrices considered were always below detection limits. In water samples, low-level substituted PCBs and PBDEs, along with more volatile PAHs, were the most common contaminants, confirming the hypothesis that lighter compounds were more prone to Long Range Atmospheric Transport (LRAT). Moreover, in sediment and soil samples, the PCB profile was mainly composed of medium-level chlorinated congeners, consistent with the theory of OC accumulation in cold, high altitude regions driven by the process of cold condensation. The overall estimation of anthropogenic organic micropollutant presence in water samples showed a strong positive correlation between concentrations of PCBs and PAHs and the altitude of the considered sites, even if the altitudinal gradient for water samples was very moderate. In contrast, a significant negative correlation was found between PAHs and altitude in soil samples, considering a wider altitudinal gradient. This inverse relation was likely due to nearby local PAH emission sources. In addition, PCB normalised concentration on organic carbon content in soil samples showed a positive significant correlation with altitude, confirming the tendency of less chlorinated congeners to be preferentially transported at higher altitudes in cold regions. The PAH profile for water and soil samples showed the main contribution of pyrogenic PAHs due to emissions of solid combustion (wood, grass, coal), whereas the profile for sediments indicated the main contribution of pyrogenic PAHs from gasoline emissions (e.g., kerosene). Results of the analyses showed that PAH levels measured in Himalayan samples must be considered as low to medium contamination, whereas the regarded Himalayan stations can be considered undisturbed remote areas concerning PCB, PBDE and OC compounds.

**WE 209**

**Long-term trends of POPs in human milk in Czech Republic**

O Mikes[1], P Cupr[1], M Cerná[2]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]National Institute of Public Health (NIPH), PRAGUE, Czech Republic

Human biomonitoring of POPs concentrations in breast milk in Czech Republic is carried out since 1994. More then 4600 breast milk samples were collected from 9 sites in the years 1994 - 2009 (about 80 samples/region/year). The human milk samples are analyzed for a number of chlorinated organic chemicals including polychlorinated biphenyls (PCBs) and selected chlorinated pesticides (OCPs). Exposure factors that may influence these levels were investigated using a questionnaire according to the WHO protocol (age of mothers, BMI - body mass index, medication, occupational exposure and lifestyle habits, above all smoking). The main aim of this study was to evaluate long-term trends of selected POPs in human milk in Czech Republic - as background levels for central Europe (as part of ArcRisk project: http://www.arcrisk.eu/). The data indicates a continuation of a long - term decreasing trend of selected OCPs over 16 years. These dangerous organic substances (neurotoxicity, carcinogenicity and endocrine disrupting effects) are widespread throughout the environment, persisting for decades. They accumulate in the fatty tissue, entering the human body through the food-chain. Human biomonitoring is a useful tool to evaluate internal exposure of humans with different chemical substances. The next aim of this project is to predict of human health risks by using of slope factor and Rfd (reference doses) approach with a spatial GIS visualisation. Relationships between exposure factors from questionnaires will be also investigated.

**WE 210**

**Temporal trends of PBDEs in gannet (Morus bassanus) eggs from two UK colonies**

JD Crosse[1], RF Shore[1], KC Jones[2], MG Pereira[1]
[1]NERC Centre for Ecology and Hydrology, LANCASTER, United Kingdom
[2]Lancaster University, LANCASTER, United Kingdom

Within Europe, varying trends in Polybrominated Diphenyl Ether (PBDE) concentrations have been observed over time across different regions and in different organisms. This variation is likely to be due, at least in part, to differences between species in routes and rates of exposure and metabolism. Although trends in PBDEs in birds have been observed elsewhere in Europe, there is little information for UK birds and no published long term time series of PBDE concentrations in fauna generally for the UK. We determined trends of PBDE concentrations in the eggs of gannets from two UK colonies off the coast of Scotland over a 30 year period (1977 - 2007). A suite of PBDE congeners, including Tri through Octa BDE homologues, was analysed for using a GC-MS in EI mode and employed C13-labelled spikes and internal standards for quality control. Fourteen separate BDE congeners were detected and all eggs throughout the time series contained BDE congeners 35, 47, 49, 99, 100, 153 & 154. BDE47 and other congeners associated with the PentaBDE technical formula dominated the profile.
No significant differences were found between ΣPBDE concentrations at the two colonies (Ailsa Craig and Bass Rock). Trends appeared to be strongly influenced by direct changes in PBDE production and emissions and also coincided with the abatement of sewage disposal at sea. At both colonies, BDEs 47, 49, 99, 100, 153 & 154 exhibited the same temporal pattern as ΣPBDE concentrations, increasing from the late 1970s, peaking in 1994 and from then on declining significantly up until the end of our time series. Levels of BDEs 47, 49 and 100 were significantly higher at Bass Rock than Ailsa Craig as were levels of BDE35 although this congener exhibited a linear decline over time at both colonies.
Throughout the time series, the contribution of the more highly brominated congeners (hexa and hepta homologues) to ΣPBDE concentrations increased relative to that of lower brominated congeners (tri-penta homologues), consistent with the hypothesis that there may be an increasing contribution to ΣPBDEs of higher brominated congeners derived from the debromination of decaBDE.

## HM04 - Sorption and bioavailability of organic chemicals: mechanisms relevant for toxicity and bioremediation

**WE 213**

**Influence of biosurfactants on microbial availability of polycyclic aromatic hydrocarbons sorbed to solid-phase organic matter and black carbon**

E Congiu[1], JR Parsons[2], JJ Ortega-Calvo[1]
[1]Institute for Natural Resources and Agrobiology of Seville, SEVILLE, Spain
[2]Institute for Biodiversity and Ecosystem Dynamics, Universiteit van Amsterdam, AMSTERDAM, The Netherlands

Biodegradation of polycyclic aromatic hydrocarbons (PAHs) in contaminated soils is often limited due to the low bioavailability of these hydrophobic organic compounds. In particular, natural organic matter (NOM) and black carbon (BC) are geochemical soil components responsible for strong PAHs sorption, resulting in a very low bioavailability and long-term persistence of PAHs in the environment. The use of biosurfactants is a promising option for enhancing the bioavailability of soil-sorbed PAHs. It is known that biosurfactants, at levels above their critical micelle concentration (CMC), can promote the dissolution of solid PAHs. However, not much is known about the effects of biosurfactants on solid-water distribution and microbial uptake of PAHs in systems containing solid-phase NOM and BC. In a well-controlled batch system, we studied the sorption behaviour of four different PAHs (pyrene, phenanthrene, fluoranthene and fluorene) with solid-phase NOM and BC and the effect of rhamnolipid biosurfactants on sorption equilibrium. Biosurfactants sorption was also determined. Biodegradation of sorbed PAHs in the absence and presence of biosurfactants was also followed using a representative PAH-degrading soil bacterium (*Mycobacterium gilvum* VM552). Experimental conditions included different sources of NOM and BC and different solid-aqueous phase ratios. The results showed that biosurfactants, especially when they were present at levels above CMC, often promoted desorption and biodegradation of PAHs.

**WE 214**

**Modeling experimental findings on sorption and biodegradation of PAHs**

A Rein[1], KEC Smith[2], UG Karlson[2], P Mayer[2], S Trapp[1]
[1]Technical University of Denmark, KGS. LYNGBY, Denmark
[2]Aarhus University / National Environmental Research Institute, ROSKILDE, Denmark

Polycyclic aromatic hydrocarbons (PAHs) in the environment are to a major degree bound to organic matter or soot particles. It is disputed whether and to which extent the adsorbed fraction of PAH in soil and sediment can be attacked by microbial enzymes, or whether dissolution in aqueous media is required. In that case, the degradation depends critically on the bioavailability, or better the bioaccessibility of PAH for microbes. The increasing non-accessibility of PAH with time ('aging') may explain the formation of a residual fraction, which has been observed in remediation projects.
A unified model for sorption, sequestration and degradation of neutral organic compounds in soils and sediments has been developed and tested (see also Trapp et al. session J01). Adsorption was considered as a two-phase process, with rapid and slow adsorption rates. Calculated or experimental sorption rates and kinetic data for growth and metabolism of PAH-degrading bacteria were obtained as input parameters. The model simulations were compared to existing solutions (such as the Best equation) and to experimental results. With this new model approach, a range of experimental observations available in literature could be simulated, encompassing various soil types and PAHs, and different bacterial strains. Own experiments are currently performed on phenantrene, fluoranthene and other PAHs and on ad/desorption as well as on biodegradation. The results shall be used to calibrate and verify the new model approach. The model was also used to simulate typical scenarios of adsorption (aging) and microbial degradation, in order to identify sensitive parameters and processes. Furthermore, the impact of dissolved organic matter and various types of amendments was studied, which potentially enhance diffusive mass transfer and biodegradation performance. The final goal is to optimize remediation options.

**WE 215**

**Sorption and desorption characteristics of two insecticides (chlordecone and cadusafos) previously used in banana plantations of the French West Indies**

JD Fernandez-Bayo[1], C Saison[1], C Geniez[1], AE Berns[2]
[1]Laboratoire d'étude des Interactions Sol - Agrosystème - Hydrosystème, MONTPELLIER, France
[2]Forschungszentrum Juelich GmbH, Inst Bio- and Geosciences, IBG 3: Agrosphere, JUELICH, Germany

Chlordecone (CLD) is a highly persistent organochlorine pesticide that was used for a wide range of pests around the world, among them, the banana weevil *Cosmopolites sordidus* in plantations of the French West Indies. It was banned in France in 1993. One of the molecules that replaced it was cadusafos, an organophosphate that has since then been removed from the market in the European Union in 2008. Nearly 20 years after its prohibition, CLD is still detected in every compartment of the environment, i.e. in soils, surface and groundwaters and some agricultural products and it is suspected to increase the prevalence of prostate cancers in exposed populations. The physico-chemical characteristics of this molecule along with its high stability due to the numerous chlorinated groups that protect the molecule from degradation, make sorption one of the most important processes that govern the fate of chlordecone in soils. However, the literature in the environmental fate of this molecule is scarce and mainly from the 80's or earlier. The aim of this work is to improve the knowledge in the sorption and desorption of CLD and cadusafos in tropical volcanic soils of the French West Indies. Sorption-desorption isotherms were carried out in batch experiments in 7 different soils and fitted to the Freundlich model. Additionally, the nature of the soil organic matter, known to be one of the determinants of the adsorption of pesticides, was examined by $^{13}$C-CP MAS NMR. Sorption of CLD in soils was very high ($26< K_f < 102$ L kg$^{-1}$) with a high hysteresis effect in 5 of the soils studied and no desorption at all in the two remaining soils. Freundlich's $K_f$ parameter of cadusafos was ranging between 0.8 and 21 L kg$^{-1}$ and contrarily to CLD, desorption was not showing a high degree of hysteresis. The $K_f$ values were correlated to the OC content ($P<0.01$) for both molecules and derived $K_{oc}$ were ranging between 1200 and 2500 L kg$^{-1}$ for CLD and between 67 and 135 L kg$^{-1}$ for cadusafos. Despite the different nature of the soils, NMR spectra for soil organic matter were very similar between the 7 studied soils. Thus, the Koc heterogeneity is not only influenced by the chemistry of the organic matter, but must also be attributed to other soil properties. In the literature, values on the $K_{oc}$ of CLD were missing, they were sparse for cadusafos and they represent a necessary piece of information for the use of models to predict the transfer of these molecules in surface and groundwaters.

**WE 216**

**On the challenge to remediate a soil contaminated with crystalline DDT by activated charcoal**

A Younas[1], I Hilber[2], M Khwaja[3], TD Bucheli[2]
[1]Environmental Science Department, PESHAWAR, Pakistan
[2]Agroscope Reckenholz Tanikon Research Station ART, ZURICH, Switzerland
[3]Sustainable Policy Development Institute, ISLAMABAD, Pakistan

The production and distribution of the insecticide dichlorodiphenyltrichlorethane (DDT) resulted in a polluted area of about 85 hectares at Nowshera, Khyber Pakhtunkhwa (KPK), Pakistan. At the factory's place the contamination is up to 800 g/kg DDT in dry soil. To reduce DDT exposure of the environment and humans, this contaminated site has to be remediated. Therefore, the aim of this joint research project is to test a remediation strategy with activated charcoal (AC) added to substantially reduce the bioavailable fraction of the aged DDT in the soil. To the best of our knowledge, AC has been used for remediation purposes in a concentration range of ppb to ppm in soils and sediments, but never in the percent range. Under these circumstances, limitations are set at extremes and are manifold. Results from this study will give important information on the performance of AC materials in a naturally contaminated soil and reveal the influence of soil treatment on the immobilization of DDT.
Pots with five kg of field soil were placed in the laboratory. Then, 2 % and 10 % GAC and 0.1 % and 2 % PAC were added. To test the influence of different soil treatments on the binding quality of the AC, the amended soil was then treated in three different ways. Some pots were watered during a month to simulate monsoon season, but left untreated for the following five months (treatment 0). Others were mixed fortnightly to simulate ploughing (treatment P) and a third group was subjected to regularly watering (treatment W) and watering and ploughing (treatment PW) over the whole period of time. After certain time periods, bioavailable DDT and metabolites were assessed by six hours Tenax® extractions with two grams of Tenax® beads and one gram of dry soil.
Results from this experiment were surprising. The Tenax® extractable DDT decreased drastically over time not only in all AC amendments and treatments, but also in the control. After 150 days, the concentration of the DDT extracted by Tenax® was very low with a few per milles. Overall, two main questions arise under this situation with extremely high DDT concentrations: 1) is Tenax® the appropriate tool to assess the bioavailability, and 2) is AC amendment capable to substantially reduce DDT exposure. These important issues will be addressed in this presentation.

**WE 217**

**Distribution of aged 14C-atrazine residues in soil following 22 years of environmental exposure.**

Y Andreou
Cyprus University of Technology, LIMASSOL, Cyprus

Distribution and localisation of pesticide residues into the different physical fractions of soil may reveal information on processes taking place in soil. Soils amended with $^{14}$C-atrazine, were aged for 22 years under environmental conditions in a lysimeter in Germany. The soil was sampled and subjected to physical and chemical fractionation before and after incubation with the earthworm Apporectodea caliginosa for 7 days. No significant change in the soil physical and chemical fractionation of the $^{14}$C-atrazine residues and organic carbon was observed in this study as a consequence of the activity of the A. caliginosa. The low organic carbon of the soil, the absence of relatively fresh organic matter and the long ageing time might explain the limited bioavailability of the $^{14}$C-atrazine to the earthworm. Approximately 9% of the applied 14C-atrazine associated activity was found to be present in the top soil layer 0-10 cm of the lysimeter. This amount represented approximately 36% of the total amount of 14C-atrazine associated activity presented in the soil after 22 years of environmental ageing. Soil half lives calculated in this study taking into account the non-extractable 14C-atrazine residues were much greater than those reported from previous studies. This finding is of particular importance given that the soil used here was aged under natural environmental conditions compared to laboratory studies.

**WE 218**

**Use of solid-phase microextraction and toxicity tests to determine the bioavailability and toxicity of hetero-PAH with the oligochaete Lumbriculus variegatus in sediment-pore water systems**

AJ Schneider[1], TB Seiler[2], K Schmidt[3], G Witt[3], B Schmidt[2], A Schäffer[2], H Hollert[2]
[1]RWTH Aachen University/Institute for Environmental Research, AACHEN, Germany
[2]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[3]Hamburg University of Applied Sciences (HAW), Faculty of Life Sciences, HAMBURG, Germany

Polyaromatic heterocycles (hetero-PAH) are N-, S-, O- substituted polyaromatic hydrocarbons (PAH). They occur together with their unsubstituted analoga e.g. at creosote-contaminated sites. Their acute, chronic and reproduction toxicity as well as their higher water solubility compared to their unsubstituted parent compounds account for their ecotoxicolgical relevance.
In the present study the chronic toxicity of two hetero-PAH acridine (AC) and xanthene (XA) in a sediment-pore water system of a spiked natural river sediment (Altrip, Rhein, Worms; AC 6.3-146.2 µg/g DW; XA 0.1-270 µg/g DW) on the reproduction of sediment dwelling endobenthic oligochaetes *Lumbriculus variegatus* was determined according to OECD guideline 225. In parallel to chronic toxicity, the freely dissolved pore water concentrations ($c_{free}$) of the substances were determined by solid-phase micro extraction (SPME) and high performance liquid chromatography.
Determined effect concentrations (ECx) for the reproduction of *L. variegatus* were based on the total sediment concentration ($EC_{50}$ AC 37.8 µg/g DW, $EC_{50}$ XA 2.4 µg/g DW), the tissue concentration ($EC_{50}$ AC 0.0052 µg/mg DW tissue) and $c_{free}$ ($EC_{50}$ AC 0.034 µg/ml). Hormesis was observed for the reproduction of *L.variegatus* at the lowest tested concentrations of both substances. Furthermore, with the SPME technique it was possible to determine cfree of both substances in sediment pore water at higher sediment concentrations (AC ≥ 30.5 µg/g DW and XA ≥90 µg/g DW) and to prove metabolic degradation of xanthene to xanthone in the sediment. In contrary, no degradation of acridine to acridone was detected in both, the sediment and *L. variegatus*.
The results emphasize, that for sediment contact tests, i.e., testing the ecotoxicity of hydrophobic organic chemicals ($\log K_{OW} < 5.7$) on endobenthic organisms, it is important to simultaneously determine $c_{free}$ of the substances to be able to link the observed ecotoxic effects to the real exposure.

**WE 219**

**Characterizing the bioavailability of cationic surfactant using passive sampler**

Y Chen[1], STJ Droge[2], JLM Hermens[1]
[1]Institute for Risk Assessment Sciences, UTRECHT, The Netherlands
[2]Helmholtz Centre for Environmental Research-UFZ, LEIPZIG, Germany

Cationic surfactants are ubiquitous contaminants that are extensively detected in sediment, sewage sludge or surface water due to their wide applications in industrial and domestic products. However, the understanding of the impact of this class of compounds on the environment is still limited. The freely dissolved concentration of an organic compound is an important parameter for accessing the environmental fate and bioavailability of the chemical. The free concentration of cationic surfactants, are difficult to determine because of their high adsorptive capacity to lab apparatus and because the difficulty to separate the bound particles from the aqueous phase.
In the current study, a solid phase microextraction (SPME) method was optimized and applied to characterize the bioavailability of two cationic surfactants, hexadecyl trimethyl ammonium chloride (IV-16) and benzyl dimethyl dodecyl ammonium chloride (C12-BAC). The effect of solution chemistry on the sorption isotherm to SPME was first examined. Sorption experiments of the two cationics to Pahokee peat and humic acid were carried out. The influence of pH and the presence of inorganic cations on the sorption behavior were examined within the range of relevant environmental concentrations. The results suggest both ionic and nonionic interactions could play a role in the sorption process for cationic surfactants.

**WE 220**

**Sorption of cationic organic compounds: how important is clay compared to organic mat-**

ter?

STJ Droge, KU Goss
UFZ - Helmholtz Centre, LEIPZIG, Germany

Many emerging environmental compounds of concern are (partially) positively charged under typical environmental conditions. Sorption to organic matter (OM) in soils, sediments and dissolved particles occurs mainly through an ion-exchange process at negatively charged groups in OM. Besides OM, most types of common clay minerals also contain negatively charged surfaces to which these organic cations may sorb. Since sorption strongly controls the bioavailability and mobility of these compounds in the environment, and in soil toxicity tests, insight is needed for which compounds the clay fraction forms a considerable sorption phase relative to the fraction of OM. In a dynamic HPLC set-up, retention of organic cations was measured on columns partially filled either with OM (micronized Pahokee Peat) or clay mineral (illite), mixed in a certain percentage with inert packing material. Clear differences between sorption affinity of quaternary amines and primary amines to OM and clay exist. For quaternary amines, retention time on a column packed with 1% illite is stronger than when packed with 1% OM, whereas for primary amines the opposite is observed. Clearly, clay minerals form a significant sorption phase for many organic cations. It will be a matter of the fraction size of OM and clay, e.g. in a river sediment, which type of substrate dominates the sorption. Besides the type of charged amine moiety, also functional groups in the nonionic part of the organic cation determine the specific affinity to either OM or clay.

**WE 221**

**Chlordecone degradation and impact on soil respiration**

JD Fernandez-Bayo[1], AE Berns[2], W Tappe[2], S Kummer[2], D Hofmann[3], D Ulrich[2], E Steffen[2], C Saison[1]
[1]Laboratoire d'étude des Interactions Sol - Agrosystème - Hydrosystème, MONTPELLIER, France
[2]Forschungszentrum Juelich GmbH, Inst Bio- and Geosciences, IBG 3: Agrosphere, JUELICH, Germany
[3]Forschungszentrum Juelich GmbH, ZCH, JUELICH, Germany

Chlordecone (CLD) is a persistent organochlorine pesticide included in the Annex A of the Stockholm Convention. Despite its prohibition in France since 1993, it was still significantly detected in 2001 in the French West Indies. The aim of this work was to study the persistence of CLD in soils, to assess its likely toxic effect in soil microbial activity and to monitor the appearance of possible metabolites. Degradation was studied in soil microcosms under controlled conditions in two horizons (NEH-A and NEH-B) from the same tropical andosol. Uniform $^{14}$C labelled CLD was used. $^{14}$C-CLD was applied at normal field dosage on both soils. Different application rates were also tested (NEH-A with twice the field dosage, NEH-B with half of it). At time intervals of 0, 32, 88, 150 and 214 days, the distribution of $^{14}$C-CLD in different compartments of the experimental system (soluble, extractable, bound and mineralised fractions) was determined. The impact of CLD in soil respiration was assessed by the Substrate Induced Response (SIR). The presence of CLD metabolites was studied using Thin Layer Chromatography (TLC) and Gas Chromatography-Mass Spectra (GC-MS). The results were similar between the different soil field application rates. Due to the low solubility of CLD, the desorbed fraction was low and constant during the incubation (2% and 8% in NEH-A and NEH-B, respectively). The bound residues fraction was similar and almost constant in both soils during the experiment (≈12%). Mineralization was higher in the NEH-A (4.9%) than the NEH-B (3.3%). This was attributed to the higher basal respiration of NEH-A. CLD did not affect SIR, although it decreased soil respiration response at longer periods of time. The TLC analysis of the standards solutions of $^{14}$C-CLD showed up to 3 different regions of radioactivity (corresponding 90% of the activity to CLD region and 9 and 1% to the other regions). GC-MS identified four different chlorinated compounds in these regions: CLD, mono-chlordecone, mirex and an unknown highly chlorinated compound. In the TLC analysis of the extractable fractions of soil NEH-A (214d) it was not possible to observe the same regions of radioactivity than for the standard. This extractable fraction was measured through GC-MS and only mirex and CLD were identified. In summary, CLD degradation is extremely low and the majority of CLD is in an extractable form, suggesting that it is potentially available for transfer into the soil solution.

**WE 222**

**Impact of ageing on bioaccessibility of pentachlorophenole in the baterial contact assay with Arthrobacter globiformis**

R Conrad[1], H Zielke[1], D Spira[2], U Feiler[2], TB Seiler[1], H Hollert[1]
[1]Institute for Environmental Research, RWTH Aachen University, AACHEN, Germany
[2]German Federal Institute of Hydrology, KOBLENZ, Germany

*Background and aim* The miniaturised bacterial contact assay is a fast and sensitive whole sediment contact test. Toxicity is determined by measuring the inhibition of bacterial dehydrogenase activity (DA). Transformation of resazurine to the fluorescent dye resorufine through DA in the samples is compared to controls using a direct fluorescence measurement. The assay can be used for aqueous and solid samples.
This project investigated the impact of short-term ageing in the bacterial contact assay. An artificial and a natural sediment were spiked with pentachlorophenol and tested at regular intervals. Based on previous studies with other specimens a fast decrease of the effect was expected. Furthermore, effects were assumed to decrease faster in the artificial sediment.
*Materials and methods* Test bacteria were incubated in 24-wellplates in an aqueous suspension of test sediment. Artificial sediment was prepared according to OECD-guideline 218 (modified). Natural sediment was sampled at Altrip, a back water of the River Rhine. Both sediments were spiked with 500 mg PCP/kg dry weight in three independent replicates. The first test was carried out immediately after spiking, subsequent tests were performed at increasing intervals of time.
*Results* Inhibition of DA fluctuated between 60 % and 100 %, thus exceeding the toxicity threshold defined for this test. No significant change occurred after 27 weeks of ageing. Furthermore, no differences between both sediment types could be determined.
*Discussion* Ageing sediments for 26 weeks did not affect the DA of *Arthrobacter globiformis* through pentachlorophenol. This observation could result from a higher bioaccessibility of the contaminant for bacteria, in contrast to organisms with different pathways of exposure. Enhanced accessibility to bacteria may also explain that no differences between sediment types were found, though both have distinctly different characteristics in terms of pH, TOC etc. This is shown especially in comparison to organisms of higher complexity and lower access to sediment-bound compounds, where such differences have been shown.
*Conclusion* The results of this study show that the size of the exposed organisms plays an important role in ageing-related changes of the biological effects observed in whole sediment contact tests. Further experiments are necessary and currently on-going in order to increase the understanding of how ageing impacts biotests with organisms of higher complexity.

**WE 223**

**Interactions of chemicals with engineered nanoparticles (quantum dots) and combined effects on bacteria**

T Gocht, I Ott, B Morasch
Center for Applied Geosciences, TUEBINGEN, Germany

The toxicity of chemicals as well as particles has become an area of intense research during the last decades in the environmental sciences. However, only few studies did address a possible modification of effects through interactions of chemicals with particles. In principle, sorption of chemicals can decrease their toxicity as their bioavailability is reduced. On the other hand, engineered nanoparticles have been shown to affect living cells in different ways. Consequently, in a ternary system of bacteria, engineered nanoparticles, and chemicals, the sorption of chemicals on such particles must not necessarily reduce the toxicity towards bacteria.
In this study, toluene and quantum dots (QDs) were selected as representatives for well-investigated organic pollutants and engineered nanoparticles, respectively. The QDs used in this study consisted of a CdSe-core that was passivated by a ZnS-shell. Finally, the surface of the QDs was coated with polyethylene glycol and functionalized with amino-groups leading to hydrophilic surface properties. The diameter of the QDs was around 9 nm, and in aqueous salt solutions they showed a tendency to form aggregates as revealed by transmission electron microscopy. First results based on sorption studies in batch experiments showed that in physiological salt solution, toluene interacted with QDs leading to reduced freely dissolved concentrations of toluene in the presence of QDs. Ongoing experiments investigate the effect of interactions between toluene and QDs on dose-response relationships.

## LC04 - Life Cycle Inventory modelling and attributional/consequential issues (LCI)

**WE 226**

**Inclusion of land use changes in LCA on bioenergy: parameterization of land use change patterns**

Y Shayeghi[1], LS Schebek[1], RS Schaldach[2]
[1]University of Technology Darmstadt, DARMSTADT, Germany
[2]University of Kassel, Center for Environmental Systems Research, KASSEL, Germany

Bioenergy is considered as an important option for the mitigation of climate change. However, the impact of land use change on soil and vegetation carbon pools may jeopardize the potentially achievable savings of greenhouse gas (GHG) emissions by the replacement of fossil fuels. In recent literature different economic and geographic model approaches are discussed in order to assess not only direct but also indirect land use changes. To develop a novel approach to consequentional LCA, we consider coupling of LCA with a land use model. Economic models calculate the interdependence between the demands for raw agricultural materials, the agricultural land needed for their production and the price correlations. Examples applied for analyzing land-use changes include GTAP (Global Trade Analysis Project, Purdue University), CAPRI (Common Agricultural Policy Regional Impact Analysis, University of Bonn) and IMPACT (International Food Policy Research Institute, IFPRI). Due to their relatively low spatial resolution (e.g. world regions, countries or districts) these models are not suitable for detailed spatially explicit environmental impact analysis. In order to overcome this limitation, we have chosen to apply the geographic model LandSHIFT which accounts for global and continental level land use change and has been developed as a new approach for spatially explicit simulations of large-scale land-use change dynamics and their environmental impacts. The model input is a set of exogenous drivers such as population and production of agricultural commodities, commonly derived from the aforementioned large-scale economic models. The model output is a time series of high resolution raster maps of the changing land use pattern. These land use maps can be processed as input for LCA respectively. The research investigation focuses on the approach of coupling the two models of interest. Using the example of different scenarios according to multiple prospective bioenergy targets the objective of our study is to assess the impact on land use change dynamics and the consequent GHG along the entire process chain in LCA especially due to land use change. Furthermore the research aim is to investigate whether land use can be modelled as a linear or nonlinear function of agricultural or resource output with increasing bioenergy production targets within the framework of LCA.

**WE 227**

**Partial and General equilibrium modelling to integrate consequential effects of indirect land use changes (ILUC) in LCA of biogas**

A Marvuglia, E Benetto, D Koster, C Jury
Public Research Centre Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg

The promotion of renewable energies, such as biomass, is at the heart of the European Community's policy actions since a decade. Policies for supporting biofuels require life cycle carbon reporting to ensure that biofuels achieve greenhouse gas reductions relative to fossil fuels. However, the use of agricultural crops for energy purposes is responsible also for several environmental impacts not related to climate change, such as eutrophication and acidification due to fertilizer runoff, and biodiversity loss. The most consensual methodology to evaluate the overall environmental impact associated with the production of energy from agricultural crops is Life Cycle Assessment (LCA). In the field of bioenergy, comparative LCAs of bioenergy production are usually of the "attributional"type. In attributional LCA (ALCA) average LCI data are used and it is generally assumed that the studied lifecycle does not affect other systems. This means that the relationships between the lifecycle and other economic systems (i.e. the market on which it operates) are disregarded. For instance in the bioenergy sector, ALCA disregards the (marginal) effects of increasing production of a specific crop in a certain area. However ALCA is a recognized simplification in the study of bioenergy systems, for which it is particularly relevant to consider the consequences of the increased use of bioenergy on other economic systems. To ameliorate this problem another approach, named Consequential LCA (CLCA), is being developed. It aims at generating pertinent (market based) information on the consequences of actions. In other words, CLCA aims at describing how the environmentally relevant physical flows to and from the technosphere will change in response to possible changes made within the life cycle, including the indirect effects on land use change and the effects on other economic systems, based on actual market conditions.
After a review of the most widespread PEMs and GEMs applied to agriculture and trade policies, the paper describes the first results of a project led by the Resource Centre for Environmental Technologies (CRTE) of the Public Research Centre Henri Tudor (Luxembourg). The main scientific objective of the project is to provide an operational methodology for the inclusion of indirect effects of land use changes into CLCA of bioenergy and then to apply the methodology to the case of biomethane production from energy maize in Luxembourg.

**WE 228**

**A constraint-based method for performing life cycle inventory analysis using the matrix model**

J Wallace[1], A Marvuglia[2], E Benetto[2], C Jury[2]
[1]University College Cork, CORK, Ireland
[2]Public Research Centre Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg

In a decision-making support process based upon environmental criteria the analyst might be interested in the definition of the system configuration(s) (different process combinations, different features of the processes input materials, etc.) consistent with a set of imposed constraints on the maximum allowed environmental burdens (and consequent environmental impacts) and natural resources consumption. While the classical matrix method for Life Cycle Inventory (LCI) compilation is the tool by which the environmental impacts linked to the studied system can be calculated, it is not very practical when one wants to automatically solve the above mentioned constraint satisfaction problem. Although optimisation methods have been proposed in connection with Life Cycle Assessment (LCA) problems, based on Linear Programming (LP) models, this has not been done in a way that is consistent with the matrix model. Nor would this have been possible with these approaches.

In this work, we present an approach based on constraint programming (CP) for a case study concerning the energy valorisation of grape marc by the production of grape marc pellets. Basically, we take the ordinary matrix model and calculate backward from a given set of burdens to the (best) possible set of inputs from the technosphere compliant with those pre-imposed burdens. Further constraints are imposed in the model in order to assure that the solutions found (if any) are also physically feasible. This optimization process could provide significant added value in decision making or ecodesign processes based on LCA, since it allows the LCA analyst to identify (if they exist) those system configurations that meet certain environmental goals, thus avoiding a time consuming and sometimes unproductive search for optimal solutions based on a conventional trial and error approach.

The technology matrix comprises over 1'600 entries and the inventory vector has over 1'500 elements, of which only a few have been selected to test the optimization algorithm. The results of the study showed that the water content in fresh grape marc entering the dehydration phase the fresh marc undergoes has a significant influence on the computed impacts. The applied CP-based approach allowed to infer the ranges of water content in fresh grape marc that were consistent with the imposed constraints at the inventory table level (environmental burdens) as well as at the midpoint indicators level (environmental impacts).

**WE 229**

**End-of-Life vehicles management: evaluation of recycling and recovery potentials in a dynamic approach**

L Ciacci, F Passarini, A Santini, I Vassura, L Morselli
Bologna University, BOLOGNA, Italy

Since its birth in 1990s, LCA has shown great potential for support decision-making, and that rapidly contributed to rise and wide the use of this methodology. Decision-making to be successful needs to identify consequences and future impacts of choices depending on marginal mechanisms and that may affect environment. In this sense, a formal distinction is now adopt between two types of LCA approaches: attributional/status-quo LCA, in which future developments and marginal effects are not considered, and consequential/dynamic LCA, which instead assumes the influence of the time-dependent parameters and changes on the system investigated. These parametersare used in consequential/dynamic LCA for modelling future systems and assess how they may affect the results [Finnveden et al., 2009].

In a previous study [Ciacci et al., 2010], a comparison among different ASR management strategies was carried out aiming at proposing alternatives to the current scenario of landfill disposal in terms of environmental benefits and reduction of waste disposal. Such ASR management strategies (landfilling, incinerating, mechanical recycling and gasification) are here adopted as a starting point for a dynamic approach of LCA methodology, according to Pehnt (2006). In particular, this study focuses on changes expected in both the composition variation in vehicle production, and for background system parameters, such as the increasing for renewable energy sources in electricity production mix. Starting from 1 ton ASR obtained from a dedicated shredding campaign, the present functional unit has been changed according to two different previsions: the first related to a reliable ASR composition in 2015, following the current increasing trend of plastic and non-ferrous metals (especially aluminum) and aimed to decrease car weight; the second is based on the application of eco-design principles towards dismantling and collecting practices. Finally, previsions on potential benefits from recycling aluminum and polyolefins (PP/PE) from ELVs are discussed. Results show benefits from mechanical recycling of plastics and aluminum particularly if eco-design application would allow a reduction of the different kinds of plastics used in cars, and then to improve polymer and non ferrous metals separation and recycling.

**WE 230**

**Combining technical optimisation in early R&D with Life Cycle Assessment - the case of micro process technology**

E Zschieschang[1], O Görke[2], P Pfeifer[2], A Patyk[3], L Schebek[3]
[1]Karlsruhe Institute of Technology (KIT), KARLSRUHE, Germany
[2]KIT, Institute for Micro Process Engineering, KARLSRUHE, Germany
[3]KIT, Institute of Technology Assessment and Systems Analysis, KARLSRUHE, Germany

New technologies in the field of decentralised small and/or mobile applications (e.g. consumer electronics) are characterised by a shorter lifetime, utilisation of multiple rare earth metals and huge production numbers. Due to the awarness of environmental impacts of these technologies during their life cycle, the optimisation of their design seems absolutly essential to obtain a more sustainable technology. Hence, the question arises how to combine technical optimisation with Life Cycle Assessment?

Micro process technology is based on chemical and physical phenomena occuring inside volumina of less than 1 mm in diameter, usually carried out in continuous flow mode. General advantages are enhanced material yield and energy efficiency in chemical processes by improved heat and mass transfer. The field of micro process technology covers developments which might substitute existing processes as well as enabling new technologies which will lead to ample changes in markets or even societal conditions.

Using the example of a micro structured reactor for gas to liquid fuel conversion in early R&D, a new methodology for combining technical optimisation with Life Cycle Impact Assessment was developed. As result, different possible micro reactor designs can be compaired due to their ecological impact using Life Cycle Assessment. Further advantages of this methodology are the identification of improvable and not-improvable technical parameters in terms of lowering environmental impact, the easy integration in other LCAs and the transfer of this methodology to other micro process technology applications.

**WE 231**

**Models of chemical inventories based on statistical analysis of on-site production data**

CM Pereira[1], S Papadokonstantakis[1], K Hungerbühler[2]
[1]Eth, ZÜRICH, Switzerland
[2]ETH Zürich, ZÜRICH, Switzerland

Chemicals are involved in the production of almost all industrial and consumer goods, therefore the improvement of the environmental performance of chemical production is a very important issue for assuring sustainability in modern life. For this purpose Life Cycle Assessment (LCA) is a suitable evaluation method. However, there is a lack of inventory data of production processes in the chemical industry, being this a significant problem for many LCA practitioners.

To overcome this problem, generic models of chemical production processes based on statistical analysis of on-site production data are being developed. These generic models will be on the level of unit processes, this means all operations that are required to achieve a change in the chemical structure (e.g. the actual chemical reaction and subsequent separation and purification steps) and will be not product specific, but reaction type specific. The main output prameters of these models include reaction yield, use of raw materials and utilities, as well as emissions to air, water and soil. These models will take the form of generic data ranges with an empirical average, minimum and maximum values, resulting in empirical confidence intervals for each process parameter. The data sources represent different chemical industry sectors, with different purposes, from basic chemicals to pharmaceuticals and pesticides. This allows a parameterization independent of the industry sector, and thus the development of generic gate to gate process models.

Using this approach, a complete synthesis can be modeled by combining individual process models. These models can be also used to fill data gaps in existing process documentation. In this way these models will allow a better assessment of the sustainability of chemical production.

**WE 232**

**An improved model for estimating pesticide emissions for agricultural LCA**

TJ Dijkman, M Birkved, MZ Hauschild
Technical University of Denmark, KGS. LYNGBY, Denmark

Credible quantification of chemical emissions in the inventory phase of Life Cycle Assessment (LCA) is crucial since chemicals are the dominating cause of the human and ecotoxicity-related environmental impacts in Life Cycle Impact Assessment (LCIA). When applying LCA for assessment of agricultural products, off-target pesticide emissions need to be quantified as accurately as possible because of the considerable toxicity effects associated with chemicals designed to have a high impact on biological organisms like for example insects or weed plants.

PestLCI was developed to estimate the fractions of the applied pesticide that is emitted from a field to the surrounding environmental compartments: air, surface water, and ground water. However, the applicability of the model has been limited to 1 typical Danish soil type and 1 climatic profile obtained from the national Danish meteorological station.

To overcome these limitations, a reworked and updated version of PestLCI is presented here. The new model includes 16 European climate types and 6 mean European soil characteristic profiles covering all dominant European soil types to widen the geographical scope and to allow contemporary (varying site and or climate condition) and future (change climate condition of a location) differentiation.

In addition, the tillage frequency is now incorporated as an input parameter. The tillage frequency has an impact on the soil permeability through its relation to the occurring frequency of macro pores in the top soil, and thus the initial leaching rate of pesticide through preferential flow.

A third improvement of the updated model is a simplified user interface which makes the model easier to evaluate and operate.

The updated PestLCI model is demonstrated on cases involving different climatic circumstances and locations presenting the resulting variations in pesticide emission patterns.

**WE 233**

**Current lack and needs for better life cycle inventory data for water footprinting**

SV Vionnet[1], AK Kounina[1], YL Loerincik[1], DF Friot[1], MM Margni[2], SH Humbert[1]
[1]Quantis, LAUSANNE, Switzerland
[2]CIRAIG, ECOLE POLYTECHNIQUE DE MONTRÉAL, Canada

Water is a growing concern in life cycle assessment. Several impact assessment methods have been developed or are being developed to assess the impacts on water. However, current inventory databases (Gabi, Ecoinvent, etc) provide only limited data on water, mainly on withdrawal, and are all mis-matching the elementary flows requirement of the methods developed recently to address the issue of water impact assessment (methods such as Pfister et al. 2010, Water Footprint Network, Motoshita et al. 2010). Indeed, most of these methods address specific water use, at inventory level, that are not included in existing life cycle databases or are difficult to extrapolate from existing data. Furthermore, a lack of sufficient and relevant data is in many cases the dominant factor limiting the ability of corporate water accounting and impact assessment (CEO Water Mandate, 2010).

In light of this issue, a project was launched by a consortium of companies - and leaded by Quantis - to create an exhaustive "water"life cycle inventory database. This water database is based on the ecoinvent (www.ecoinvent.ch), for approximately 4'000 processes and will include:

- A full balanced water accounting taking into account water flows that are addressed in the recently developed accounting and impacts methods
- Different regionalization possibilities at the level of the country, the level of the watershed or using an archetype approach
- A preset choice of impact assessment methods applied to the inventory flows

The applications in life cycle inventory and impact assessment ranges from assessing a large number of products, assessing the supply chain and indirect water consumption of materials and energy for corporate reporting, water management and risk assessment. The use of this database will also make possible for researchers to apply and develop further methods to assess the different types of environmental impacts related to water. The availability of inventory data will make it possible to widen the scope of actual "water footprint"(at inventory and impact levels) studies and include in-stream and off-stream water uses, consumptive, non-consumptive and degradation water uses in a consistent way. Result on a case study will be presented.

**WE 234**

**Modeling global crop water demand using a life cycle approach**

RZ Johnston[1], M Matlock[2], A Brown[2], H Sandefur[2], E Cummings[2]
[1]University of Arkansas, FAYETTEVILLE, AR, United States of America
[2]Biological and Agricultural Engineering; University of Arkansas, FAYETTEVILLE, United States of America

Global water resource demand is expected to increase by as much as 50 percent in the next 40 years as the human population tops nine billion. Agricultural water use accounts for as much as

70 percent of total water use. Increasing demand for food, feed, fiber and fuel will increase demand for irrigation water. Global climate change will shift rainfall patterns, resulting in potential increase in water stress in certain regions. We developed a crop water demand simulation process incorporating the CERES 4.0 Maize model in the Decisions Support System for Agrotechnology Transfer (DSSAT) program. The goal of this project was to simulate global corn yield based on a range of input parameters at the highest geospatial resolution supported by the data. A customized user-interface in the MATrix LABoratory program (MATLAB) was created to allow for the input of global or regional datasets within DSSAT. Preliminary objectives of this project were to calibrate the CERES-Maize model for the Untied States using corn yield data from National Agricultural Statistics Service over a 10 year period and apply the calibrated model to future climate scenarios.
Once applied, water use impacts related to maize production were assessed based on future irrigation demands. Both water use efficiency and evapotranspiration were also calculated for each pixel. There values, along with predicted irrigation withdrawals were overlaid with water scarcity indices to forecast areas of high risk under future climate conditions. The model will help present policy makers plan for the agricultural water demands of tomorrow. Future studies will involve adapting the previously described methodology to a global scale and extend crop coverage to soybean, rice, and wheat. After future water demands for all crops are found, this information can be applied to environmental impact assessments that are lacking data for agricultural water use.

**WE 235**

**Assessing water quality compensation treatments and related inventory in LCA**

AM Boulay[1], E Loiseau[2], C Bouchard[3], L Deschênes[1], M Margni[1]
[1]CIRAIG - Ecole Polytechnique, MONTREAL (QC), Canada
[2]AgroParisTech - Engref, PARIS, France
[3]Department of Civil Engineering, Laval University, QUÉBEC, Canada

Impacts from a lack of functional water for human uses in Life Cycle Assessment can be generated directly on Human Health, if they occur in a region affected by water-related diseases or malnutrition, or through the use of compensation strategies when the socio-economic context allows it. Compensation refers to the adaptation by the human users to a change in the water availability in order to still meet their needs. These strategies can refer to compensation to achieve functional/good quality water from non-functional/poor quality water, by water treatment, or to compensate for a physical lack of water, by other scenarios like importation for example. Both these types of strategies will generate impacts which should be included when evaluating impacts from water use in LCA. The water treatments required to compensate water quality will vary according to the available water and desired final quality, and these treatments need to be identified in order to properly assess the impacts from this compensation.
The work presented here proposes a methodology to evaluate the sequence of different treatment steps required, as well as the related additional inventory required for the compensation of a degraded water quality, based on fixed input and output quality. Seven water categories describing the quality and users for which each category is functional are first presented. Decision trees created to generate relevant treatment sequences for moving from one category to another are then described and used to evaluate the 25 different possibilities of water quality compensation, based on the water categories presented. Five different treatment sequences result and the inventory from each is assessed. This method is then used to assess impacts from a pulp and paper plant releasing different water qualities in a traditional LCA framework.

**WE 236**

**Life Cycle Assessment of urban water cycle in Mediterranean cities**

MJ Amores Barrero, JP Pasqualino, MM Meneses, FC Castells, IB Butnar, EG Gemechu
Universitat Rovira i Virgili, TARRAGONA, Spain

Given the increasing demand of urban water for both potable and non-potable applications, in many countries urban water authorities are struggling to satisfy the demand meanwhile improving the environmental profile of the urban water system.
The main goal of this study is the environmental analysis of the whole urban water cycle, taking into account all its elements: potable water treatment plants, water distribution system, water use, wastewater treatment plants (WWTP) and sewage systems. Based on the methodology of Life Cycle Assessment (LCA), we assessed the current urban water systems on the Spanish coast of the Mediterranean Sea and proposed possible scenarios for improving their environmental performance in order to find out the best scenario for the urban water management.
Urban Water Cycle here considered includes potabilization, distribution, collection, treatment and optional wastewater reclamation. Inventory analysis was performed based on local operation data complemented with Ecoinvent Database whenever the local data were missing. The environmental profiles of the different water system scenarios were analysed based on CML 2001 and Eco-Eficiency indicators. The results show that Global Warming Potential, GWP impact in the considered water system without water reclamation is divided in 44% potabilization, 38% distribution and collection and 18% water treatment. When water reuse is included, the GWP of the water system remains practically unchanged because the inclusion of an obligatory tertiary treatment is balanced by the credits obtained by the fertilizers saving in agricultural uses. Nevertheless water reclaiming provides water that can be used for non-drinking uses and consequently a net reduction on freshwater consumption indicator is obtained. The study also considered a hypothetical situation of drought conditions, when a new desalination plant has to be included in order to cover the water requirements. Results show that this solution would imply an increase of about 30% of the environmental impact of the global water system and therefore, it should be used only to complement the purification process already existing. This study demonstrate the usefulness if LCA for the assessment of the urban water systems enabling the identification of critical processes and the potential improvements of the system.

**WE 237**

**Life cycle assessment of decentralized combined heat and power plants based on difficult fuels**

KP Sartorius, WR Poganietz, L Schebek
Karlsruhe Institute of Technology, EGGENSTEIN-LEOPOLDSHAFEN, Germany

In combined heat and power (CHP) plants waste heat can be used for district heating or process steam. By this, the efficiency of the power plant can be increased to about 90 %, which saves primary energy and reduces ecological impacts.
There is a broad range of fuels which can be used in a CHP plant. A research project at Karlsruhe Institute of Technology (KIT) aims to enlarge the scope of fuels to so-called 'difficult' fuels: these are materials with various disadvantages like low heating value or low ash melting temperature and may be renewable (e.g. straw, forest residues) or non renewable materials (e.g. refuse derived fuels, litter). Advantages of these fuels are that they are so far mostly unused and that they are available on a regional scale (within a radius of 100 km around the CHP plant). This keeps the transportation costs low and reduces environmental burdens. Regional fuels also result in lower dependency in imported fuels.
For LCA of this new type of CHP concept, a modular model has been developed which may be used in future studies of consequentional LCA of regional energy provision. This model enables to compare different fuels and types of heat use. It consists of transporting, drying and crushing the fuels as wells as of modules for the CHP plant itself. The data for combustion is generated in laboratory scale and pilot plants. After combustion, the flue gas runs over a steam generator, which produces high pressure steam. The whole water-steam cycle, including steam turbine and heat exchangers is simulated. After the steam generator, the cooled flue gas is cleaned by state of the art technology. That means, depending on the kind of fuel, SO2 and NOx reduction as well as a filtration of fly ash.
The LCI model itself as well as first assessment results will be presented.

**WE 238**

**Energy production from microalgae - a contribution to a sustainable energy supply?**

A Weiss, A Patyk, L Schebek
Karlsruhe Institute of Technology, EGGENSTEIN-LEOPOLDSHAFEN, Germany

By 2020, 20% of the energy consumption in Europe should come from renewable energy sources. This is set as a mandatory target by the renewable Energy Directive of the European Union. Microalgae have the potential to serve as a renewable and sustainable energy source in the future. Microalgae, such as green algae and cyanobacteria generate biomass by photosynthesis. The biomass is a form of chemical energy which can be further converted into hydrogen, biodiesel or other forms of liquid or gaseous fuels. The production of energy with microalgae can be more sustainable than its alternatives concerning some important criteria: algae can be grown in closed systems on non-arable land, need CO2 as only carbon source and can also grow in salt or wastewater. However, up to now (based on lab and small pilot plant experiences) net energy generation from microalgae is negative and there is no functioning system of energy production with microalgae in use, yet.
Until now, microalgae have been used to produce high value chemicals, such as proteins or colorants for food and chemical industry. When algae should contribute to a sustainable energy supply, the production process should be energy-efficient as well as competitive concerning economic and ecologic criteria.
To account for this, progress in the development of bioreactors will have to ensure a positive energy balance. In addition to that, new concepts of energy production with microalgae are arising, integrating biomass and energy production into a larger system to achieve synergy effects and an overall positive net energy generation.
In this work, a first assessment of different processes of energy production with microalgae has been carried out with a detailed life cycle model. Within this model, different methods and process combinations can be compared to each other and to fossil based systems. Benefits and drawbacks of different systems can be discovered. LCA results will be used to support developers of a novel bioreactor and to give suggestions for further research.

**WE 239**

**Life Cycle Assessment of the production of Succinic Acid: a contribution to consequentional LCA of biorefinery**

O Mrani, L Schebek
TU Darmstadt / Institute IWAR,, DARMSTADT, Germany

In recent years there has been increasing interest in the concept of biorefinery which denotes the idea of a future broad use of biomass substituting present day petrol-based chemical production. The core of chemical industry production of bulk and fine chemicals is only one area within concepts of biorefinery, but is of high interest because it is based on carbon chemistry and therefore will always be dependent from carbon feedstock. LCA on future biobased chemical production has to account for the fact, that - like in present day chemistry - also processes of "green"chemical production will be highly interconnected: therefore not simply one petrol-based product will be substituted by one biobased product, but major changes in production routes and their interlinkages will be introduced.
As an example for the comparison between petrol- and bio-based products an LCA of the production process of succinic acid has been carried out.
Regarding the wide range of possible applications, LCA of production processes for succinic acid seems interesting in it self, but also of high interest as a first step for a modular approach to Consequentional LCA of future biorefinery concepts.
Succinic acid is currently produced also from a petroleum-based process. However, it was found that bio-based versus petroleum-based succinic acid production is not an adequate comparison. Currently, petroleum-based maleic acid, instead of succinic acid, is used in industry as a building blockplatform chemical for the same products for which bio-based succinic acid will be used within the concept of biorefinery. As a functional unit 1000 kg was adopted also for maleic acid. One important conclusion is, that comparison of the same compound from biomass and from fossil resources may not be the approrioate approach. Instead, function within production chains of petrochemistry compared to future production chains of biomass has to be taken into account. This will lead to comprehensive picture of the interlinked processes of today's chemical industry compared to biorefinery as a basis for assessment of possible benefits from bio-based production as a whole. To elucidate this, further building blocks derived from sugar platform chemicals shall be investigated including assessment of the respective petroleum-based counterparts.

## NM02 - Fate and effects of nanoparticles

**WE 244**

**Research needs for nanosafety - activities of the German Federal Environment Agency**

D Voelker, K Schwirn
Federal Environment Agency, DESSAU-ROSSLAU, Germany

The Federal Environment Agency (UBA) - for human and environment - is Germany's central federal authority on environmental matters. The aims of the UBA in terms of Nanotechnology are:

- to evaluate the chances and risks of nanotechnology,
- to further develop and/or adapt the existing strategies for testing and evaluating nanomaterials,
- to close gaps of information concerning risks of nanomaterials,
- to adapt the existing laws of the Chemical`s Act, and
- to strengthen national and international activities for coordinated risk analysis.

Therefore UBA detects and supports the need of research to evaluate the chances and risks of nanotechnology. For this aim it participates at the OECD Working Group for Manufactured Nanomaterials (WPMN) and coordinates the German Activities in the OECD Sponsorship

Programme for the safety testing of a representative set of manufactured nanomaterials. Within the Sponsorship Programme UBA is responsible for the testing of TiO2 nanomaterials and partly responsible for nano silver, as well as it contributes data to four additional nanomaterials.
At our poster we will present the aims and activities of the UBA in terms of chances and risks of nanotechnologies and will especially focus on currently running research projects.

**WE 245**

**Malformations and toxicity mechanism of silver nanoparticles in the medaka fish embryo model**

Y Nakagame[1], SK Kashiwada[1], HT Takei[1], EA Ariza[2], TK Kawaguchi[2], BJ Jayasinghe[2], TS Sabo-Attwood[2], PF Ferguson[2], HN Nakamura[3], YK Kagami[3], TC Chandler[2]
[1]Toyo University, GUNMA, Japan
[2]University of South Carolina, SC, United States of America
[3]Ecogenomics, FUKUOKA, Japan
Silver nanomaterials are one of the major components of healthcare products. This study explores the toxic mechanisms of silver nano-sized colloidal particles (AgNPs; average particle size 3.6 diameter nm, purity 99.99%, pure water solution) using the medaka fish embryo model. Three different developmental stages of medaka embryos (stage 11, blastula stage; stage 21, brain regionalization and otic vesicle formation; and stage 30, blood vessel development) were exposed to several concentrations of SNC. SNC produced morphological changes in the embryos such as blood clots, percardiovascular edema, tubular hearts, and spinal deformities at 0.5 and 1.0 mg/L. Reduced and delayed hatching were observed as well. Stage 21 embryos were most susceptible among all embryo stages tested. To determine the distribution of SNC medaka egg embryos were exposed to 0.5 mg/L for 6 days, and embryo, chorion and embryonic fluid were isolated and subjected to ICP-OES analyses. Silver was detected in a single medaka embryo and chorion at levels of 16.6 ± 9.3 pg and 720 ± 29 pg, respectively. Furthermore, TEM analyses showed SNC adhered onto the surface of the chorion and inside the chorion layer. To investigate oxidative mechanisms of injury, reactive oxygen species scavengers GSH (0.5 mM) and NAC (0.05 mM) were evaluated for their potential to rescue embryos exposed to 10 mg/L SNC. NAC rescued all embryos by 96 hr following treatment while GSH did not. NAC was able to block the process of lipid peroxidation by inducing a decrease in MDA levels, whereas SNC did not affect CAT and SOD activities. To elucidate AgNPs' effects on gene expressions, medaka embryos exposed from stage 21 for 48 hours were subjected to medaka embryo microarray. Two important genes relative to phenotypic development were influenced; HoxB6B gene was up-regulated and retinol-binding protein gene was down-regulated, respectively. Disruptions of those genes were well known to induce malformation in organisms. The two genes may have important roles to cause embryonic malformation through AgNPs exposure. Here, there has been a problem regarding AgNPs' toxic mode of action whether AgNP or Ag ion cause toxic effects. A new tool for Ag ions released from AgNPs is developed and medaka embryos are subjected to the assay to test toxicity of Ag ion only.

**Silver Nanoparticles effects on diatom Thalassiosira pseudonana and cyanobacterium Synechococcus sp.**

A Burchardt[1], AV Valente[1], GD Gilliland[2], RNC Carvalho[1], GT Tanet[1], RP Passarella[1], VP Pedroni[1], FR Rossi[2], TL Lettieri[1]
[1]EU JRC/ Institute for Environment and Sustainability, ISPRA, Italy
[2]EU JRC, Institute for Health and Consumer Protection, ISPRA, Italy
Engineered nanoparticles are used in a wide range of industrial applications including electronics and commercial products. Because of their large surface area and high reactivity, nanosized metal particles display remarkable physical, chemical and biological properties (Maynard, Aitken et al. 2006; Nowack and Bucheli 2007) .
Silver nanoparticles (AgNP) are one of the most frequently used nanomaterials due to their antibacterial properties and it is likely that they will be released in the aquatic environment (Navarro, Piccapietra et al. 2008) , therefore it is critical to assess the potential toxic effects of AgNP on the aquatic organisms. We studied the toxicity of AgNP towards two selected organisms, the marine diatoms Thalassiosira pseudonana and the freshwater cyanobacterium Synecocchocus sp., and link those effects to the size of nanoparticles.
Furthermore, we developed a procedure to measure the kinetic release of silver ions from nanoparticles in marine and fresh water system to simulate the habitat of the diatoms and cyanobacteria, respectively.
The poster will show the growth inhibition of diatoms and cyanobacteria upon exposure to three different size of AgNP. The analysis of silver ions release into their respective media suggest that the observed effects of toxicity are due to the silver nanoparticles.

**Toxic effects of silver nanoparticles to natural freshwater microbial communities**

MK Halling, M Matzke, JA Gallego, M Hassellöv, T Backhaus
University of Gothenburg, GÖTEBORG, Sweden
The toxicity of silver nanoparticles (AgNPs) to aquatic natural freshwater microbial communities (biofilms composed of algae and bacteria) was determined. Those organism groups might be especially at risk when exposed to AgNPs since silver is known to possess specific antibacterial properties. The aim of the presented study was to evaluate the toxic effect of two sizes of AgNPs to natural freshwater microbial communities and to compare the toxicity of AgNPs with the bulk material, AgNO3. The study is part of the Nanosphere research environment, in which one overall aim is to investigate whether conventional testing approaches are valid for assessing the impact of engineered nanoparticles on aquatic ecosystems or whether (and which) adaptations are necessary.
The biofilms were exposed in natural water to a concentration series of 10-1000 nmol/L AgNP10 (total silver content, 10 nm nominal particle size, no coating) and 5-1000 nmol/L AgNP40 (total silver content, 40 nm nominal particle size, citrate coating) for four days under semi-static conditions. The toxicity of $AgNO_3$ treatments with the corresponding total silver concentrations was analysed additionally. Effects on the algal community fraction of the biofilm were studied by HPLC-based pigment profiling: growth was measured as chlorophyll *a* content, species composition and interferences with specific physiological processes were estimated as changes in pigment patterns. The activity and composition of the bacterial community in the biofilm was analysed by metabolic profiling in so-called ecolog-plates. 1000nmol/L AgNP40 completely inhibited algae as well as bacteria. 100 nmol/L AgNP40 caused only 40% algal growth inhibition, the same concentration of $AgNO_3$, however, still caused a 90% effect. The uncoated 10nm AgNPs caused no measureable growth inhibition at concentrations up to 1000 nmol/L. All experiments were backed up by analytical measurements, measuring total silver content (ICP-MS), dissolved Ag+ (ICP-MS after ultrafiltration or centrifuge-aided membrane filtration) and particle size distribution (NanoSight).

**WE 248**

**Assessment of silver toxicity to aquatic organisms: effect comparison of silver nanoparticles with ionic silver**

MAF Fernandes[1], FT Jesus[2], AJA Nogueira[2]
[1]Department of Biology, University of Aveiro, AVEIRO, Portugal
[2]CESAM & Department of Biology - University of Aveiro, AVEIRO, Portugal
Silver nanoparticles (Ag NPs) are used in about one quarter of the commercialized products made from engineered nanomaterials. Due to the higher surface area per mass of silver, Ag NPs have an higher release capability than bulk silver metal. The main goal of this work is to present the comparison of the toxicity of Ag NPs and $Ag^+$ to *Pseudokirchneriella subcapitata* and evaluation of the toxicity of Ag NPs to *P. subcapitata* and *Daphnia magna.* Algae were exposed to Ag NPs or $AgNO_3$ in medium TM2 and allowed to grow during 72h at 25ºC.
The growth inhibition rate was determined according to OECD Guideline 201. Acute tests with D. magna followed OECD Guideline 202 (acute immobilization tests) and were carried out in ASTM hard water. Neonates were exposed for 48 h to 0-250 µg/L of Ag NPs (experiment without food) and 175-400 ug/L Ag NPs (experiment with food: $3x10^5$ cells/ml/daphnid). Feeding inhibition tests with D. magna were conducted with juvenile daphnids (4th instar) exposed to 175-800 µg/L Ag NPs in the presence of food ($3x10^5$ cells/ml/daphnia) and allowed to feed during 6h in the dark. Feeding rates were determined using standard procedures.
Ag NPs are toxic to algae and daphnids at low concentrations: 348 µg/L. Tests with algae show that AgNPs are less toxic than the ionic form in a mass basis. Altough growth curves of *Daphnia* exposed to NP's in water and in algae do not exhibit differences between treatments, the size-specific fecundity is affected suggesting that energetics of daphnids is affected resulting in changes of relative allocation of resources to growth and reproduction.

**WE 249**

**Fate and effects of engineered silver nanoparticles in a terrestrial environment**

R Johnson, J Banks, E Boyd, C Suedel, A Weiss, J Bednar, G Coleman, A Steevens
US Army Engineer Research & Development Center, VICKSBURG, United States of America
Silver nanoparticles (nano-Ag) are engineered nanoparticles with the highest number of commercial applications due to its anti-microbial activity. Many nano-Ag products may be directly applied to soil (e.g., pesticide applications) or disposed in traditional landfills, resulting in possible leaching into surrounding soil. There is a paucity of information regarding the environmental fate and effects of nano-Ag, as well as guidance concerning the disposal of engineered nanoparticles. Thus, the aim of this study was to study the leachability of nano-Ag in soil, as well as the potential effects on terrestrial invertebrates (the earthworm Eisenia fetida). Soil column studies were conducted with field soil spiked with nano-Ag, micron (µm)-sized Ag, and polyvinylpyrrolidone (PVP)-coated nano-Ag (35 nm, 1.5-2.5 µm, and 20 nm, respectively, at 0.01 and 100 mg/kg) as a function of particle size, coatings, and/or leachate solution pH. Leachate samples were collected every hour for 48 hours and were analyzed for total Ag by inductively coupled plasma-mass spectrometry. The analysis revealed that for 100 mg/kg spiked soils, nano-Ag, micron-sized Ag, and PVP nano-Ag were not mobilized through the soil when leached with ultrapure water, however, silver mobility did increase when leached with a 1% nitric acid solution. The nano-Ag soil leached less Ag when compared to micron-sized Ag and PVP nano-Ag soil, yet Ag was detected earlier in the leachate series when the soil was spiked with PVP nano-Ag. The use of artificial rain water (pH 4.2 for eastern U.S., pH 5 for western U.S.) resulted in no Ag detected in leachate from all three spiked soils. Behavioral tests using E. fetida demonstrated that the earthworms did not avoid soil containing micron-sized Ag (NOAEL > 100 mg/kg), but earthworms did significantly avoid soils containing nano-Ag in a dose-dependent manner (NOAEL = 10 mg/kg, LOAEL = 100 mg/kg). However, PVP-coating of nano-Ag resulted in no soil avoidance similar to micron-sized Ag. The present experiments indicated that it is unlikely that Ag from engineered nano-Ag will leach from a soil system except under extremely acidic conditions, resulting in an increased potential for exposure to terrestrial organisms (e.g., epigeic and endogeic earthworms). However, terrestrial invertebrates will begin to avoid nano-Ag laden soil at sublethal concentrations, resulting in a reduced risk to terrestrial fauna.

**WE 250**

**Effects of titanium dioxide nanoparticles on aquatic invertebrates**

S Giebner, D Kaiser, C Völker, J Völker, M Oetken, J Oehlmann
Goethe University Frankfurt am Main, FRANKFURT, Germany
Photocatalytically active titanium dioxide nanoparticles ($nTiO_2$) are produced for large scale applications as component of desinfectants, self-cleaning glass, solar cells, electric devices, food additives, pharmaceuticals and cosmetic products. Due to its increasing use, it is most likely that $nTiO_2$ will enter the aquatic environment as a result of accidental spills during manufacturing, transport or its presence in waste and sewage.
Information on the ecotoxicity of nanoparticles in aquatic systems is rare. There are only few studies - by the majority on acute effects - on the toxicity of $nTiO_2$ using aquatic species as test organisms. Aquatic invertebrates are able to accumulate particles by means of water filtration and surface contact with the risk of consequent biomagnification along the food chain. *Daphnia magna* is a primary consumer in aquatic environments and an important food source for secondary consumers. Therefore we consider it important to understand biological responses of *D. magna* to $nTiO_2$.
In this study we investigated the impact of $nTiO_2$ (P25) with a nominal particle size of 21 nm in different concentrations on mortality and reproduction of *D. magna*. To analyse potential differences between different exposure routes, chronic reproduction tests were performed at two exposure systems: water and food. The size distribution and shape of P25 particles in aqueous media were assessed by dynamic light scattering (DLS) and scanning electron microscopy (SEM).
First results indicate that the chronic exposure of P25 to *D. magna* leads to an increased mortality and a reduced reproduction and growth. Feeding *D. magna* with exposed algae (*Scenedesmus obliquus*) even resulted in higher toxicity of $nTiO_2$ in comparison with the water exposure. Long-term exposure to P25 may affect populations of aquatic organisms and may accumulate along the food chain. The findings lead to the conclusion that food chain studies with *D. magna* appropriate to study potential environmental pathways of $nTiO_2$.

**Evaluation of TiO2 manufactured nanoparticles toxicity toward bacterial model in Seine freshwater**

LC Planchon[1], O Spalla[2], R Ferrari[3], F Guyot[4], N Menguy[4], A Gelabert[3], A Thill[2], MF Benedetti[3]
[1]CNRS/CEA, PARIS, France
[2]LIONS/CEA, SACLAY, France
[3]LGE/IPGP/CNRS, PARIS, France
[4]IMPMC/UPMC, PARIS, France

Despite the increased production and use of engineered nanoparticles (NPs), environmental concerns still remain owing to the potential toxicity of these components on human health and natural environment.
In the framework of two actions, a regional research network "C'Nano - En Seine"and the international Gdr I'CEINT, we are studying ecotoxicological impact of different NPs. Our main objective is to gain understanding at the microscopic scale of the interaction between micro-organisms and manufactured NPs [1,2,3] with a focus on the use of natural freshwater as the medium of contact. In the present work, the effects of $TiO_2$-NPs toward *Escherichia coli* have been assessed in the freshwater from the Seine river (Paris). The two components (bacteria and NPs) have been considered on an equal footing of importance. First, a complete characterization of NPs morphological and physico-chemical state during the contact has been carried out using Small Angle X-ray Scattering, AFM, cryo-TEM, zeta and DLS. This allows the set up of reproducible and standardized experimental protocols of contact. Then, their cytotoxicity toward E.coli (impacts on morphology, metabolism or survival) has been evaluated using both traditional methods (optical density and CFU counting) and new reliable microplate techniques. In order to understand the toxicity mechanisms, the interaction between bacteria wall and NPs has been observed at the nano-scale thanks to accurate imagery techniques such as Transmission Electron Microscopy (TEM) or Atomic Force Microscopy (AFM).
The correlations between the state of dispersion of the NPs, their concentration, chemical nature and the toxicity will be presented.

**WE 252**

**Impact of nano-TiO2 to marine organisms: Phaeodactylum tricornutum and Artemia franciscana**

D Minetto, GL Libralato, CL Losso, AVG Volpi Ghirardini
Cà Foscari University, VENICE, Italy

Nano-TiO2 is employed in different categories of products for its antibacterial and depollutant properties (i.e. in air and water depuration systems, as road and pavement additive for NOx abatement or on self-cleaning surfaces) due to its ability to generate hydrossic radicals. Anyway, it is massively use (about 70%) in most common consumer products like cosmetics and sun-screens. Thus, it has been recognised that it enters directly or indirectly into the marine environment where salinity and ionic strength may act on the stability of nano-TiO2 dispersions. In particular, it may be affected the size of their aggregates, potentially speeding up nano-particles sedimentation processes. As a result nano-TiO2 bioavailability is continuously changed, making the analysis and interpretation of results really hard. The purpose of this study is to evaluate the in vivo toxicity of nano-TiO2 via the growth inhibition test with the unicellular green alga *Phaeodactylum tricornutum* and the anostracan crustacean *Artemia franciscana* following the relative standardised protocols. In the case of *A. franciscana* besides the traditional exposure conditions, two alternative scenarios were considered: "no light, but feeding"to observe potential photocatalytic effects and "no feeding, but light"to verify effects on starvation. Results evidenced an EC50 in the range 25-64 mg L-1 to *P. tricornutum*, while toxic effects were observed to A. franciscana after 24 h between 25-67 mg L-1. The scenario "no light, but feeding", highlighted that the absence of light reduced the nano-TiO2 toxicity, leading to the observation of very slight toxic effects after 24-96 h exposure (maximum affect at 96 h = 47% at 16 mg L-1). The scenario "no feeding, but light"showed increased toxicity level at all exposure times, in particular the maximum effect was identified after 96 h.

**WE 253**

**The effect factor for nano TiO2: preliminary toxicity tests on Daphnia magna and future developments**

S Righi[1], BS Salieri[1], AP Pasteris[1], EB Borsella[2], RD D'Amato[2]
[1]University of Bologna, RAVENNA, Italy
[2]ENEA-UTRAPAD, FRASCATI (ROME), Italy

Nanotechnologies are being developed for application in a large variety of sectors, from food industry to environmental remediation technology. However, numerous uncertainties exist regarding their possible impacts on the environment and human health. The Life Cycle Assessment (LCA) methodology could be a tool to evaluate, analyze and manage the environmental and health effects for the emerging technologies. The evaluation of the environmental performance of nanotechnologies trough LCA is not always possible due to the lack of data regarding the environmental pathway of NPs. The focus of the present research is to evaluate the freshwater ecotoxicological Effect Factor (EF) for TiO2 nanoparticles (which are widely used in different applications as sunscreens, solar cells, ecc.), following the framework of the USEtox model. This model is used for the Life Cycle Impact Assessment (LCIA) phase and is aimed to provide the Characterization Factor (CF) for the ecotoxicity impact category. The CF is quantified trough the evaluation of the Fate Factor (FF) and Effect Factor (EF). The latter is based on chronic or acute toxicity value as EC50. In order to establish the acute EC50 for nano TiO2, two preliminary toxicity tests on Daphnia magna (72h) have been performed. The particles were prepared following two different treatments. In the first case the nano TiO2 suspensions were stirred for 24 h only before the test; in the second case the particles were maintained in agitation also for the whole duration of the bioassay. No adverse effects have been observed for the concentration applied, this contrasts with the findings of other studies that reported effects of nano TiO2 on D. magna. The future developments of our research are to conduct other toxicity tests on D. magna, following different treatments of the sample (example: irradiation with UV-A, filtration etc), and to conduct toxicity test on different trophic level (algae, crustaceans, fish) as suggested by USEtox framework. The research is intended to identify suitable treatments for nanoparticles to be used in toxicity test, taking into account their tendency to aggregate and precipitate and that this could influence the results of the tests. The suitable treatment should also reproduce the actual exposure modality of the organisms in the field.

**WE 254**

**Environmental fate of aquatic nanoparticles: case study TiO2 NP**

JA Gallego Urrea, J Perez-Holmberg, CM Jonsson, A Bijedic, A Toab, M Hassellöv
University of Gothenburg, GOTHENBURG, Sweden

Titanium dioxide nanoparticles were synthesized using a wet-chemical method based on the hydrolysis of TiCl4. Stable suspensions of positively-charged TiO2 were obtained at pH 2.5. One batch of this product was quickly shifted above of the point of zero charge to pH 12. These stock dispersions were used in batch adsorption experiments with three different types of well characterized macromolecules, Sodium alginate, Fulvic acid and Humic acid, and evaluated in terms of final surface charge (Zeta potential), final size and adsorption efficiencies.
The stability of nanoparticle dispersions with and without sorbed molecules was investigated by monitoring the aggregation behaviour of TiO2 nanoparticles in different electrolyte environments (NaCl, CaCl2 and Na2SO4) and at varying pH. these aggregation rates were used to determine the attachement efficiencies as a function of pH, counterion valence and macromolecule concentration. These attachement efficiencies can be related to more complex mathematical models in order to evaluate and predict the effects of environmental macromolecules on the fate of aquatic nanoparticles.

**WE 255**

**Interactions between TiO2 nanoparticles and cadmium: consequences for uptake and ecotoxicity**

B Hartmann, A Baun
Technical University of Denmark, KONGENS LYNGBY, Denmark

As a consequence of the increasing use of engineered nanoparticles in e.g. industrial applications and consumer products, these particles will be released into the aquatic environment. They will be present in the water phase where they are likely to form aggregates/agglomerates. Through sedimentation, the sediments are expected to be a sink for nanoparticles. Both in the water phase and in sediments they will mix and interact with other environmental pollutants, including heavy metals. In this study the toxicity of cadmium to three relevant freshwater species, green algae Pseudokirchneriella subcapitata, crustacean Daphnia magna and sediment organism Lumbriculus variegatus, was investigated both in the absence and presence of TiO2 nanoparticles. Also uptake of cadmium in D. magna and L. variegatus was investigated in tests where organisms were exposed to cadmium in sublethal concentrations in the absence and presence of 2mg/L TiO2 nanoparticles (P25 Evonic, d: 30 nm). Mass balances for cadmium in the test systems were determined. A high degree of sorption of cadmium onto TiO2 particles was found, which makes TiO2 nanoparticles potential carriers for cadmium. The observed toxicity was higher than expected based on water phase cadmium concentrations, and results shows that adsorbed fraction of cadmium is bioavailable.

**WE 256**

**Fate and behaviour of three different TiO2 nanomaterials in soils**

C Nickel[1], B Hellack[1], St Gartiser[2], St Gabsch[3], M Stintz[3], A Schaeffer[4], S Damme[4], L Erdinger[5], TAJ Kuhlbusch[1]
[1]Institute of Energy and Environmental Technology - IUTA e.V., DUISBURG, Germany

[4]RWTH Aachen University - Institute for Environmental Research, AACHEN, Germany
[5]Universitätsklinikum Heidelberg - Dept. of Medical Microbiology and Hygiene, HEIDELBERG, Germany

Titanium dioxide nanomaterials are commonly used in many everyday life products (e.g. paints, cosmetics). First studies indicated that nanomaterials can be released from products during their life cycle (Kaegi et al. 2008) and can reach the environment.
In the presented study laboratory experiments were performed to investigate the fate and behaviour of different (functionalised and non-functionalised) TiO2 materials (P25, PC105, UVTitanM262) in soil compartments. More specifically adsorption / desorption tests and the mobility studies in soil columns in a laboratory scale were conducted (according to OECD Guidelines No 312 and 106). Different soil types were used to identify and assess the effect of different soil characteristics like clay content, pH-value, organic matter, grain size or cation exchange capacity on the adsorption and mobility behaviour.
Preliminary results showed no mobility of the titanium dioxide nanomaterial in soil columns, if dry powder of the titanium dioxide material were applied to the soil before percolation with water. Therefore titanium dioxide powders suspended in water containing smaller agglomerates (compared to the powder) were used in the following investigations, for which a higher mobility of TiO2 was expected. A Standard Operating Procedure (SOP) for maintaining stable nanomaterial suspensions with respect to a constant particle size distribution and zeta potential for a minimum of 24h, essential for such experiments, is currently evaluated in a round-robin test. Detailed results on the mobility of nanomaterials in soils under such conditions will be presented and discussed.
This study was sponsored by the Federal Environment Agency (UBA) within the framework of the "Umweltforschungsplan" - FKZ 3709 65 417: " Environmental risk of nanomaterials: Environmental fate of selected nanomaterials in relation to shape, size and surface properties ".

**Behaviour of nanoscale titanium dioxide in laboratory wastewater treatment plants according to OECD 303A**

S Gartiser[1], C Nickel[2], M Stintz[3], S Damme[4], A Schaeffer[4], L Erdinger[5], TAJ Kuhlbusch[2]
[1]Hydrotox GmbH, FREIBURG, Germany
[2]Institute of Energy and Environmental Technology e.V, DUISBURG, Germany
[3]TU Dresden - Institute of Process Engineering and Environmental Technology, DRESDEN, Germany
[4]RWTH Aachen University - Institute for Environmental Research - Biology V, AACHEN, Germany
[5]Universitätsklinikum Heidelberg - Dept. of Medical Microbiology and Hygiene, HEIDELBERG, Germany

Titanium dioxides are used in huge amounts as white pigment or UV-filter in consumer products such as paints, paper coatings, plastics, and sunscreens. Industrial applications include its use in self-cleaning coatings as well as a photocatalyst in advanced wastewater treatment. The use of nanoscale $TiO_2$ is predicted to increase in the near future. While the clearance efficiency of microscale $TiO_2$ (> 0.7 µm) in sewage treatment plants (STP) has been determined to be in the order of 70-85% (Kiser et al. 2009), no data on the behaviour of nanoscale $TiO_2$ in STP are available so far.
In the presented study the fate and behaviour of $TiO_2$ nanomaterials (P25 with an average

particle size in suspension < 250 nm) in the laboratory sewage treatment plants simulation test (LSTP) according to OECD Guideline 303A has been investigated. The nanoscale suspensions were stabilised with sodium metaphosphate (SMP) and added continuously in a ten-fold concentrated suspension to reach a final concentration of 1, 5, and 10 mg $L^{-1}$ $TiO_2$ and 1 g $L^{-1}$ SMP. The organic synthetic wastewater (final concentration 50 mg $L^{-1}$ DOC) was added as a concentrate to matrix of synthetic drinking water. After one week acclimatisation the test was run for one week per concentration. Sampling for TiO2 measurement was carried out daily in the outflow and in the surplus sludge for enabling a $TiO_2$ balance.
The biodegradation and nitrification of the synthetic wastewater in the test LSTW was comparable to that of the reference LSTP (DOC-Elimination 98%-100%, $NH_4$-N < 0.2 mg $L^{-1}$).
In the outflow of the test LSTP an increase of suspended solids (activated sludge flocs) was observed which was explained with the use of the dispersant SMP. Preliminary results of the $TiO_2$ measurements indicate that more than 90% of the nanoscale $TiO_2$ introduced was bound to the activated sludge.
This study was sponsored by the Federal Environment Agency (UBA) within the framework of the "Umweltforschungsplan" - FKZ 3709 65 417: " Environmental risk of nanomaterials: Environmental fate of selected nanomaterials in relation to shape, size and surface properties.

### WE 258
**Ecotoxicity of photocatalytically active titanium dioxide nanoparticles: the impact of UV-exposure on toxicity to Caenorhabditis elegans**
J Angelstorf, S Heise
Hamburg University of Applied Sciences, HAMBURG, Germany
Titanium dioxide nanoparticles (nTiO2) are used in a variety of consumer products like cosmetics, paints and self-cleaning surfaces. The detection of nTiO2 in facade runoff and surface waters nearby indicates that at least part of the nTiO2 is released into the aquatic environment (Kaegi et al. 2008). With the number of applications still rising, it has been suggested, that also the flux to the environment will increase significantly within the next years. The knowledge concerning the ecotoxicological relevance of TiO2, however, is still very fragmentary and insufficient for reliable risk analysis.
In this study we will try to elucidate the impact of light exposure on the toxicity of TiO2 doted sediment in the presence of photosensitive contaminants.
As test organisms, the nematode *Caenorhabditis elegans*, a multicellular model organism living in soil was chosen because of its ecological relevance. Within the range of TiO2-nanoparticles, P25, a photocatalytically active titanium dioxide with a nominal particle size of 21 nm was applied. In nematode testing without light exposure, P25 only showed a significant effect at relatively high concentrations (35 % reduction in progeny at 100 mg nTiO2/L). As nTiO2 is a photocatalyst and induces the formation of reactive oxygen species in cells when exposed to UV irradiation we are currently testing the following hypotheses:
a) (Prolonged) irradiation leads to elevated toxicities of nTiO2 and indicates an elevated risk for those ecosystems exposed to both, sunlight and nTiO2 at the same time.
b) As a photocatalyst, TiO2 influences the toxicity of co-contaminants via photo modification or photosensitization processes.
First results of the ongoing exposure experiments will be presented in this poster.
Kaegi et al. 2008. Synthetic TiO2 nanoparticle emission from exterior facades into the aquatic environment. Environmental Pollution 156(2), 233-239.

### WE 259
**CdSe quantum dots in seawater: chemical stability and effects on a marine microalga**
E Morelli, E Balestreri, P Cioni, E Gabellieri
CNR - National Research Council, PISA, Italy
QDs are nanocrystals with a heavy metal-containing reactive core, exhibiting unique optical properties, which make them one great promise for biomedical and microelectronic technologies. Because of their increasing use, it is expected that they end up in natural water bodies, from freshwater to the sea. Lack of knowledge about the stability and bioavailability of these newly synthesized particles in the aquatic systems represents a novel problem for the environment. Only very recently, some papers report data on the transformations of QDs in aquatic environments and toxicity in living organisms. The few studies regard freshwater systems and so far, to our knowledge, no study has been carried out in seawater. In the present work we report preliminary results on: 1) the characterization of the chemical behaviour of QDs in seawater; 2) the uptake and response of the marine diatom Phaeodactylum tricornutum to QD exposure. To this purpose, CdSe QDs (Sigma) were solubilised in water by encapsulating with the amphiphilic polymer PSMA (poly(styrene-co-maleic anhydride)) and ethanolamine (Lees et al., 2009. ACSNano 3: 1121-1128). After dispersion in natural seawater, the optical properties were followed as a function of time and salinity. Absorption spectra of water-soluble QDs exhibited a steady increase in absorbance as the wavelength decreased from 600 nm towards the UV-region, with a characteristic peak at 540 nm. The time course of the absorption spectra after re-suspension in seawater exhibited a progressive flatting of the peak at 540 nm, suggesting a partial degradation of the nanoparticles. This effect decreased at lower salinity. The interactions between the microalga and QDs were tested by measuring: 1) the cellular concentration of Cd, 2) the synthesis of phytochelatins (PCs) as a biomarker of the bioavailability of heavy metals, 3) the activity of antioxidant enzymes as an indication of oxidative stress. Short-term experiments (5 h) showed that P. tricornutum responded to QDs exposure by synthesizing PCs and by increasing the intracellular pool of glutathione. The presence of PCs suggests the occurring of bioavailable Cd species, derived from a partial degradation of QDs. Since glutathione is a main cellular antioxidant, the concomitant increase of glutathione seem to suggest the occurring of oxidative stress. Experiments are in progress to assess the enzymatic antioxidant response of P. tricornutum.

### WE 260
**Stability and uptake by daphnia of QDs with three different coatings in synthetic fresh water**
BT Lee[1], F Ranville[2]
[1]Gwangju Institute of Science and Technology, GWANGJU, South-Korea
[2]Colorado School of Mines, GOLDEN, United States of America
CdSe/ZnS quantum dot (QD) is widely used for biomedical purpose as a diagnostic tool. Its exposure into environment is being a threat against the ecosystem by releasing toxic metals such as Cd and Se as well as nanoparticle itself. CdSe/ZnS coated with three different polymers (amphiphilic polymer, amphiphilic polymer/PEG, and amphiphilic polymer/PEI) were purchased and introduced into synthetic surface water (hard, moderately hard, and soft water). Optical properties were measured with time and sedimentation was observed with the change of Cd concentration at the upper layer of suspension by ICP-AES. Different coatings had significant role in the sedimentation. PEG coated QDs which had neutral surface charge significantly sedimented in all synthetic waters and loosed optical property measured by fluorescence. Highly positive charge on PEI QDs remained stable for 48h. Interestingly, fluorescence of PEI QDs significantly increased with time in all three synthetic waters. All QDs did not release Cd and Zn for 48 h. Daphnia uptakes and depurations were monitored in moderately hard water by measuring Cd concentrations in daphnia. Three QDs were well accumulated into daphnia for 24 h. During uptake, dissolved Cd concentrations increased significantly implying in-vivo dissolution of QD by daphnia. QDs with neutral and negative charge at surface depurated quickly from daphnia while significant amount of positively charged QDs remained in daphnia after 48 h depuration. The study concluded that surface coatings played significant role in bioaccumulation by daphnia as well as stability in fresh water.

**Effects of nano sized CuO and ionic Cu: Toxicity to Daphnia magna and tight epithelial cells**
A Thit[1], H Selck[1], HF Bjerregaard[1], S Misra[2], D Berhanu[2], A Dybowska[2], P Reip[3], E Valsami-Jones[2]
[1]Roskilde University, ROSKILLDE, Denmark
[2]Natural History Museum, LONDON, United Kingdom
[3]Intrinsiq Materials Ltd, FARNBOROUGH, United Kingdom
Nanoparticles (NPs) have unique chemical and physical properties caused by their small size and high surface area to volume ratio. This means that the NPs can be more reactive and potentially more toxic than their bulk counterparts. This study focuses on toxicity of two CuO NPs; monodispersed spherical 7 nm and highly polydispersed polyhedral 10-100 nm, respectively, compared to copper ions (Cu2+) to the crustacean Daphnia magna and epithelial kidney cells from the aquatic toad Xenopus laevis (A6 cell line) as a model for tight ion-transporting epithelia. D. magna was exposed to both CuO NPs and Cu2+ for 48 h according to OECD Guideline 202. In addition, epithelial cells (dividing and differentiated cells) were also exposed to CuO NPs and Cu2+ in an in vitro study for up to 7 days. The study demonstrated similarity in the toxicity of CuO NPs (7 nm) and Cu2+ to D. magna, whereas toxicity of polydispersed CuO NPs occurred at much higher concentrations. For epithelial cells, exposure to both sizes of CuO NPs and Cu2+ caused significant increases in cell death (most likely via apoptosis), and morphological changes, but after different times of exposure. For cells exposed to polydispersed CuO NPs the increase in apoptotic bodies occurred within 48 h of exposure, whereas the effects of both CuO NPs (7 nm) and Cu2+ occurred much later (after 3 and 5 days of exposure, respectively). The mechanisms by which the copper forms exhibit toxic effects differ such that Cu2+ and CuO NPs (7 nm) decrease cell proliferation and influence cell cycle progression, whereas polydispersed CuO NPs cause the formation of apoptotic bodies almost instantaneously. Furthermore, the effects of the different forms of copper on cells seem to depend on cell cycle stage. The implications from the study are that the toxic effects of copper depend on the form and size of the metal oxide particles.

### WE 262
**Copper oxide nanoparticles induce oxidative stress, DNA strand breaks and laccase activity in aquatic fungi**
A Pradhan[1], D Schlosser[2], S Seena[3], S Helm[4], K Gerth[4], D Wesenberg[4], C Pascoal[3], F Cássio[3]

[4]Institute of Biochemistry and Biotechnology, Martin-Luther-University, HALLE (SAALE), Germany
The extensive use of nano metal-based products increases the chance of their release into aquatic environments and may put biota and associated ecological processes at risk. Fungi play a key role in organic matter turnover in freshwaters while they transfer carbon and energy to higher trophic levels. Although aquatic fungi are common in clean and well-aerated freshwaters, they also occur at hyperpolluted sites. We investigated the effects of nano CuO (4 levels, ≤ 100 mg $L^{-1}$) on fungal biomass production, extracellular laccase activity, accumulation of reactive oxygen species (ROS), plasma membrane integrity and occurrence of DNA strand breaks, after 5 and 12 days, in 4 fungal isolates: *Phoma* sp. UHH 5-1-03 (Ph) and *Articulospora tetracladia* UMB-072.01 (At72) collected at clean sites, and *A. tetracladia* UMB-061.01 (At61) and *Heliscus lugdunensis* H-4-2-4 (H4) collected at polluted sites. Fungal biomass was inhibited by the increase in nano CuO concentration and incubation time. After 12 days, the strongest inhibition in biomass production was found in At72 (95.5%) and Ph (81.2%) exposed to 100 mg $L^{-1}$ nano CuO, while the lowest effects were observed in At61 (59.4%). Laccase activity was induced by all nano CuO concentrations after 12 days, except in At61; maximum activities were found in Ph followed by At72 and H4 (2823, 474 and 166 U $g^{-1}$, respectively) when exposed to 100 mg $L^{-1}$ nano CuO. ROS accumulation increased with increasing nano CuO concentration at both times in all fungi. After 12 days, severe plasma membrane disruption was found in At72 exposed to all nano CuO concentrations and in Ph exposed to 100 mg $L^{-1}$ nano CuO. Severe DNA strand breaks were observed in At72 and Ph exposed longer to 100 mg $L^{-1}$ of nano CuO. The increase in nano CuO concentration and exposure time led to an increase in DNA strand breaks, which is a signature of an apoptotic process. Overall results suggest that nano CuO is toxic to aquatic fungi, particularly to those isolated from clean streams.

### WE 263
**Effects of copper on Enchytraeus crypticus (Oligochatea): comparison of exposure to Cu-NP, Cu-salt and historical contamination, including in depth characterisation**
SIL Gomes[1], MJB Amorim[2], MT Nielsen[3], SM Christiansen[3], AMVM Soares[2], JJ Scott-Fordsmand[4]
[1]University of Aveiro & CESAM, AVEIRO, Portugal
[2]Dept Biology & CESAM, University of Aveiro, AVEIRO, Portugal
[3]Department of Earth Sciences, Aarhus University, AARHUS, Denmark
[4]Dept Terrestrial Ecology, NERI, Aarhus University, SILKEBORG, Denmark
The aim of this study was to compare the effects on Enchytraeids of copper-nanoparticles (Cu-NP) laboratory spiked soil, with copper-salt (Cu(NO3)2) laboratory spiked soil, and with soil contaminated in the field. Enchytraeids are small soil inhabiting oligochaetes, which actively contribute to the acceleration of organic matter decomposition and nutrient recycling processes. In the study we used a broad series of different characterization techniques including both direct and indirect measures of nanomaterials, including possibly presence of ions in the soils pore

water. The measures were attempted to link with the survival and reproduction of Enchytraeus crypticus. Results showed clear reproductive effect of all forms of Cu, the effects were more pronounced by exposure to the Cu-salt form, than the Cu-NP, and with field soils causing least effects. The physical chemical characterization displayed differences between all exposures regimes, although free ions measures were not able to explain differences in toxicity. The physical chemical characterization could to some extend explain toxicity observed.

**WE 264**

**Nano copper oxide is a threat to an endemic shredder of the Iberian Peninsula**

A Pradhan[1], S Seena[2], C Pascoal[2], F Cássio[2]
[1]CBMA,, BRAGA, Portugal
[2]CBMA, Department of Biology, University of Minho, BRAGA, Portugal

The increased usage of nano metal-based products enhances the possibility of its release into freshwater ecosystems and this may put aquatic biota and ecological processes at risk. Invertebrate shredders mostly use leaf litter as a food resource and play a key role in the energy and nutrient transfer in aquatic detritus foodwebs. In this study, we assessed the sublethal toxicity of nano CuO on the growth and feeding behaviour of larvae of the shredder *Allogamus ligonifer* (Thricoptera, Limnepilidae), an endemic species in streams of the Iberian Peninsula. The experiment was carried out in glass containers with sterile stream water, each housing a larva (15 replicates). The invertebrates were allowed to feed for 10 days on microbially colonized alder leaves according to the following treatments: (1) leaves previously treated for 5 days with 25 or 75 mg $L^{-1}$ nano CuO and stream water, (2) untreated leaves and stream water with 25 or 75 mg $L^{-1}$ nano CuO, and (3) untreated leaves and untreated stream water (control). The experiment was replicated in the absence of invertebrates to discriminate the contribution of microbes to leaf litter decomposition. Microbes contributed with 23% to total leaf mass loss in control, and microbial decomposition decreased with the increase of nano CuO concentration. Leaf consumption rate by the invertebrate was 0.27 mg leaf DM $day^{-1}$ $mg^{-1}$ animal DM. The highest inhibition of leaf consumption (48 %) was found in the treatment in which the animals were exposed to water with 75 mg $L^{-1}$ nano CuO, followed by the treatment in which the animals were fed on leaves previously exposed to 75 mg $L^{-1}$ nano CuO (26%). A similar response pattern was found for the growth rate of invertebrates when exposed to nano CuO via stream water or leaves (56 in control vs 30 and 41 µg individual DM $mg^{-1}$ individual DM $day^{-1}$ in treatments). Results will be interpreted based on the adsorption and accumulation of nano and/or ionic copper in invertebrates (body and case) and leaves.

**ZnO nanoparticles in soil: testing different spiking procedures**

PL Kool, M Diez Ortiz, CAM van Gestel
Vrije Universiteit, AMSTERDAM, The Netherlands

Due to complex behaviour of nanoparticles in soil, realising realistic exposure in ecotoxicity testing poses major challenges. Soil by definition is heterogeneous, which requires conscientious introduction of any test compound and oftentimes sub-samples are analyzed to ensure a homogeneous distribution of the compound. In general, manufactured nanoparticles are insoluble in water, making it a difficult task to obtain homogeneity of nanoparticle distribution in spiked soil. Depending on their physical and chemical properties as well as soil properties, nanoparticles tend to form aggregates and are likely to settle within a relatively short time. The present study investigates the spiking of natural soil with two sizes of zinc oxide particles (30 and 200 nm) using two different spiking procedures, namely as dry powder and as suspension in soil extract.
Five samples per treatment were randomly taken from the batches of spiked soil and analysed for total zinc concentration by flame Atomic Absorption Spectrometry. Scanning electron microscopy (SEM) was applied in an attempt to visualize zinc oxide nanoparticles in our test soil. SEM did not allow to see whether particles were present as such or as aggregates or agglomerates. Both spiking procedures show a good recovery (> 85%) of the metal zinc and based on total zinc concentrations no difference was found between the two spiking methods. Both spiking procedures resulted in a fairly homogeneous distribution of the zinc oxide nanoparticles in soil, as evidenced by the low variation between replicate samples (<10% in most cases). We conclude that spiking with dry powder or suspension does not influence zinc distribution in the soil.

**WE 266**

**Evaluation of the bioavailability of nanosized and bulk ZnO in soils and solutions using two recombinant sensor bacteria**

M Diez, PL Kool, CAM van Gestel
Institute of Ecological Sciences, AMSTERDAM, The Netherlands

The environmental hazard of metal-containing nanoparticles (NPs) in soils depends to a large extent on their bioavailability. The approach used in this study enables the determination of bioavailable fractions of metals from metal-containing NPs in a combined approach involving chemical analysis and recombinant metal-specific microbial sensors. Bioavailability of Zn was evaluated in aqueous solutions and soil suspensions spiked with nano ZnO, bulk ZnO and $ZnCl_2$ and compared with the bioavailability of Zn in the soil pore water from freshly spiked and 3 months aged soils using the recombinant zinc sensor bacteria *Pseudomonas fluorescens* (OS8::KnztRPzntAlux) and *Escherichia coli* MC1061 (pSLzntR/pDNPzntAlux). The soil used was Lufa 2.2. standard soil. Bulk ZnO and the respective soluble salt ($ZnCl_2$) were used as controls for size-dependent and solubility effects. Response of the sensor bacteria to bioavailable Zn was detected by an increase in luminescence and expressed as increased induction (folds) of luminescence compared to the background values. $Zn^{2+}$ from $ZnCl_2$ was considered 100% bioavailable and used as standard. Luminescent control strains *P. fluorescens* (OS8::Knlux) and *E. coli* MC1061 (pDNlux), not induced by zinc, were used to correct for potential reduction in luminescence by turbidity/color of samples. Zn concentrations in all solutions were measured by atomic absorption spectroscopy.
At Zn concentrations up to 10 mg $l^{-1}$, ZnO (nano and bulk) was fully dissolved and bioavailable in Milli Q water. However, when spiked to soil extracts, only 30 % and 15 % of Zn proved bioavailable for bulk ZnO and ZnO NP, respectively. Chemical analysis showed that both nano and bulk ZnO yielded similar dissolved Zn concentrations with only 1 to 5 % of the total Zn extracted from the soil into the soil pore water. Higher Zn concentrations were measured in soil pore water after 3 months ageing under laboratory conditions. The bioavailability of ZnO (bulk and nano) measured with the biosensor bacteria, ranged from 1% to 5% in freshly spiked soils and 5% and 11% in aged soils.

**Comparative investigation of zinc oxide nanoparticles and ionic zinc toxicity towards soil organisms**

S Manzo, ML Miglietta, G Rametta, R Carotenuto, F de Luca Picione, A Rocco, G di Francia
ENEA, PORTICI (NAPLES), Italy

The huge advances of nanotechnologies pose an urgent need in the development of analytical tools to correctly assess the related potential risks for the environment and human health. A high priority is given to the toxicity assessment of ZnO nanoparticles (NPs) which potential toxicological impact is still largely unexplored with the exception of freshwater systems and some studies on humans [1,2,3]. In most of these cases, soluble $Zn^{2+}$ from ZnO seems to be the main source for the (eco)toxicity [1]. In comparison to freshwater, much less data were reported on the NPs effects in soils although the soil solid phase is a primary, large sink for any human waste.
In this work the impact of ZnO NPs on terrestrial organisms was comparatively investigated with the one produced by the same amount of ionic zinc, together with the evaluation of the contribution of the soluble fraction of ZnO NPs, as $Zn^{2+}$. At this aim, a battery of toxicity contact tests with different organisms: *L. sativum*, *H. incongruens*, *F. candida* and a genotoxicity test with *V. faba* were performed. The OECD soil samples spiked with ZnO NPs and $ZnCl_2$ were extensively characterized to verify the actual dimension of the dispersed nanoparticles and the oxide solubility.
An overall higher toxic effect of ZnO NPs in its insoluble, nanostructured form with respect to the one exerted by the same amount of ionic zinc was observed. The ostracods were the most sensitive organisms showing a clear link to stress/stimuli caused by the peculiar characteristics of the nanostate. *L. sativum* was also mainly affected by ZnO NPs, while collembolan reproduction test produced similar results for both the zinc forms. Slight genotoxic effects with *V. faba* micronucleus test were observed with both soils.

**Do nanoparticles create super-stress for all growth stages in isopods?**

GC Ferreira[1], P Tourinho[1], A Amaro[1], MVM Soares[1], CAM van Gestel[2], S Loureiro[1]
[1]CESAM & Dep. Biology, University of Aveiro, AVEIRO, Portugal
[2]Vrije Univ Amsterdam, Dpt Anim Ecology, AMSTERDAM, The Netherlands

In a field situation, populations of organisms exposed to a stressor generally consist of organisms representing large ranges of age, growth or moulting stage and gender ratio. To reduce variation in responses, laboratory toxicity tests usually use age-synchronized animals of pre-determined age, size and gender ratio.
Over the last years several ecotoxicity studies have been focused on the comparison of several endpoints (e.g. survival, reproduction) when organisms are exposed to stressors, but no information has been presented considering effects within different life stages and related to life-stage specific sensitivities or detoxification capacities.
In this study, terrestrial isopods (Porcellionides pruinosus) from three life stages (juveniles, pre-adults and adults) were exposed during a 7-day period to bulk zinc oxide (ZnO) and nano zinc oxide (nano- ZnO) particles using a concentration below the EC50 for all stages.
Biomarkers (e.g. AChE, LPO, GST, CAT, etc.), energy reserves content (lipids, carbohydrates and proteins), energy consumption and cellular energy allocation (CEA) were determined after exposure. Results showed a correlation between responses and life stages. As expected, oxidative stress was observed upon exposure to both bulk ZnO and nano-ZnO and the physiological adaptation to these stressors was not equal for all stages. Biomarkers did not respond or evolve in the same way when considering the different age ranges.

**WE 269**

**Comparing ecotoxicity of nano and bulk forms of CeO2**

T Sovova, V Koci, H Motejlova
Institute of Chemical Technology in Prague, PRAGUE, Czech Republic

The development and use of engineered nanomaterials (NMs) is increasing at an ever accelerating rate even if little is known about their likely inputs, fate, behaviour and effects in the environment. Moreover, concerns are being expressed whether NMs would not pose a serious environmental threat.
Ecotoxicological data concerning nanomaterials are also generally lacking even if the investigation of the environmental effects on NMs is of utmost importance, especially in the aquatic environment since it will ultimately receive the run-off and wastewater from domestic and industrial sources and has been targeted for some nano-scale environmental remediation techniques. Already published ecotoxicity studies have shown that in many cases, NMs may pose an increased health and environmental risk if compared to bulk forms of the same substances.
The aim of this work was to evaluate acute aquatic toxicity of $CeO_2$, in both nano and bulk forms. The nano $CeO_2$ is being used in ceramics, optics, as a cleansing agent and has been tested as a gasoline additive to enhance combustion. We have tested several types of nano $CeO_2$ that differed in particle size and method of preparation. The toxicity was evaluated using a soil worm *Enchytraeus crypticus*. The tests confirmed differences in toxicity between the nano and bulk form and between the different forms of nano $CeO_2$.

**WE 270**

**On the controversial biological response of a model aquatic organism exposed to single walled-carbon nanotubes**

J Bonzongo, X Youn, N Mclaughlin, J Clar, B Deputy
UNIVERSITY OF FLORIDA, GAINESVILLE, United States of America

This study investigates the biological response of P. subcapitata exposed to single-walled carbon nanotubes (SWNTs). The effects of SWNTs and surfactant types and concentrations on P. subcapitata were determined. Changes in algal biomass and cell morphology associated with specific SWNT-treatments and types were monitored, and the mechanisms of the different biological responses investigated through a combination of biochemical and spectroscopic methods. Results show either growth inhibition or stimulation depending on the type of surfactant used, and the speciation of SWNTs into metallic versus semi-conducting fractions. Trends of glutathione concentrations determined in culture media and the presence of high levels iron-based impurities in SWNTs used suggested the presence of reactive oxygen species and the resulting induced oxidative stress as main cause of observed growth inhibition. TEM observations of control and treated algal cells and the determination of SWNT aggregation states in culture media through spectroscopic techniques were used to investigate other potential toxicity mechanisms

**WE 271**

**Assessment of the toxicity of organic and inorganic nanomaterials on two species of freshwater green algae**

TP Galindo[1], RMO Pereira[1], TAP Rocha-Santos[2], MGBV Rasteiro[3], AMVM Soares[1], FJM Gonçalves[1], IMCA Lopes[1]
[1]University of Aveiro, AVEIRO, Portugal
[2]Instituto Piaget Viseu, VISEU, Portugal
[3]Department of Chemical Engineering, COIMBRA, Portugal

Nanotechnology refers to the manipulation and study of structures and devices with size scales in the range of 1-100 nanometers, in at least one dimension. The research of nanotechnology has grown exponentially in the last decades, contributing to the release of these newly produced materials to the environment, namely to the aquatic ecosystems. Algae are essential in aquatic ecosystems since they are the first trophic level in the food chains and the group providing oxygen and organic substances to other forms of life, guaranteeing the sustainability of freshwater ecosystems. Accordingly, this study aimed at investigating the effects of aqueous media contaminated with seven nanomaterials (NM) (vesicles of sodium dodecylsulfate-dodecyldimethylammonium bromide SDS/DDAB, vesicles of monoline/sodium oleate Mo/NaO, Fe/Co, nanogold rods, quatum dot LumidotTM CdSe/ZnS 530, TiO2, and TiSiO4) in the growth rate of two species of green algae: Pseudokirchneriella subcapitata and Chlorella vulgaris. The toxicity of NM contaminated media for these two species of green algae was studied by conducting 72-h growth inhibition tests. Each species was exposed to a series of ten dilutions of each NM-contaminated media. The zeta potential, hydrodynamic diameter and surface charge of the NM-suspensions were characterized using the methodology of dynamic light scattering. The obtained results showed that SDS/DDAB, gold nanorods and quantum dots significantly inhibited the growth of freshwater green alga . These results emphasize the importance of systematic studies of nanoecotoxicological effects of different nanoparticles.

## RA03 - Developments in assessing the bioconcentration of chemicals and its ecological relevance

**WE 274**

**Bioaccumulation in fish - revision of the OECD-testguideline**

CA Rauert[1], EAJ Bleeker[2], DAS Merckel[3], TP Traas[2]
[1]Umweltbundesamt, DESSAU-ROβLAU, Germany
[2]RIVM, BILTHOVEN, The Netherlands
[3]Environment Agency, WALLINGFORD, United Kingdom

Bioaccumulation is a key element within the environmental hazard and risk assessment of substances. The OECD test guideline 305 addressing determination of bioconcentration is currently under revision within the OECD test guideline programme.

The test measures a chemical's bioconcentration factor (BCF; the ratio of the concentration in the fish to the dissolved concentration in the water) in fish ;by exposing fish to the chemical dissolved in the water. This particular method is used in regulations for industrial chemicals, plant protection products, biocides and pharmaceuticals, for risk assessment, Classification and Labelling and in PBT assessment.

The guideline will be expanded with a new possible method, exposing test animals to food spiked with the test substance, which results in a biomagnification factor (the ratio of the substance in the animal's body to the concentration in its food) rather than a BCF. Validation testing needs to be conducted to demonstrate reproducibility of results and provide information on interlaboratory variation for this new method.

A number of laboratories have volunteered to conduct studies for this validation exercise, using rainbow trout and carp. Five test substances will be tested in each study, with the substances being concurrently "spiked"to fish food on which the test fish are fed daily during a set exposure period. This exposure period is followed by a depuration phase, in which the fish are fed a clean diet for a set period. Chemical analysis of fish tissue during the depuration phase, coupled with set test substance concentrations in the food and feeding rate, and known fish weights, and fish and food lipid contents allows the calculation, for each test substance, of:

- a depuration rate constant
- the assimilation efficiency
- the growth rate constant
- the biomagnification factor

It is also possible to produce a kinetic BCF (range) from the data, if an uptake rate constant can be estimated.

In the poster, the envisaged changes and first ringtest results will be described.

**WE 275**

**Saving test animals, time, and costs in fish bioconcentration tests**

MS Mclachlan, M Adolfsson-Erici, G Åkerman
Department of Applied Environmental Science (ITM) Stockholm University, STOCKHOLM, Sweden

The OECD 305 protocol for determining the bioconcentration factor (BCF) in fish is long, costly, and test animal intensive. Commonly an uptake phase of 28 days is followed by a depuration phase of 56 days, and a minimum of 40 fish are required. In an effort to reduce the costs and test animal requirements, a revised protocol was tested. The key elements of the revised protocol included:

- Shortened uptake and elimination phases (4/10 days)
- Reduced number of fish (8)
- Simultaneous study of several chemicals
- Use of internal benchmarking to increase accuracy and precision

The revised protocol and the OECD 305 protocol were run for 10 chemicals using rainbow trout. Good agreement was found between the BCFs measured with the two methods. This supports the feasibility of reducing the cost and animal requirements of fish bioconcentration experiments. The revised protocol should be particularly useful in assessing whether chemicals lie above or below regulatory thresholds, as the internal benchmarking facilitates the determination of relative bioaccumulation behaviour.

**WE 276**

**A partition based dosing method for fish bioconcentration experiments**

K Adolfsson-Erici[1], G Åkerman[2], A Jahnke[2], P Mayer[3], MS Mclachlan[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Department of Applied Environmental Science (ITM), STOCKHOLM, Sweden
[3]National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark

Creating and maintaining a constant freely dissolved concentration of test chemicals in water is a requirement for laboratory bioconcentration experiments. This can be difficult, particularly for poorly soluble chemicals. Generator columns have been used, but they are limited to dosing at the aqueous solubility limit. We developed a new partition based dosing method using a silicone membrane module consisting of 15 000 silicone microtubes through which water is pumped. The silicone was loaded with the chemical by pumping a methanol solution into the tubes and stepwise displacing the methanol with water. Water was then pumped through the tubes into an aquarium. The system was tested using a mixture of 10 organic chemicals with log KOW ranging from 3.95 to 6.60. The concentrations in the aquarium water were measured using both solid phase extraction and passive sampling. The concentrations of most chemicals were maintained within _10 % over a 4 week period. A decline in concentration of some of the low KOW chemicals was observed. The concentrations in the water could be easily controlled by regulating the water flow through the passive dosing module. The reproducibility of the water concentrations obtained using different passive dosing modules was also investigated.

**WE 277**

**Comparison of in-tissue passive sampling and whole fish extraction to measure elimination kinetics of organic chemicals in fish**

K Adolfsson-Erici[1], G Åkerman[2], A Jahnke[2], MS Mclachlan[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Department of Applied Environmental Science (ITM), STOCKHOLM, Sweden

Fish bioconcentration and bioaccumulation tests such as OECD 305 measure the change in chemical concentration in the fish over time, i.e. during chemical uptake and depuration experiments. This requires that fish be sacrificed at a number of time points during the experiments, and it means that the bioaccumulation behaviour is not being measured in individual fish, but rather using a collection of data points, each from a different fish. In an effort to reduce the animal requirements for these tests and to enable the study of bioaccumulation kinetics in individual organisms, a passive sampling method was developed that could be employed in-vivo in fish. The passive sampler consisted of an acupuncture needle with a sleeve of silicon tubing. Rainbow trout were simultaneously exposed to 10 organic chemicals for 25 days and then allowed to depurate for 56 days. The depuration kinetics were studied using both the novel in-tissue passive samplers and ii) by the traditional sacrifice/extraction/analysis of whole fish. There was good qualitative agreement between the kinetics measured with the two methods. However, the variability was considerably higher using the passive samplers, and some chemicals could not be quantified. The results suggest that in-tissue passive sampling method has the potential to be useful in laboratory bioconcentration experiments, lowering the costs for sample preparation and helping to reduce the number of test animals required. However, it also has several disadvantages in this context including the need to use large fish to allow deployment of the samplers and the need to expose the fish to high chemical concentrations due to the higher LOQ of the passive sampling method compared to whole fish extraction.

**WE 278**

**Comparison of liquid-liquid-extraction (LLE) and solid-phase microextraction (SPME) to determine aqueous analyte concentrations in fish bioconcentration studies according to OECD TG 305**

C Schlechtriem[1], L Böhm[2], RA Düring[2]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), SCHMALLENBERG, Germany
[2]Inst. of Soil Science and Soil Conservation, Justus Liebig University, GIEβEN, Germany

Measured bioconcentration factors (BCF) and n-octanol-water partition coefficients (Kow) of hydrophobic organic chemicals (HOC) show a curvilinear relationship up to log KOW 5-6. BCF values of more lipophilic substances tend to level of or decline (hydrophobicity cutoff). Debated reasons are steric effects, but also measurement artefacts. Jonker and van der Heijden (2007; Environ Sci Technol 41:7363) suggested that the overestimation of bioavailable aqueous HOC by the presence of non-bioavailable HOC bound to dissolved organic matter, might lead to an underestimation of the true uptake. This was supported by the determination of freely dissolved aqueous concentrations by solid-phase microextraction (SPME).

The suitability of SPME to measure highly hydrophobic substances is described in the literature. However, the standard method for sample preparation in BCF-tests according to OECD TG 305 is liquid-liquid-extraction (LLE). The aim of this study was to investigate the potential of SPME with regard to the determination of aqueous analyte concentrations in fish BCF studies with special reference to different contents of organic matter (OM).

Water with different concentrations of organic matter was spiked with five test substances (log KOW 5.3 - 8.1) and analyzed at equilibrium conditions. Analysis of samples with SPME was compared to conventional sample preparation with LLE. With SPME, the detection of freely dissolved analyte concentrations is possible, as is the determination of sorption. Extraction of samples with LLE yields total analyte concentrations. Results show, that the freely dissolved concentration of highly hydrophobic analytes (which corresponds to the bioavailable fraction) is significantly reduced due to sorption to OM - already beneath the permitted concentration of 2 mg L-1 TOC in the dilution water according to OECD TG 305.

In a further approach, the sorption potential of different types of OM was investigated. Generally, sorption to Aldrich humic acid was stronger than sorption to all natural OM tested. Results are discussed with reference to BCF-tests. The BCF is defined as the ratio of concentration (fish) to concentration (water) at steady-state. SPME measurements should not replace LLE procedures to keep the results of BCF studies comparable, however, SPME can give important information on the ratio between bound and freely dissolved compounds and help to estimate suitable TOC for highly lipophilic substances prior to a BCF study.

**WE 279**

**Can high concentrations of perfluorinated organic compounds in fish be explained by dietary accumulation?**

C Schlechtriem[1], I Goeritz[1], S Falk[2], H Jürling[1], TY Stahl[2]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), SCHMALLENBERG, Germany
[2]Landesbetrieb Hessisches Landeslabor, WIESBADEN, Germany

Perfluorinated organic compounds (PFC) are a large group of chemicals which have been used since the 1950s because of their unique properties such as chemical inertness, resistance to heat and their ability to repel water and oil. We are only now beginning to realize that these environmental contaminants may have serious environmental and health effects. PFCs have been detected in aquatic and terrestrial organisms with the highest concentrations found in top predators. High concentrations of PFC (i.e. PFOS and PFOA) were found in fish collected from different German rivers, although the analytical results were variable between species and the different tissues analysed (www.lfu.bayern.de). Apart of a few studies on bioaccumulation in fish, a sound evaluation of the trophic transfer of PFC in the food chain is missing. Martin et al. (Env. Tox. Chem. 22, 189-195, 2003) investigated the dietary accumulation of PFC in juvenile rainbow trout but dietary exposure did not result in biomagnification. The authors emphasized that extrapolation of the estimated bioaccumulation factors to larger fish should not be performed because the half life, especially of the more hydrophobic compounds, can be higher in large or mature fish than in smaller animals of the same species. The aim of this study was to compare the dietary accumulation potential of different perfluorosulfonates (PFOS, PFHxS, PFBS) and perfluorocarboxylates (PFOA, PFNA) in small and large rainbow trout. A dietary accumulation study was carried out on juvenile rainbow trout (2g) according to the draft document of the revised OECD TG 305. Biomagnification factors (BMF) were calculated for each of the five PFCs tested. In a further experiment large rainbow trout (400g) were fed for four weeks an experimental diet spiked with the same compounds followed by a depuration period lasting four weeks. The trajectories of tissue concentrations were analysed. Kinetic BMF factors were calculated and compared with the results obtained for juvenile animals. The results of both studies are summarized and discussed with regard to the accumulation of PFC in the aquatic food web and the potential impact on human health.

**WE 280**

**Exploring a new in vivo screening technique for assessing the bioconcentration potential of pharmaceuticals in fish**

LA Constantine
Pfizer, GROTON, United States of America

Understanding whether an active pharmaceutical ingredient is likely to be taken up from the aquatic environment by fish and bioaccumulate has triggered the need to conduct bioconcentration studies in fish. Such studies are typically considered appropriate for pharmaceuticals having a logD value > 3 and required, as per EMEA Guidelines, for pharmaceuticals having logD values > 4.5.

The standard OECD Guideline 305 includes an exposure (uptake) phase followed by a post-exposure (depuration) phase typically equal to ½ the duration of the uptake phase. Based on the sampling schedule outlined in the guideline, >100 fish per study may be required to determine a kinetic BCF value. Based on the resources required to conduct the full bioconcentration study and the potential for fish to metabolize xenobiotics, alternatives to the current bioconcentration tests as a first tier have been explored and employed for the last several years. A new approach was used explore the possibility of developing a new screening tool to assess the bioconcentration potential in fish. Results of this research will be presented.

**WE 281**

**Extrapolation of BCF from the in vitro rainbow trout (Oncorhynchus mykiss) liver S9 metabolic assay results**

CE Cowan-Ellsberry[1], MR Embry[2], MJ Bernhard[3], SD Dyer[3], B Escher[4], K Johanning[5], J Nichols[6], D Huggett[7]

[7]University of North Texas, DENTON, TX, United States of America

In many bioconcentration models, the bioconcentration factor BCF is assumed to be driven by hydrophobicity; therefore, the octanol-water partition coefficient log Kow is the main and sometimes only parameter used for estimation in these models. However, bioconcentration in reality integrates all processes related to absorption, distribution, metabolism and excretion (ADME). Internationally accepted extrapolation models for BCF, which include the metabolism parameter, have been available for selected mammalian species. However, this type of model did not previously exist for fish. This need to address metabolism in fish in bioaccumulation predictions and the need for a standard approach for measuring metabolism led to the development of an in vitro rainbow trout liver S9 assay. This S9 metabolism assay has been successfully applied to nine chemicals in several laboratories. A previous presentation provided a summary of the data obtained to-date. This presentation will focus on describing the structure of an extrapolation model that can be used to estimate the BCF in trout from these S9 assay data and the improved parameterization using new insights into fish physiology and measured protein binding parameters. The extrapolation model predictions of BCF are compared to measured values of BCF to assess the validity of the S9 assay and extrapolation model and demonstrate the validity of this approach

**WE 282**

**The development and evaluation of a mass balance bioaccumulation model for ionogenic chemicals in fish**

JM Armitage[1], JA Arnot[1], F Wania[1], D Mackay[2]
[1]University of Toronto (Scarborough), TORONTO, Canada
[2]CEMC, Trent University, PETERBOROUGH, Canada

Approximately 33% of the tens of thousands of organic chemicals listed on Canada's Domestic Substances List (DSL) and the European Union chemical management program (REACH) are ionogenic and are expected to dissociate under environmentally relevant pH conditions. Measured bioaccumulation data are limited for legislated hazard and risk evaluations in general, and for ionogenic chemicals in particular. Quantitative Structure-Activity Relationships (QSARs) and mass balance models have been developed to quantify bioaccumulation processes for neutral organic chemicals (e.g., uptake by gill respiration and diet; elimination by gill respiration, fecal egestion, metabolic biotransformation and growth dilution). There is a need to develop and evaluate mass balance models for ionogenic chemicals that synthesize the available kinetic and chemical partitioning information into a holistic bioaccumulation framework. Such a model can then be used to identify key processes contributing to bioaccumulation, to develop hypotheses for strategic laboratory testing, and to provide screening level estimates for chemical assessment programs. A new mechanistic bioaccumulation model in fish is presented that integrates the available information on ionogenic chemicals. This model includes a mechanistic approach to address dissociation in the water and its influence on mass transfer and chemical uptake at the gills. It also quantifies the partitioning of the ionic and neutral forms of a chemical between the internal compartments of a fish, such as water, protein, storage lipid and membrane lipid. The new model's predictions are compared with measured rate constants and bioconcentration factors for ionogenic chemicals and with existing regression-based BCF and mass balance models. Future research needs to reduce uncertainty in the model predictions are highlighted.

**WE 283**

**Using molecular dimensions to evaluate bioaccumulation potential**

NC Petry, C Durou, P Adrian
CEHTRA, SAINTE-EULALIE, France

In the REACH Regulation, PBT and vPvB assessment is compulsory for all chemicals produced or imported above 10 t/year. Although the main regulatory criterion for B or vB attribution is the aquatic bioconcentration factor (BCF) (REACh Annex XIII), an evaluation of all available information is necessary and screening criteria, as log Kow, can be used. So, when direct comparison with criterion lay down in REACh Annex XIII is not possible, other indicators are to be considered in a weight of evidence approach. Among these, the molecular size and molecular weight (MW) can indicate a low bioaccumulation potential. Several descriptors can reflect molecular size but at present, the most reliable is the "average maximum diameter"(Dmax aver) developed by Mekenyan and Dimitrov . These authors showed that a chemical may be considered as not bioaccumulative if Dmax aver > 1.7 nm and MW > 1100 g/mol because very bulky molecules pass the cell membranes with difficulty . To calculate Dmax aver, conformational analysis is necessary and OASIS is the reference software to obtain energetically stable conformers representing conformational space of the molecules. As OASIS is a very expensive program, our aim was to find an alternative and equivalent tool. Basing our work on the review of Brooke and Cronin , we examined and tested different modeling softwares giving descriptors related to molecular dimensions. By this way, we led to the combination of two softwares : Spartan was used for modeling calculations whereas the BBX descriptor from Mol2Mol furnished a surrogate for Dmax aver. This new procedure was tested on a set of 18 molecules reflecting a wide structural diversity and results were compared with data obtained with OASIS. In this communication we will so present this work and discuss the scope and limitation of our method in the context of PBT assessment.

**WE 284**

**The CEFIC ECO16 project: critical body residue validation for aquatic organisms exposed to chemicals causing toxicity by baseline narcosis.**

A van der Heijden[1], JA Arnot[2], JLM Hermens[1], MTO Jonker[1], D Mackay[3], P Mayer[4], LS McCarty[5]
[1]Utrecht University, UTRECHT, The Netherlands
[2]Simon Fraser University, BURNABY, Canada
[3]Trent University, PETERBOROUGH, Canada
[4]National Environmental Research Institute, ROSKILDE, Denmark
[5]L.S. McCarty Scientific Research and Consulting, MARKHAM, Canada

Biomembrane homeostasis can be disturbed by partitioning of any organic chemical into the membrane structure, which may ultimately lead to narcosis. Due to the non-specific nature of this mechanism, the membrane-disrupting potential of one molecule is generally considered equal among all chemicals. As a result, chemicals that primarily exert toxicity via a narcotic mode of action may be expected to display equal critical body residues (CBRs). Although this theory could greatly facilitate environmental risk assessment for these chemicals, a considerable variation is observed in CBRs reported in the literature. The main cause for this variation is thought to be related to the disregard of the process of internal distribution. This oversimplification leads to the faulty assumptions that (a) the quantity of a narcotic chemical, which caused lethality in an organism, is present in lipids, while in fact it may be divided among other compartments (e.g. proteins, carbohydrates), and (b) the concentration in the storage lipid phase is equal to the one in membrane lipids, though the phases may show differential sorption behavior. Until now, few attempts have been made to accurately determine the concentration of a narcotic toxicant actually present in the membrane phase of an exposed organism at the time of death. The objectives of the current CEFIC ECO16 project are to get more insight into the variation in CBRs of different chemicals and in different organisms by (1) compiling a comprehensive CBR database, (2) developing a sophisticated model to describe the process of internal distribution of narcotic toxicants and implementing it in the gathered data, and (3) acquiring experimentally derived data to provide the model with appropriate partitioning parameters and accompanying CBR data of a number of benchmark chemicals.

**WE 285**

**PBT assessment and trophic dilution - Regulatory consequences**

EAJ Bleeker, EMJ Verbruggen, JA de Knecht, TP Traas
National Institute for Public Health and the Environment (RIVM), BILTHOVEN, The Netherlands

The identification of substances which are persistent, bioaccumulative and toxic, so-called PBT substances, is important in the prioritization for regulatory action in the EU as well as globally. The bioaccumulation potential of a substance gives an indication that higher concentrations of a compound are found higher in the food chain and this may become harmful to ecosystems and humans. As a measure for accumulation the bioconcentration factor (BCF) of a compound is used. This is defined as the ratio between the uptake rate of a compound from water into the organism and its elimination rate to water. In the evaluation of the bioaccumulation potential of substances, the European REACH guidance on PBT assessment makes in principle no difference in which species the bioaccumulation has been measured. In general, other regulations focuses on higher trophic levels, <i*e.* fish, where data on invertebrates are only considered when data on fish are not available. This may lead to a bias due to unbalanced weighing of available data. It also raises the question on how to consider substances that will accumulate in lower trophic levels, like mussels, but do not fulfil the bioaccumulation criterion in fish and do not biomagnify through the food chain (*e.g.* PAHs). This so-called trophic dilution in food webs is the result of efficient metabolic transformation at higher trophic levels. For compounds that are not easily metabolized (*e.g.* PCBs) it can be hypothesized that bioaccumulation will occur in all trophic levels, resulting in biomagnification in the food chain. Consequences for the assessment of bioaccumulation in a regulatory context, caused by data gaps or data availability for certain trophic levels, are discussed.

**WE 286**

**Simulated trophic magnification factors: sensitivity analysis and comparison to human exposure modelling**

TN Brown[1], E Undeman[2], A Hong[1], MS Mclachlan[2], F Wania[1]
[1]University of Toronto Scarborough, TORONTO, Canada
[2]Stockholm University, STOCKHOLM, Sweden

In this study two ecosystem level bioaccumulation screening metrics are simulated and compared.

Trophic magnification factor (TMF) is a metric applied to chemical measurements collected from a range of biota in a localized food web, and is interpreted as an approximation of the average biomagnification factor (BMF) for the chemical in the analyzed food web. Many confounding factors such as species-specific metabolic elimination and food web structure mean that the TMF of a chemical measured in one food web cannot be used to assess the bioaccumulation of the chemical in another food web. Another metric for evaluating bioaccumulation potential is the human emission ratio (HER) which relates the amount of chemical in the physical environment directly to the human end-point. HER is also strongly dependent on the structure of the food web and other factors. A linked chemical fate and bioaccumulation model (CoZMoMAN) is applied to a set of environmentally relevant chemicals, and the model results are used to calculate TMF and HER values in several different ecosystems. Comparison to experimentally measured TMF values and human monitoring data are made, when possible, to test the validity of the modelling outcomes. Subsequently, a set of hypothetical chemicals is used to perform a model sensitivity analysis to test the relative influence of chemical properties (partitioning, biotransformation) and ecosystem properties (food-web structure, physical environmental) on the two different bioaccumulation screening metrics.

**WE 287**

**Applying multimedia models to calculate trophic magnification factors (TMFs): exploring basic assumptions and the role of the physical environment**

A Arnot[1], LP Burkhard[2], L Reid[3]
[1]University of Toronto Scarborough, TORONTO, Canada
[2]United States Environmental Protection Agency, DULUTH, United States of America
[3]CEMC, Trent University, PETERBOROUGH, Canada

The trophic magnification factor (TMF) is considered to be a useful metric for assessing the bioaccumulation potential of organic chemicals in food webs. Fugacity is an equilibrium criterion and thus reflects the relative thermodynamic status of a chemical in the physical environment (air, water, soil and sediment) and in aquatic, terrestrial, and human food webs. For most neutral organic chemicals the TMF is calculated using lipid normalized concentrations measured in organisms of a food web and their relative trophic position. This lipid normalized TMF calculation is analogous to calculating the change in chemical fugacities in organisms of a food web with respect to their relative trophic position. Fugacity based fate and food web bioaccumulation models have been used to estimate the fate and bioaccumulation of organic chemicals in the environment. The Risk Assessment IDentification And Ranking (RAIDAR) model is a fugacity based mass balance model that combines environmental fate and food web calculations to assess exposures and potential risks. RAIDAR includes representative species comprising aquatic, terrestrial, agricultural and human food webs. The RAIDAR model was used to calculate fugacity ratios in representative food webs (i.e. TMFs) and to illustrate the range of TMFs as a function of chemical partitioning space. Screening-level model predicted TMFs are in good agreement with measured TMFs for many well studied chemicals (e.g. PCBs, HCB, PBDEs, HCHs, pyrene). Model sensitivity and uncertainty analyses provide guidance to improve the model calculations. The model was used to show how disequilibrium conditions in the physical environment (air, water, soil and sediment) influence steady state TMFs. These results highlight the need to clearly define the TMF with respect to the analyzed components of the food web and the need to consider holistic methods that include environmental fate and food web bioaccumulation for screening chemicals and for chemical exposure assessment.

## RA06 - Monitoring and risk-assessment of organic compounds in developing countries

**WE 290**

**Monitoring of organic pollutants in the South African marine environment - which are better mussels or artificial devices?**

V Wepener[1], N Degger[1], J Richardson[2], SS Wu[3]
[1]University of Johannesburg, JOHANNESBURG, South Africa
[2]City University of Hong Kong, HONG KONG, Hongkong
[3]The University of Hong Kong, HONG KONG, Hongkong

The developed global community is increasingly aware of man's activities on environmental sustainability; however the developing world has yet to realise its toxicological and ecological impact due to the increased discharges of effluents containing pollutants such as organic contaminants. A distinct lack of historical and current data on the status of organic pollutant contaminants within the South African marine environment has been acknowledged. The last published assessment of dissolved hydrocarbons conducted in Table Bay Harbour was in the 1980s. As a consequence there is increased awareness to conduct more current organic pollutant assessments. Brown mussels (P. perna) and artificial devices, semi-permeable membrane devices (SPMDs) were transplanted at five South African harbours for 10 weeks to assess organic bioaccumulation. The SPMDs are well documented in literature for their efficiency at indicating trace organic contaminants in the water column as well as their ability to provide standardised results between varying localities worldwide. Spatial patterns of PAH and PCB contaminants were determined by GC-MS and GC-ECD after appropriate sample preparation according to methods. Significant ($p < 0.05$) spatial differences were identified between the five harbour sites, and as observed, contaminants measured in the mussel tissue deviated from those represented by the SPMDs. Results indicated no positive correlations between the SPMDs and the transplanted mussels, however the SPMDs provided complementary information which may be of toxicological significance. They were able to positively identify petrogenic contaminants from a known oil spill event and their ability to accumulate dioxin-like PCBs which were not detected in the mussels. Differences occurring between the uptake profiles of the SPMDs and mussels can be attributed to the passive device monitoring contaminants in the dissolved phase from the water column whereas concentrations reflected by the mussels are a net result of dietary exposure and passive diffusion. The results indicate that information provided by both the mussels and SPMDs allow for a more in depth scrutiny of environmental conditions as a result of anthropogenic influence. They further provide resource managers with an effective tool and methodology to identify and correct issues before they become problematic.

**WE 291**

**Evaluation of the genotoxicity of 17a-methyltestosterone on Oreochromis niloticus widely used in pisciculture to induce monosex males**

GR Wendt, LM Vilela, MF Ferreira, HL Loudovani, CK Grisolia
UNIVERSIDADE DE BRASÍLIA, BRASÍLIA, Brazil

The hormone 17 $\alpha$ - methyltestosterone (MT) is used in fish farms through animal feed to produce monosex males. In Brazil, this substance is still used without registration. The purpose of this study is to investigate the genotoxic effects of this hormone on Oreochromis niloticus. Tilapia is grown in fish farms due to its strong commercial interest. Evaluation of the genotoxicity was carried out through micronucleus test (MN), comet assay (CA) and nuclear abnormalities (NAs) in individuals with reproductive and non reproductive maturity. Fish were purchased from the Federal District Government fish farm. The animals were exposed to the substance diluted in water for 96 hours at concentrations of 0.01, 0.1 and 1mg/L, not exceeding 0.04% of ethyl alcohol in the solution. Then, reproductively mature individuals, measuring 09-12 cm, were kept for 28 days in fish tanks in our laboratory and fed the same diet used to produce monosex male larvae. Finally, O. niloticus were collected at the end of 28 days of feed administration containing MT in a batch of larvae produced in the pisciculture (in situ). Our results showed that MT was genotoxic after exposure to 96 hours when compared with the negative control and control with alcohol. After 28-day of exposure to MT in the diet, no genotoxicity was observed. Results from in situ exposure study showed an increased level of MN. According to the literature, 17 $\alpha$ - methyltestosterone is degraded in the liver of animals, so it can be suggested that the route of exposure can influences on the genotoxicity of the MT. Regarding the results obtained from the in situ study, we can observed that in the early developmental stages MT present genotoxic risks.
Key words: genotoxicity, methyltestosterone, Oreochromis niloticus
Support: Brazilian Reseaarch Council (CNPq) and University of Brasília.

**WE 292**

**Identification and quantification of organic contaminants in fish from the Tonlé Sap watershed, central Cambodia**

C Kelly[1], S Bayen[1], BH Tan[1], N Steenkeste[2], M Chou[3], P Lim[4]
[1]National University of Singapore, SINGAPORE, Singapore
[2]Fondation Merieux, PHNOM PENH, Cambodia
[3]Faculty of Pharmacy, University of Health Science, PHNOM PENH,, Cambodia
[4]Ministry of Water Resources and Meteorology, PHNOM PENH, Cambodia

The Tonlé Sap watershed is a unique freshwater lake-river system in central Cambodia. The lake, which undergoes dramatic changes in size between wet and dry season, supports a highly productive inland fishery and is home to several floating villages. The objective of the present study was to investigate the occurrence and levels of organic contaminants in fish from this important watershed. In November, 2010, several samples of fish and prawns originating from the Tonlé Sap were obtained from local markets near Phnom Pehn, Cambodia. Fish were both from culture and natural origin. Fish species included tilapia, snakehead, catfish, and silver barb. Both fish muscle and liver were collected. Fish and prawn tissues were solvent extracted and analyzed by gas chromatography - mass spectrometry (GC-MS) or Liquid chromatography-electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) techniques. Target analytes included legacy persistent organic pollutants (POPs) but also emerging contaminants such as brominated flame retardants (BFRs), perfluoroalkyl chemicals (PFCs), synthetic musks and plasticizers. QA/QC included blank measurements, recovery tests with spiked 13C mass-labeled compounds and replicate analyses. Based on the measured residue concentrations, daily intake of the various contaminants were assessed for the population of this region of Cambodia and compared with similar data from elsewhere. The results from this pilot study highlight the need for a larger scale study of the fish stocks in the Tonlé Sap.

**WE 293**

**Water-related complex pollution in Central Asia**

B Hadjamberdiev, IM Damulajanov, VA Shablovsky, V Ponomarev
Network Water Pollution, BISHKEK, Kyrgyzstan

We studied pollutant contents in upper, ground, and drinking waters - in the worst polluted areas of CA states (Tadjikistan, Uzbekistan, Kyrgyzstan, Kazakhstan) in 2000-2009 years. The pollutants are: a) hydrocarbons aromatic, pesticides mostly - ground, drinking water and vegetables; b) bio-pollutants (abdominal typhus, coli bacteria, cholera, 4 helminthes). We have created 5 ranks maps of each impact by human toxicity. And then we created common (complex) map by superposition methods, which shows scale of water-polluted areas of CA. We have referred created ranks by analysis of base human health markers (immunity level 6 tests, genetic disorder 3 tests). Results of both studies were correlated each other. The first consequence of studies is detection of most vulnerable areas in CA that need immediately rescuing. It has been offered/improved the water-toxicants alleviation methods: a) twice prolongation of water staying in sediment basin (in water-purified stations); b) protecting 5 tailings from rivers (we did project for protecting genetic of vulnerable groups (install 17 updated drinking water filters in schools, nursery, hospitals); c) there are 3 common projects for gathering obsolete pesticides and keep in contemporary warehouses, we created filter system for chromium purify; d) bio-pollutants is a results of human and animals fertilize utilization and toilets absent, we installed composting toilets in rice-land and in Alpine area.

**WE 294**

**Risk assessment in the jungle: the use of glyphosate to control the production of coca in Colombia**

R Solomon[1], EJP Marshall[2], G Carrasquilla[3], C Bolognesi[4], M Bernal[5]
[1]Centre for Toxicology, GUELPH, Canada
[2]Marshall Agroecology Limited, MARSHALL AGROECOLOGY LIMITED, United Kingdom
[3]Universidad del Valle, CALI, Colombia
[4]National Cancer Research Institute, GENOA, Italy
[5]Universidad del Tolima, IBAGUÉ, Colombia

Conducting risk assessments in remote locations is logistically challenging but can be very useful as an educational tool is scientists from the region can use the exercise a learning tool. To address identified data needs, laboratory studies with 8 species of tadpoles of frogs from Colombia were conducted. This involved using local facilities as well as residue analysis with ELISA in pace of the more widely used LC-MS. These studies showed that under laboratory conditions LC50 values ranged from 1,200 to 2,780 µg glyphosate a.e./L. However, under realistic field conditions in sediment-bottomed microcosms, LC50s ranged from 5,963 to 7,303 µg glyphosate a.e./L when treated with an overspray to mimic aerial application. Bioassays with terrestrial stages of frogs (juveniles and adults) were conducted with simple equipment obtained from local farm and garden suppliers. Spraying was conducted with a modified atomizer to apply consistent volumes of spray solution. These studies, carried out under conditions that mimicked the field, produced LC50 values between 4.5 and 22.8 kg a.e./ha. A human health-effect study was carried out in volunteers from 5 Colombian regions. These regions were characterized by different exposure to glyphosate and other pesticides and the study was to assess the effects of exposure to eradication and other sprays on the frequency of binucleated lymphocytes with micronuclei (BNMN). This study was conducted through the use of local medical health workers from regional clinics who were familiar to the volunteers and would be trusted as impartial. Blood was collected before spraying, 4-5 days and 4 months post-spraying. The samples were processed in a local laboratory and prepared for assessing Italy. These results showed that the highest frequency of BNMN was in Boyacá where no aerial eradication spraying of glyphosate was carried out and Valle del Cauca where glyphosate was used for maturation of sugar cane. There was no significant association between self-reported direct contact with eradication sprays and frequency of BNMN. Overall, these results suggest that genotoxic damage associated with glyphosate spraying, as evidenced by the MN test, is small and transient. These data were used in a risk assessment which concluded that risks to sensitive wildlife and human health from the use of glyphosate in the control of coca production in Colombia are small to negligible.

**WE 295**

**Fuzzy approach for risk assessment of brominated flame retardants in aquatic ecosystems of Latin America**

A Àgueda[1], S Betrò[1], E Pujolasus[1], J Casal[1], W Ocampo-Duque[2], E Eljarrat[3], DB Barcelo[4], RM Darbra[1]
[1]CERTEC, BARCELONA, Spain
[2]Facultad de Ingeniería, Pontificia Universidad Javeriana., CALI, Colombia
[3]Departament Environmental Chemistry, IDAEA-CSIC, BARCELONA, Spain
[4]Institute of Environmental Assessment and Water Research, BARCELONA, Spain

Brominated flame retardants (BFR) are pollutants that represent a threat to human health and the environment due to their industrial use, their persistence and their ability to bioaccumulate and biomagnify in food chains, especially in the aquatic one. For the last ten years contamination levels for this type of compounds have been reported for European, North American and Asian human tissue, sediments and biota samples [1-3]. However, monitoring efforts on the assessment of BFR contamination levels in Latin America are scarce.

Contamination levels, bioaccumulation and biomagnification in the aquatic trophic chain of two groups of BFR compounds (polybrominated diphenylethers (PBDEs) and hexabromocyclododecane (HBCD)) are currently being evaluated in two Latin American ecosystems, one from Chile (San Vicente bay and Lenga estuary) and another one from Colombia (delta-estuary of the Magdalena river) under the framework of an international research project titled BROMACUA. Within this framework, a methodology based on fuzzy logic has been developed to evaluate the risk due to contamination in aquatic organisms by using experimentally determined levels of contamination and data from the literature. Fuzzy logic is characterized to be conceptually easy to understand and is based on natural language. It has been used successfully to model non-linear functions, to establish inference systems on top of the experience of experts and to deal with imprecise data. Fuzzy approaches can be very useful in the environmental field due to the uncertainty associated to this type of data.

A description of the fuzzy model proposed is given in this work, including a summary of the main outcomes of a questionnaire (replied by 38 international experts) that has been created to obtain information on different topics relevant for the model development. Results associated to the behavior and the sensitivity of the proposed model are also presented.

**Good quality of groundwater sources as the challenge for science and sustainability**

MB Vojinovic Miloradov[1], I Spanik[2], D Milovanovic[1], M Miloradov[3], M Djogo[1], M Dimkic[4]
[1]Faculty of Technical Sciences, NOVI SAD, Serbia
[2]Institute of Analytical Chemistry, BRATISLAVA, Slovak Republic
[3]Academy of Sciences and Arts of Vojvodina, NOVI SAD, Serbia
[4]Water Research Insitute Jaroslav Cerni, BELGRADE, Serbia

Ground water sources are strategic resource for every country and population. It's availability and sanitary safety is strongly connected with human health, protection of environment and economy status. Good quality of groundwater sources, providing safe drinking water for population, became the priority, and, at the same time, a big challenge for science and sustainability, and healthy, clean environment. Groundwater is the largest reservoir of fresh water in the world. About 75 % of the European population uses groundwater as their water supply. Groundwater is traditional water supply resource in Serbia, as well. It is exclusive source of water supply of central and northern Serbia - region of Vojvdina, with only exception in city of Belgrade, where part of the water supply originates from Sava river. More than half of the abstracted water is groundwater from alluvial aquifers, and therefore 80-90 % originates from infiltrated water from rivers. These aquifers belong to the so called rapidly rechargable aquifer since they depend on hydrologic regime of water. In some groundwater sources, during previous research, emerging substance of concern have been detected, such as carbamezapine and benzotriazole. Ten years after NATO's intervention in Serbia and the destruction of city of Novi Sad's oil refinery, bridges and water supply, providing safe drinking water and protecting the environment is still a major challenge. Integrated early warning system (EWS) for the detection of organic and inorganic contaminants in the source water will be developed and implemented, to gain more insight into the quality of the water used for drinking water production at Novi Sad and evaluate the risks for human health and the environment. The monitoring data of the EWS's individual components are stored in a database, fully compatible with standard European data collection systems, to share obtained knowledge and improve the protection of the Danube River and Novi Sad's inhabitants. This data is evaluated with the help of a novel QSAR-based procedure for the selection of hazardous substances. The results of the monitoring efforts and the QSAR-evaluation is then used as a basis for the improvement, integration and harmonisation of risk assessment and risk management standards for the protection of drinking water resources.

**WE 297**

**Uncertainty assessment by a Monte Carlo simulation for methylmercury from hair of Colombian population**

G Johnson-Restrepo
University of Cartagena, CARTAGENA, Colombia

Mercury (Hg) is a ubiquitous contaminant of aquatic ecosystems causing a global environmental concern. Mercury levels are biomagnified in fish tissues from prey to depredator in the food chain, and them humans as top consumer. Risk of exposure to mercury can be reached by eating freshwater fish, seafood, and shellfish. Mercury has been widely distributed in aquatic ecosystems by natural process and human activities in which anthropogenic sources are a consequence of the huge pollution that has been caused since the past 20th century. Mercury contamination in Colombia has been documented for different types of matrices related principally with informal gold mining activities, where the metal is released into the atmosphere after burning amalgam in the gold refining process and also poured directly into body waters. These studies reported concentration of mercury in fish from different trophic levels in the San Jorge and Magdalena basins, and the Cartagena bay. The aim of this report is model the exposure and risk assessment to methyl mercury associated with fish consumption from fishermen Colombian population. Type and amount of fish consumed by the individuals as well as the concentration of fish were obtained from previous published data from our research group. The probabilistic dose intake was accomplished by Monte Carlo simulation by 100.000 random samplings. Internal dose of methyl mercury in blood and hair were also simulated using one-compartment model based on a review of literature to the specific model input parameters. Overall, mean of methyl mercury dose intake estimated for Colombian population was 0.68 µg/day-Kg bw and mean values of methyl mercury in blood and hair were 42.5 µg/L and 10.5 µg/g, respectively. This report intended to related methylmercury concentrations of hair from a cross-sectional study on Colombian population that frequently consumes fish. The results of the model estimated the methylmercury concentration in hair in good concordance. However, the exposure assessment model is a good starting point to attempt predicts the risk-benefit analysis of fish consumption.

**Uptake of pesticides in potatoes grown in Colombia: monitoring, modelling, and human health risk assessment**

R Juraske[1], CS Mosquera Vivas[2], A Erazo Velásquez[2], G García Santos[3], MB Berdugo Moreno[4], J Diaz Gomez[4], CR Binder[5], S Hellweg[1], JA Guerrero Dallos[2]
[1]ETH, ZURICH, Switzerland
[2]Uni Nacional, BOGOTA, Colombia
[3]University of Zurich, ZURICH, Switzerland
[4]Uni Boyaca, TUNJA, Colombia
[5]University of Graz, GRAZ, Austria

A dynamic model for uptake of pesticides in potatoes is presented and evaluated with measurements performed within a field trial in the region of Boyacá, Colombia. The model takes into account the time between pesticide applications and harvest, the time between harvest and consumption, the amount of spray deposition on soil surface, mobility and degradation of pesticide in soil, diffusive uptake and persistence due to crop growth and metabolism in plant material, and loss due to food processing. Food processing steps included were cleaning, washing, storing, and cooking. Pesticide concentrations were measured periodically in soil and potato samples from the beginning of tuber formation until harvest. The model was able to predict the magnitude and temporal profile of the experimentally derived pesticide concentrations well, with all measurements falling within the 90% confidence interval. The fraction of chlorpyrifos applied on the field during plant cultivation that eventually is ingested by the consumer is on average $10^{-4}$-$10^{-7}$, depending on the time between pesticide application and ingestion and the processing step considered.

**Assessment of the effects of Anopheles breeding environment' chemistry on the development of malaria vectors larvae in Mount Cameroon Region: an ecofriendly control solution**

FF Mafo[1], CM Tanga[1], WS Wanji[2], TF Tchuente[3]
[1]UNIVERSITY OF YAOUNDE I, CAMEROON, YAOUNDE, Cameroon
[2]University of Buea Cameroon, BUEA, Cameroon
[3]Institute for Agricultural Research and Development, BUEA, Cameroon

Mount Cameroon region is a malaria endemic area with high transmission level, particularly among women and young children in Cameroon Tea Estate (CTE) settlements. Understanding Anopheles ecology is therefore crucial to achieve effective control of malaria.

A study was therefore designed and carried out in 6 CTE settlements to assess the influence of physicochemical quality of water and environmental characteristics of Anopheles breeding sites on Anopheles distribution and densities. Breeding sites were surveyed and larvae collected and identified morphologically to species. 25 water samples from representative breeding sites were analyzed. The influence of environmental (vegetation, surface debris, predators, turbidity, exposure to sunlight, and distance to the nearest inhabited house- DNIH) and physicochemical (temperature, pH, calcium, potassium, sodium, chloride, carbonate, bicarbonate, ammonium, nitrate, phosphate, magnesium, sulphate ions, and conductivity) parameters on larval densities and distribution was assessed.

2096 Anopheles larvae were collected from the various breeding sites. The morphological identification yielded 8 species: An. gambiae, An. marshallii, An. funestus, An. moucheti, An. sergentii, An. hargreavesi, An. hancocki, and An. concolor. Potassium, DNIH, type of breeding sites and predators ($p < 0.05$) were key factors determining the presence of Anopheles larvae in breeding sites. .An. gambiae showed a clear preference for temporary breeding sites close to inhabited houses (DNIH > 20m) with high larval densities.

The potassium comes from the fertilisers profusely used by CTE farmers. Education of the farmers on appropriate hygiene measures and application of chemicals to be observed in CTE plantations, are essential to suppress the increasing vector densities and malaria transmission intensity in the area.

## RA10 - Risk assessment of chemical mixtures: how can we crack the nut?

**WE 302**

**Statistical approaches for distinguishing individual chemical toxicity thresholds in potentially complex mixtures**

C Simpson[1], A Peters[1], L Surl[1], M Crane[1], P Whitehouse[2]
[1]WCA environment, FARINGDON, United Kingdom
[2]Environment Agency, WALLINGFORD, United Kingdom

It is not known how closely the protection afforded by an Environmental Quality Standard (EQS) corresponds to the definitions of 'Good' ecological status under the Water Framework Directive (WFD) i.e. are the requirements for 'Good' status between chemistry and biology consistent? This could have important implications for deriving EQS and it is important to understand how EQSs compare to field data. An analysis of "matched"biological quality element and chemical monitoring data from England and Wales was undertaken. It is important to consider that ecological communities are subject to numerous stressors (both physical and chemical), including exposure to mixtures of both anthropogenic and naturally occurring chemicals. Quantile regression (QR) was used to investigate the relationship between chemical concentration and biological quality and to distinguish between the impact of a single chemical and the effects of complex mixtures. QR can be used to identify a concentration of a stressor which is likely to result in a limitation of ecological quality, and is particularly useful in cases where it is not possible to exclude all of the potentially confounding factors (e.g. co-exposure to other chemical stressors in a mixture). Forty determinands (including metals, pesticides and sanitary determinands) were included in the analysis. "Thresholds"of chemical exposure consistent with definitions of "high", "good"and "moderate"ecological quality under the WFD could be derived for some, but not all, chemicals; primarily because of limited dataset size for many of the chemicals and the high prevalence of censored chemical exposure data (i.e. below LOD). An analysis of co-variance was also undertaken. These thresholds are useful for calibrating the relative stringency of EQS compared with ecological protection goals. In most cases, existing EQS appear to offer adequate protection for ecological communities.

**WE 303**

**Evaluation of tank mixing in British agriculture: environmental implications**

C Simpson, M Crane, M Gross
WCA environment, FARINGDON, United Kingdom

Tank mixtures of pesticides have the potential to introduce different levels of toxic impact to the environment than is accounted for by single product risk assessment and authorisation. We have reviewed the evidence for the action (concentration or response additive) and interaction (synergistic or antagonistic) effects of pesticide mixtures. In common with the conclusions of several other reviews over the past decade, we present clear evidence of concentration or response addition effects when chemicals, including pesticides, are found in mixtures. Toxic Units (TUs) were calculated for the individual components of commonly used UK binary and ternary tank mixtures, using waterflea, algal and fish EC50 data and conservative exposure estimates. These TUs were then summed under the assumption of concentration addition and compared with individual component TUs. This showed that reliance on single substance risk assessment could under-estimate the toxicity of the mixtures that were analysed by up to 70% for this data set, although the mean discrepancy was much lower, at around 12%. Risk assessment of mixtures should therefore include consideration of additive effects, under the assumption of concentration addition, which is marginally more conservative than the response addition model. Although it was difficult to demonstrate interaction effects such as synergy, the possibility of synergy should not be discounted. Rather it should be carefully evaluated on the basis of existing knowledge of synergy between pesticide active ingredients. A simple, reasonably conservative rule of thumb for synergy that could be used as an initial ranking tool for potentially risky mixtures for further, refined investigation would be to assume that all tank mixtures are 2.5 times more toxic than the concentration addition of their component pesticides.

**WE 304**

**The fish embryo toxicity (FET) test as a screening method to support a component-based risk assessment of biocidal products**

A Coors[1], J Dobrick[1], A Kehrer[2], M Möder[3]
[1]ECT Oekotoxikologie, FLOERSHEIM, Germany
[2]Federal Environment Agency (UBA), DESSAU, Germany
[3]Helmholtz-Zentrum für Umweltforschung (UFZ), LEIPZIG, Germany

The aim of the present project was to investigate the suitability of the fish embryo toxicity (FET) test as a screening method to check for concentration-additive behaviour of biocides. Five commercial wood protection products, the three biocidal active substances contained in these products as well as six different generic binary mixtures of these active substances were investigated in fish embryo toxicity tests. Median lethal concentrations (LC50) estimated from the concentration-response curves and corrected for measured concentrations of the substances were compared to the toxicity predicted by the concept of concentration addition. Less than 2fold deviation between measured and predicted toxicity was observed for all binary mixtures of the active substances and for three of the five biocidal products. The detected underestimation of the toxicity of two products by the mixture toxicity prediction could be explained by the influence of certain formulation additives. Overall, the FET was found to be a suitable tool for verifying whether the toxicity of formulated biocidal products can be reliably predicted by the concept of concentration addition. Applied as a quick and simple non-vertebrate screening test, the FET may support approachs of applying component-based mixture toxicity predictions within the environmental risk assessment of biocidal products in justified cases.

**WE 305**

**Should the receiving environment be considered a mixture in chemical risk assessment. If so, how?**

C Simpson, D Taylor, M Crane
WCA environment, FARINGDON, United Kingdom

There are three different types of mixtures that could be of concern in terms of impacts on humans and the environment: products consisting of multiple components, wastes and effluents which contain a variety of materials, and finally the receiving environment itself which will contain a vast number of substances of anthropogenic and natural origin often at very low concentrations. Establishing the effects of the first two mixture types is straightforward since the mixture itself is both bounded and physically available. As such the developing techniques for mixtures assessment can be readily applied. However in the case of the receiving environment, the problem is not how to measure the toxic effects of the mixture but how to identify which components, out of all those available, should be included in the mixture to evaluate. This poster presentation will outline this critical issue in more detail, review the current methods that might be used and suggest further avenues for research.

**WE 306**

**Risk assessment of mixture of herbicides: the case study of lake Geneva**

V Gregorio, N Chèvre
University of Lausanne, LAUSANNE, Switzerland

In surface waters, aquatic organisms are not only exposed to single substances but typically to mixtures. Therefore joint action of toxicants should be taken into account in ecological risk assessments. However, few approaches have been proposed to reach this goal until now. In ecotoxicology, mixtures effects prediction is largely influenced by toxicological theory. In concrete terms, two concepts/models are particularly used and play a pivotal role: concentration addition (or dose addition) and response addition. Synergetic and antagonistic effects are generally neglected because of their complexity to predict. To assess the ecological risk of substances, these two models could be combined with either the Assessment-Factor method or the species sensitivity distribution (SSD) curves. Nevertheless these approaches aren't common applied for two major reasons: the gap of data (ecotoxicological data, information on mechanism of action, etc.), and the lack of predictions validation. In this study, we propose to assess the risk of mixture of similar and dissimilarly acting pesticides. This approach combines the use of SSD curves and joint action models and is illustrated based on long-term monitoring data of lake Geneva, Switzerland. The assumptions underlying the approach will also be presented and discussed. The results show a decrease of toxicity of herbicides mixture since 2004 and lead to the question whether this improvement is observable in term of algal communities response. However, due to the low toxicity and its correlation with phosphorous change in the lake, the main nutrient driving, it is difficult to link phytoplankton species abundance with toxicity change. A traits-based approach and a classification in functional groups may provide a better answer along this environmental gradient.

**WE 307**

**Effects of s-triazines and metolachlor on chlorpyrifos toxicity in Zebrafish (Danio rerio) early life-stages**

JR Pérez, SM Loureiro
CESAM & University of Aveiro, AVEIRO, Portugal

Previous work showed the existence of ecotoxicity of water samples from the Alqueva reservoir (south of Portugal) due to the presence of significant concentrations of herbicides (e.g. atrazine, simazine, terbuthylazine and metolachlor) and the insecticide chlorpyrifos. Here we examine the effects of these pesticides singly and as binary mixtures on Zebrafish (Danio rerio) early life-stages through a Fish Embryo Toxicity (FET) Test, in the lab.
Our results indicate patterns where deviations from the conceptual models CA (concentration addiction) and IA (independent action) like synergism, antagonism, and dose ratio or level dependencies were observed. As examples, there was an increase in the toxicity of chlorpyrifos on the triazines-treated embryos, possibly due to the biotransformation of chlorpyrifos into more toxic o-analog metabolites.
This study represents an important step to understand the interactions among various pesticides detected in the Alqueva´s reservoir.

**WE 308**

**Learning lessons from exposure assessment of complex metal mixtures**

FJ Claeys[1], D Cholakova[2], F Verdonck[1], K Lacasse[2], K Delbeke[2]
[1]ARCHE, GENT, Belgium
[2]ECI, BRUSSELS, Belgium

REACH requires registration in 2010 of all substances that are produced above 1000 tonnes/year in Europe. As such, a chemical safety assessment (CSA) needs to be developed. Complex substances like intermediates from metal production processes, ores and concentrates, slags and alloys contain different metals in several species or mineral forms. The uptake of these species by living organisms is related to the solubility and bio-availability of the metal bearing species (determined through transformation/dissolution and in-vitro bio-solubility tests). However, guidance on exposure and risk assessment of such complex materials is scarce. Consequently, there was a need to develop a scientific but pragmatic approach to assess the complex metal mixture exposure and risks.
The copper slags risk assessment will be presented as an example. Cu slags are co-produced out of the process of recovering copper and used in various applications like abrasive blasting, embankments and road construction. The exposure and risk assessment of this substance is successfully developed. These assessments are focused on release/exposure of critical trace metals of potential concern and compared to the DNELs and PNECs for these selected metals. The (site-specific) exposure assessment for the production process is based on measured values of releases to environment and inhalation exposures of the selected critical metals. Relative contributions towards total dust or copper were derived and used if no measured inhalation data were available. The exposure scenarios of the downstream uses are also based on individual constituents and focused on the main driver(s) based on leaching and hazard information. The human health risk management measures include mainly automated and closed systems, local exhaust ventilation and/or respiratory protection. Fume/dust cleaning and removal of metal trace constituents in direct cooling water and effluent aim to protect the local environment.
Some challenges were identified during the assessment. The existing metal CSRs are based on different approaches, which in the slag assessment had to be combined: some CSRs took an added versus total approach, DNELs were based on respirable versus total inhalable dust and some risk assessments were only based on biomonitoring data versus others took into account biomonitoring and inhalation data. The question how to deal with "mixture toxicity"in such complex risk characterizations was another overarching issue.

**WE 309**

**Environmental risk assessment of complex mixtures of some PPCPs in Tunisian WWTPs (Parabens/estrogens)**

I Bazin[1], HA Had Hassin[2], MW Mnif[2], SS Spinelli[1], BA Bartegi[2], GC Gonzalez[1]
[1]Ecole des Mines d'Ales, ALES, France
[2]Biochimistry institute, MONASTIR, Tunisia

Parabens are a group of alkyl esters of p-hydroxybenzoic acid. Parabens (or their salts) are widely used as preservatives and bactericides in cosmetics, toiletries, and pharmaceuticals (deodorants, bath gels, shampoos, cream etc.). Various in vitro assays shown paraben can bind to the estrogen receptor (Darbre et al. 2002). From the environmental point of view, information concerning levels and potential long term effects of parabens are missing. Some laboratory studies have confirmed that the presence of weak estrogenic species (genistein, bisphenol A, etc.), are able to act together to produce significant effect at concentration below its individual NOEC (Silva et al 2002). Alone or in combinations with other compounds, esters of 4-hydroxybenzoic acid may be present in the environment. The main goal of our works is to assess the occurrence of joint estrogenic action of various parabens present in water sample. We evaluate whether mixtures, between parabens and other estrogenic compounds (17-_-Estradiol (E2), Estriol) have synergistic or additive effect using a recombinant yeast (YES) assay, (Garcia-Reyero et al. 2001). To this end, concentration-response analyses with single agent were firstly carried out. Then, based on the activity of 17-_-Estradiol in the YES assay, we calculated predictions of concentration-response curves for different mixtures assuming additive combination effect. Evaluation of estrogenic activity of different treated sewage waters (influent and effluent of Tunisian WWTPs located near an industrial or tourist area) will be compared with a conventional HLPC DAD analysis. Thus the impact of estrogenic compounds on estrogenic activity of a water sample can be estimated

**WE 310**

**Direct Toxicity Assessment of mixtures in effluents: current UK experiences**

C Simpson, DH Leverett

WCA environment, FARINGDON, United Kingdom
Direct Toxicity Assessment (DTA) is the process of measuring the environmental hazard (toxicity) posed by a complex chemical mixture. The DTA approach has advantages over chemical-specific methods, in particular in its ability to provide an integrated assessment of the effects of all constituents, including unknown substances and those for which standards or analysis methods are not available. DTA was implemented into the UK regulatory framework under the Integrated Pollution Prevention & Control (IPPC) regime to assess the risk posed by complex industrial discharges to local receiving environments. DTA is used to provide a robust prediction of the acute hazard (toxicity) posed by a complex effluent which can then be used within a tiered risk assessment approach. Under the IPPC regime, industrial sites with liquid discharges must undertake DTA on their effluent(s) if they directly discharge more than 100 $m^3$ of effluent per day to controlled waters and cannot demonstrate that their effluent is "simple". A "simple"effluent is one where all the components have been identified and the toxicity of the effluent can be explained by the chemical properties of the components. Of the 150 UK sites estimated to have complex effluent discharges, approximately half have undertaken DTA as required by the regulations (2006 to date), and the majority have successfully demonstrated that the discharges posed no significant risk to the local receiving environment. In a small sub-set of sites, DTA demonstrated that the local environment may be at risk and has enabled measures to be taken to reduce that risk to an acceptable level. This poster reviews the current state of regulatory DTA in the UK, evaluates its success to date in addressing the environmental effects of complex effluents, and provides recommendations for the improvement of the existing UK regulatory DTA regime.

**WE 311**

**Chemical mixture risk assessment in the context of multiple environmental stressors**

KE Kapo[1], SD Dyer[2], D De Zwart[3], L Posthuma[3]
[1]Montani Run, LLC, KENNA, United States of America
[2]The Procter & Gamble Co., CINCINNATI, United States of America
[3]RIVM, BILTHOVEN, The Netherlands

The importance of a multiple-stressor perspective when considering chemical mixtures in ecological risk assessment and management is demonstrated in a case study of the Hocking River watershed (Ohio, USA). A variety of assessment approaches ranging from single-chemical, chemical mixture, and multiple stressor assessments were applied to identify sites within the watershed at risk for biological impacts based on the environmental conditions present. The results of each approach were compared with observed biological impacts. The traditional single-chemical approach identified sites exceeding U.S. EPA water quality criteria based on single-chemical species sensitivity distributions, however this approach missed the majority of observed biological impacts. Chemical mixture approaches, such as toxic pressure quantified as multi-substance Potentially Affected Fraction ('msPAF') using a mixed-model approach, significantly improved the identification of impacted sites. The most effective identification of impacted sites was achieved when chemical mixture toxicity was integrated into a multi-stressor approach along with other stressors such as physical habitat quality and water chemistry. Within this context, the influence of chemical mixtures on biological impact in the watershed was determined to be outweighed by other stressors. The results suggest that a sole focus on chemical mixtures in retrospective assessments creates a scenario for potential over-management of chemicals, with less-than-expected ecosystem recovery after chemical exposure is reduced. Additionally, evaluation of chemical mixtures based on a criterion-risk assessment with a safety factor can further overestimate mixture effects, identifying more sites as impacted by mixtures when in fact other stressors are responsible for the observed impacts. This case study illustrates that while management of chemicals is enhanced by a chemical mixture perspective, the placement of this stressor in the context of other environmental stressors is critical for effective ecosystem protection and management.

**WE 312**

**Assessing the impact of mixtures in the environment, an ECETOC taskforce**

M Hamer[1], S Dyer[2], K den Haan[3], K Jenner[4], M Junker[5], L Pope[6], M Galay Burgos[7]
[1]Syngenta, BERKSHIRE, United Kingdom
[2]P&G, CINCINNATI, United States of America
[3]Concawe, BRUSSELS, Belgium
[4]Givaudan UK Ltd, KENT, United Kingdom
[5]BASF, LUDWIGSHAFEN, Germany
[6]Unilever, BEDFORD, United Kingdom
[7]ECETOC, BRUSSELS, Belgium

The toxicity of mixtures can be predicted when the properties and chemical components are known. However, it is more problematic to assess the potential interaction of chemicals in the environment when not all components of the mixture are known. This leaves industry vulnerable to criticism for not determining whether chemicals present in the environment, including those at concentrations below their predicted no effect concentrations (PNECs) may act additively to cause an overall effect - so-called low dose effects.
As it is usually not possible to know all the potential combinations of chemicals in the environment, prospective risk assessments of mixtures may be limited. However, retrospective approaches that compare predicted risks from chemicals as well as other factors such as instream habitat, and altered hydrology and other factors to measured biological quality (e.g. structure and function) provide an integrated/holistic approach. This enables the relative importance of chemical mixtures in causing adverse biological responses to be determined. In essence, these retrospective approaches provide an ecological reality check by identifying priority concerns pertinent for appropriate management of water quality, including Environmental Quality Standards set within the WFD.
However, this is not a simple activity and requires the development of methods to discriminate the impacts of chemicals and other stressors from natural environmental variation. This poster summarises existing methods for retrospectively assessing the impact of mixtures in the environment, including methods to assess the degree to which a site is impaired and the eco-epidemiological methods used to attribute the cause of such impairments. Guidance will be presented on suitable methods and future research needs.

**WE 313**

**Displacement of test chemicals from serum constituents in mixtures and its effect on free concentrations and in vitro assay results**

NI Kramer, CAG van Daele, BJ Blaauboer, M van den Berg, JLM Hermens
Utrecht University, UTRECHT, The Netherlands

*In vitro* assays may be used to estimate the toxicity of chemical mixtures. The concentrations of chemicals in these assays are normally expressed as nominal concentrations. However, the freely available concentrations may be much lower than the nominal concentrations because the chemicals may bind to serum constituents in the culture medium. When chemicals are exposed to an *in vitro* assay in a mixture, one chemical that is normally bound to serum proteins (and thus has a low free concentration) may be displaced from serum proteins by another chemical that binds more strongly to these proteins, thus increasing the free concentration and response of the first chemical in the assay. When nominal concentrations are used, one could falsely attribute this increase in response as being a direct effect of the second chemical. Therefore, the aim of this study was to measure the free concentration of polychlorinated biphenyls (PCBs), individually and in a mixture, in a CAFLUX assay, using solid phase microextraction (SPME). Results indicate that mixture effects attributed to non-AhR agonists may in part be explained by the displacement of AhR-agonists (PCB 118, 126, 156) from serum constituents by non-AhR agonists (PCB 28, 138, 153).

**WE 314**

**Mixture toxicity in practice: what are the needs?**

PY Kunz[1], C Kienle[1], L Aicher[2], M Junghans[1], I Werner[1]
[1]Ecotox Centre, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL, DÜBENDORF, Switzerland
[2]SCAHT, Swiss Centre for Applied Human Toxicology, BASEL, Switzerland

Addressing the topic of mixture toxicity and its integration into risk assessment is an important task, which requires close collaboration between science and regulatory authorities. Furthermore it is essential to sensitize different stakeholders, such as industry, authorities, and research organizations, as well as the general public to this problem. With this aim, a workshop on mixture toxicity organized by the Swiss Centre for Applied Ecotoxicology, in collaboration with the Swiss Centre for Applied Human Toxicology, took place in Switzerland in November 2010.
During/at this workshop, participants from various stakeholder groups and international experts on mixture toxicity discussed the available models and assessment methods (including risk assessment of mixtures), whereby not only component-based mixtures, but also interactions of substances with abiotic stressors were considered. Insight into regulatory challenges resulting from mixture toxicity was presented, and the workshop was concluded by group discussions and an overall discussion on important issues in mixture toxicity. Challenges for assessing mixture toxicity were identified by representatives from practice, regulation and science, and several examples were presented on how those difficulties can be overcome.
The participants addressed the need for good communication between science and regulation, and supported the effort to jointly - that is with participants from eco- and human toxicology - tackle the challenges in mixture toxicity and effect assessment. Effect based biotest systems were highlighted as useful tools to assess the toxicity of mixtures, however, the costs of those assays as well as the applicability for regulation were important points and concerns. Here the desire to have a 'tool box' for measuring and assessing mixture toxicity was expressed. The poster gives an overview of the problems identified, suggestions how to solve them and lessons learned.

**Environmental and health impact of unknown / unregulated chemical mixtures - case study of the State of Punjab, India**

V Saini
Sunrakshan Foundation, FARIDABAD ( HARYANA ), India

Sunrakshan Foundation shares its experience in the mind set of the regulators, both at the Centre and State level. The problems of keeping a check on the complex chemical mixtures finding its way into agriculture and its impact on human health. The various laws available and enforced still have a loophole in controlling such mixtures finding its way into the environment, primarily as a result of unorganized industrialization. A typical problem in Punjab, the bread basket state and pioneer of the famous Green Revolution of INDIA.

## S07P - Special Poster Session: 30 years of Environmental Systems Research - A tribute to Michael Matthies

In the last 30 years, considerable progress was achieved in the field of environmental research by means of systems analysis and application of mathematical simulation models with active and envisioning contributions from Michael Matthies. Some landmarks of his scientific career are highlighted in this poster session.

Predicting the fate of the numerous environmental contaminants is a major challenge in chemical risk assessment and management. The development of multimedia fate and transport models was motivated by the objective to simulate the environmental fate of organic chemicals more realistically. Explicit modelling of partitioning into and transport between different environmental compartments beyond simple equilibrium approaches allow considering the effects of the emission compartment, kinetics of inter-media transfer and loss processes. To reduce the effort in the determination of substance specific input parameters, quantitative structure-activity relationships (QSAR) were developed. These methods predict substance properties by correlating them with chemical structure.

Introduction of specific measures such as overall persistence (Pov) and characteristic travel distance (CTD) within the model ELPOS constitutes a well acknowledged contribution in the field of assessment of chemicals with respect to their persistence and long-range transport potential (LRTP). Bioaccumulation potential as of specific interest for PBT assessment was recently integrated into ELPOS by combining a food chain model with the fate model. In this way, multimedia models have become a powerful tool for the assessment of organic chemicals according to prevailing legislations like the Stockholm Convention and the European chemical legislation REACH.

Michael Matthies was among the first researchers to investigate the uptake of organic pollutants into plants and subsequent accumulation therein. With a simple one compartment model, he was able to predict internal concentrations of plants based on a few physico-chemical parameters. Advanced model approaches split up the plant into separate compartments such as root, stem, leaves or fruits and consider temporal variability. These models proved to be useful tools e.g. to predict concentrations of chemicals in plants in the scope of risk assessment procedures.

Basic research elucidating the possible need to refine environmental risk assessment for veterinary antibiotics took advantage of model-based analysis and integration of experimental results. Simulation models for the fate of the sulfonamide sulfadiazine in soil were coupled via cellular uptake with the effect on the cellular level and furthermore used to predict effects concerning soil nitrification and the selection of antibiotic resistance genes.

Early Environmental Information Systems basically followed database driven approaches and provided access to homogenous datasets. A major focus was on chemical data needed for environmental exposure assessment and hazard management. Later on, Matthies and colleagues used information systems to structure the growing amount of heterogeneous environmental data for use in appropriate simulation models. With the development of Geographic Information Systems (GIS) consideration of the spatial dimension of environmental problems became possible, for instance in impact assessment of atmospheric heavy metal deposition or regional groundwater contaminations.

Environmental exposure assessment of aquatic micropollutants needs to consider spatial and temporal variability of concentrations in river basins. The software tool GREAT-ER (Georeferenced Regional Exposure Assessment Tool for European Rivers) has been developed to simulate surface water concentrations as an effect of overlying multipoint and diffuse sources into receiving waters under the aegis of Michael Matthies. The model considers emissions from local sources and calculates concentrations in whole river basins on a high spatial resolution (≤ 2000 m) taking into account removal and transport processes. It has been successfully applied to simulate surface water concentrations of typical household chemicals, pharmaceuticals and metals in various catchments. Temporal variability can be included within a Monte-Carlo type probabilistic simulation routine. By coupling with a GIS, resulting concentration patterns can be visualized in form of digital colour-coded maps or concentration profiles of selected rivers. This enables investigation of spatial concentration variability and analysis of exceedance of environmental quality standards. The model can be embedded in integrated river basin management systems which constitutes a useful tool in water quality management of aquatic micro pollutants. It was already successfully linked to an environmental information system and coupled with analysis tools to build up a Decision Support System (DSS) for integrated management tasks in the Elbe catchment.

[5]Cornell University, ITHACA NY, United States of America
[6]Aerosol doo, LJUBLJANA, Slovenia
OBJECTIVE: To verify if the Black Carbon (BC) measurements could detect and demonstrate more suitably than PM differences in local urban air quality among three traffic scheme zones: unrestricted traffic, Ecopass zone with traffic restrictions, and pedestrian zone in the Milan city center.
METHOD: Instruments: measurements of BC with Aethalometer AE51 by Magee Scientific, USA and $PM_{10}$, $PM_{2.5}$, $PM_1$ with a mass precalibrated Aerocet 531 by Metone Instruments Inc. USA.
Procedure: concurrent measurements in three fixed stations within the three different zones repeated in three different days and from 8.00 am till 7.00 pm and with different weather conditions.
RESULTS: campaign day 1: 6.3 (2.9); 3.1 (1.7); 1.6 (0.3), Campaign day 2: 5.2 (2.3); 2.8 (1.4);,2.0 (0.4) Campaign day 3: 3.3 (1.9); 2.6 (1.8); 1.5 (0.5) mean BC (SD) levels µg/m$^3$ for unrestricted, ecopass and pedestrian zones respectively. The differences in mean BC levels in the same day in the different traffic scheme locations were highly significant for each comparison ($p < 0.0001$). Mean $PM_{10}$, $PM_{2.5}$, $PM_1$ concentrations did not show significant differences among the different traffic zones on the different campaign days. BC/$PM_{10}$ ratios decreased significantly from the unrestricted zone to the pedestrian zone: on average, the BC content in $PM_{10}$ decreased by about 52% and 65% in the Ecopass zone and the pedestrian zone, respectively, as compared to the no-restriction zone.
CONCLUSION: Different city areas with different traffic intensity and quality showed different black carbon levels. Traffic reduction within the Ecopass zone results in a significant reduction in black carbon concentrations compared to the no-restriction zone, while the pedestrian zone rated even better. These data suggest that black carbon is a highly relevant metric of traffic pollution and should be taken into consideration in demonstrating the effectiveness of air quality mitigation measures.

**Influence of Outdoor Smoking on Urban Pollution. PM and Black Carbon (BC) Concentration Measurement over a Typical Summer Weekend in the Pedestrian Brera Historical District of Milan, Italy**
A Ruprecht
SIMG, BAREGGIO (MI), Italy
INTRODUCTION. Historical Milan City Center is characterized by "street canyons", some pedestrian islands and some open car traffic. On the pedestrian areas many people are smoking worsening the outdoor air quality.
SCOPE. To compare $PM_1$, $PM_{2.5}$ and $PM_{10}$ and BC concentrations in pedestrian Via Brera with parallel high trafficked Via Pontaccio, on summer weekend.
METHODS. Two analysers (Aerocet 531, MetOne) were used to record $PM_1$, $PM_{2.5}$ and $PM_{10}$ and BC with two micro Aethalometers AE51 (Magee). They were placed concurrently from Friday until Monday on the balcony at first floor flats, one in Via Brera, the other in Via Pontaccio. Outdoor nicotine vapour phase was sampled using passive samplers at the same position and time of the other instruments and analysed using gas chromatography. Cigarette consumption and traffic density were estimated.
RESULTS. In the rush hours :458 smokers/h in Brera and 922 cars and motorbikes/h in Pontaccio. Means (SD) of data recorded are reported in Table 1. BC in Via Brera reached but not overcome Pontaccio concentrations during crowded hours, but all PM increased more in Brera than in Pontaccio by a increase factor of 2.38, 2.30 and 2.08 in Brera and 1.19, 1.21 and 1.22 only in Pontaccio for $PM_1$, $PM_{2.5}$ and $PM_{10}$ respectively. Nicotine was below detection limit on Pontaccio (>0.02 µg/m$^3$) and 0.26 µg/m$^3$ confirming presence of ETS.
CONCLUSIONS. Outdoor ETS increase PM concentrations during the crowded hours in the pedestrian street more than in the trafficked nearby street. BC also showed an increase in the pedestrian street during the rush hours, but the difference was not as much relevant.

**Measurements of Particulate Matter (PM) pollution in the Subway System of the City of Milan, Italy**
A Ruprecht[1], G Invernizzi[1], C De Marco[2], R Mazza[2], D Westerdahl[3], C Sioutas[4], G Mocnik[5]
[1]SIMG, BAREGGIO (MI), Italy
[2]National Cancer Institute, MILANO, Italy
[3]Cornell University, ITHACA NY, United States of America
[4]University of Southern California, LOS ANGELES, United States of America
[5]Aerosol doo, LJUBLJANA, Slovenia
Background. Restrictions to vehicular traffic in cities are increasingly implemented in order to reduce pollutant emission with an increase in the utilization of the subways system in the metropolitan cities. A strict monitoring of the index of air quality (IAQ) in the underground transportation system should be therefore carried out.
SCOPE. To assess the concentration of particulate matter (PM) in the subway system of Line 1, 2 and 3 of the Milan subway
METHODS. Analyzer: portable laser mass analyzer model Aerocet 531, MetOne, USA precalibrated to record $PM_1$, $PM_{2.5}$ and $PM_{10}$. Procedure: complete journeys on the three subway lines measuring the stations outdoor, the platforms and the carriages concentrations.
RESULTS. Mean (SD) outdoor: $PM_1$ 14.6(13.3); $PM_{2.5}$ 29.5(24.3); $PM_{10}$ 49.5(27.2) ug/m$^3$. Mean(SD) platforms: $PM_1$ 19.7(9.5); $PM_{2.5}$ 62.4(29.5); $PM_{10}$ 141.8(64.6). Mean(SD) carriages:

$PM_1$ 21.9(11.1); $PM_{2.5}$ 100.8(65.7); $PM_{10}$ 253.0(134.1) ug/m³. The PM concentrations on the platforms resulted 1.2, 2.1 and 2.9 times greater than the outdoor for the $PM_1$, $PM_{2.5}$ and $PM_{10}$ respectively and in the carriages of 1.3, 3.4 and 5.1.
CONCLUSIONS. PM levels were much higher in the whole underground system as compared to outdoor pollution. In the whole network $PM_{10}$ concentrations always exceeded EU outdoor limits of 50 ug/m³ and the suggested 25 ug/m³ for the $PM_{2.5}$ Extremely high concentrations (over 250 ug/m³) were found inside subway carriages. Such an exposure is considered hazardous for sensitive groups of people (respiratory and cardiovascular patients, children, pregnant women). We suggest that the air quality should be constantly controlled with fixed monitoring sites at platforms and with portable analyzers in the carriages, as in other subways in the world. Improvement in filtration efficiency on the carriages and installation on all platforms of screen door equipments is envisioned to reduce avoidable exposure to peak PM concentrations of thousands of commuters.

**WT 341**

**The impact of no-traffic Sundays on atmospheric pollution in the City of Milan, January 2011: black carbon concentration measurement as a reliable traffic pollution metric**

A Ruprecht[1], G Invernizzi[1], C De Marco[2], C Sioutas[3], G Mocnik[4], D Westerdahl[5], R Mazza[2]
[1]SIMG, BAREGGIO (MI), Italy
[2]National Cancer Institute, MILANO, Italy
[3]University of Southern California, LOS ANGELES, United States of America
[4]Aerosol doo, LJUBLJANA, Slovenia
[5]Cornell University, ITHACA NY, United States of America

INTRODUCTION. On February 2011 the $PM_{10}$ concentrations in Milan exceeded the limit of 50 µg/m³ for 35 days and the Municipality decided to stop the traffic on two consecutive Sundays.
SCOPE. To evaluate the efficacy on air quality of Sundays traffic limitation measuring Black Carbon (BC) content in Particulate Matter (PM).
METHODS. Analyzers: A precalibrated analysers (Aerocet 531, MetOne) was used to record mass of $PM_{10}$ and a micro Aethalometer AE51 (Magee) for BC. Procedure: PM and BC concentrations were measured at fixed minitoring site at the same hours at the curbside of a high-traffic street of Milan city center and from Friday 4th until Sunday 6th February, 2011. During the Sunday they also measured the concentration before and after the cessation of the traffic restrictions. Traffic density was also measured.
RESULTS. On Friday, Saturday and Sunday $PM_{10}$ mean (SD) concentrations were 89.8 (10.6), 78.3 (15.9) and 120.6 (42.23) µg/m³, while BC concentrations were 9.5 (3.0), 11.4 (3.7) and 8.1(1.8), respectively. The percent of BC in $PM_{10}$ was 10.6, 14.6 and 6.6 percent respectively. Traffic density was 1,600/2,000 and 350/400 vehicles/h on no-restriction and restriction time, respectively. The BC in $PM_{10}$ percent increased from 6.6 to 12.4 one hour after the cessation of traffic restrictions on Sunday. Mean (SD) BC was 8.1(1.8) and 17.6(3.9) µg/m³ in the last hour of restriction and in the first hour after resumption of full traffic, respectively ($p < 0.0001$).
DISCUSSION. Despite the considerable increase in $PM_{10}$ on Sunday as compared with Saturday, BC concentrations were lower both in absolute values and in percent in $PM_{10}$ indicating a reduction in carbonaceous pollutants.
CONCLUSIONS. No-traffic Sundays seem to bring immediate benefits in air quality regardless the absolute values of PM concentrations. This effect is limited to the interested zones; however the benefits disappear after less than one hour after normal traffic resumption.

**WT 342**

**Seasonal source apportionment of volatile organic compounds in Windsor, Ontario**

X Xu, Z Li
University of Windsor, WINDSOR, Canada

Air quality in Windsor, Ontario Canada is heavily impacted by the automotive industry within the city, the industrial sources in Ohio and Michigan (US), and the large volume of car and trucks crossing the border on Huron Church road leading to the Ambassador Bridge. Both emissions and ambient concentrations are expected to change with season. A source apportionment study was conducted using the Chemical Mass Balance (CMB) model. Once every 6-day, 6 Liter Summa canisters were used to collect 24-hr air samples at Windsor West Station operated by Environment Canada. There were 25 samples in 2005 during winter (Jan-March) and fall (Oct-Dec). The samples were analyzed, yielding concentrations of 188 volatile organic compounds. Source profiles were selected based on a previous study in Windsor. The CMB results showed large inter-season and intra-season variability. Vehicle emissions (Diesel Exhaust, Gasoline Exhaust, Liquid Gasoline, Gasoline Vapour) were consistently the greatest sources, 54% in winter and 60% in fall. Contribution from Industrial Refinery was higher in winter (21%) than in fall (18%). Significant contributions from Commercial Natural Gas (17%) and Liquefied Petroleum (7%) were observed in both seasons. The contributions from Biogenic and Coating sources were small and varied little between the two seasons.

**WT 343**

**Simulation and instrumental data conjugation for ambient air monitoring**

V May, V. Zaitseva
Federal Scientific Center for Medical and Preventive Health Risk Management Tech, PERM, Russian Federation

The proposed method includes the conjugation of simulated air pollutant dispersion (in Russia, atmospheric diffusion simulation based on the comprehensive solution of atmospheric ground layer thermo-hydrodynamics equations and turbulent diffusion equations is used) and data obtained by measurements.
Air quality measurements are known to be characterized by high accuracy but low spatial reliability. Simulation of pollutant distribution provides a reliable spatial exposure assessment but it is not sufficiently accurate. The conjugation of spatial distribution characteristics obtained by measurements and simulation data allows us to reduce uncertainties in both methods.
The technique includes the conjugation of field data interpolated to the system of points within the studied area using Delaunay triangulation, and simulation data in the same points. It also calculates compliance coefficients in the points of measurements (fixed monitoring stations) and then approximates the coefficients over the studied area.
The method was applied in the city of Perm with the total area of 799.68 km2 and the population estimated at 985 000 people. In Perm, 125.0 thousand tons of more than 340 pollutants are annually emitted into the atmosphere. Pollutant distribution simulation and the conjugation of the simulation data and instrumental data from seven monitoring stations were carried out for 7.5 thousand points within residential districts. The verification of the obtained data by check measurements showed an improvement of simulation and instrumental data convergence up to 70-95% compared to the previously recorded convergence of 8-50%. We also determined zones with high air pollution levels which could not be identified using linear interpolation of instrumental data and/or were not estimated as polluted zones by the analysis of pollutant distribution simulation.
The method can be used for sanitation and epidemiology studies, investigations, expert examinations and assessments

**Application of Adsorption Sampling and Thermal Desorption with GC Analysis for the Measurement of Low-Molecular Weight Polycyclic Aromatic Hydrocarbons in Ambient Air**

SO Baek, YK Seo
Yeungnam University, GYEONGSAN, South-Korea

Polycyclic aromatic hydrocarbons (PAHs) have been of particular concern since they are present both in the vapor and particulate phases in ambient air. Historically, polyurethane foam(PUF) or XAD-2 have been widely used for the vapor phase PAHs. However, they have shortcomings such as breakthrough of samples and inevitable pressure drop during sampling. Furthermore, collected samples may be significantly lost during solvent extraction and concentration procedures. In this study, a simple method was applied to determine gas phase PAH, and the performance of the new method was evaluated with conventional method. The method was based on adsorption sampling and thermal desorption with GC/MS analysis, which is generally applied to VOC measurement. Target compounds included two rings PAH such as naphthalene, acenaphthylene, and acenaphthene. As a reference method for comparison purposes, adsorption sampling using XAD-2 and solvent extraction with GC analysis was adapted. The performance of the adsorption sampling and thermal desorption with GC analysis for the measurement of low-molecular weight PAHs in ambient air were evaluated to be satisfactory because repeatabilities of standard sample and target sample are all within 20%. Also, lower detection limits value was estimated to be less than 0.1 ppb. The results from comparison studies between two methods for real air samples revealed the correlation coefficients were more than 0.8, and the difference between two groups of data from the two different methods appeared to be all statistically not significant. Although the adsorption sampling and thermal desorption method tested in this study has shortcomings that the method can not determine higher-molecular weight PAHs in the particulate phase, the method is very simple, rapid, and reliable for lower-molecular weight PAHs. In addition, the method can be used for the simultaneous measurement of toxic VOCs, including benzene, toluene, xylenes, and naphthalene.

**Exposure and toxicity assessment for size-related airborne particulate matter from nearby traffic in Seoul**

JY Kim, JY Yang, SH Kim, YW Lim, CS Kim, DC Shin
Yonsei Univ., SEOUL, South-Korea

Automobiles are considered as the primary source of air pollution and many studies are being conducted especially on the risk of particulate matter (PM). We investigated the particle size distribution and chemical properties in the urban air and the capacity of PM to induce cytotoxicity in human bronchial epithelial (BEAS-2B) cells. We collected PM, sized from 0.056 to 10um on the road side, using MOUDI in Seoul, Korea from Dec. 2007 to Dec. 2009.
Concentrations of PM showed bi-modal distribution (peaking at 0.18-0.32 and 1.8-3.2um) and average concentrations of PM10 and PM1.0 were 38.3ug/m³ and 21.9ug/m³, respectively. Our study shows that the particle size was affected by the seasonality and traffic condition, such that the concentration increased in 0.1-1.0um size as the number of vehicles increased.
We observed PM concentration-dependent cytotoxic effects in BEAS-2B cells. We found that exposure to PM2.5 and PM10 from nearby traffic area induced significant increase in gene expression of inflammatory cytokines (IL-6 and IL-8). The cell death rate and release of cytokines in response to the PM2.5 treatment were higher than those of the PM10. The occurrence rates of reactive oxygen species (ROS) were also higher in the order of PM1.0, PM2.5 and PM10 at same treated PM dose. We constructed a dose-response profile by fitting BMD models on oxidative stress considering ROS generation as the endpoint.

**Research and Analysis on the Current Situation of the Noise Pollution in Xi'an City's Acoustic Environmental Domains**

Junhan Liu, Lun Yan, Xiaochuan Pan
Peking university, BEIJING, China

Objective: To find out the noise pollution situation in the acoustic environmental domains in Xi'an city. Method: Measure the noise level in Xi'an city's domains day and night during a year around, and report the monitor result in the seasonal average and year average of equivalent sound level. Result: The monitor result of the noise pollution in Xi'an city's five kinds of acoustic environmental domains is listed as follows: Special residential area's daytime noise all the year is within the national standard, yet the night noise is all beyond it; Residential culture and education area only has one kind of noise level within the national limit, which is the daytime of the second season; The mixed area's daytime noise is without the limit in the second season; The industrial area's daytime noise is all within the limit, however the night is beyond the limit; The area around the main transportation routes has qualified daytime noise for all four season, yet the night noise is beyond the limit. Conclusion: The situation of noise exceeding the national limit exists in all domains in the city, and the night noise situation is more serious. Besides, the noise levels in the night time of the third season in the industrial area and the daytime of the second season of the mixed area have an obvious increase compared with other seasons, which might affect the Xi'an city residents' normal quality of life, and should be controlled.

**Transfer of chlorinated volatile organic compounds from soil and groundwater into indoor air buildings.**

A Thiam, G Gay, C Rollin, B Hazebrouck, C Hulot
INERIS, VERNEUIL-EN-HALATTE, France

Soil vapor migration into house, with subsequent inhalation, is often the main exposure pathway to humans at sites contaminated with Volatile Organic Compounds (VOCs). Two approaches are commonly used for quantification of indoor concentrations: indoor gas measurement or transfer modeling from the source.
Model development is relatively well advanced [1-3] but measurements for model calibration and 'validation' hardly exist in the literature. Furthermore, predictions of indoor gas concentrations

from different models may vary by several orders of magnitude, depending on the application [4]. The PhD work presented here consists in comparing modelled results and experimental measurements on a test site. The site is a factory, contaminated with chlorinated solvents in unsaturated soils and groundwater. Measurements concerned contaminant concentrations and fluxes in different media and at different transfer stages, but also key model parameters. The equations of Johnson & Ettinger and VOLASOIL models were used for this comparison.

**Characterizing the spatial heterogeneity of on-road motor vehicle intake fraction**

B Lobscheid[1], TE McKone[2], M Spears[1], A Horvath[3]
[1]Lawrence Berkeley National Laboratory, BERKELEY, United States of America
[2]Lawrence Berkeley National Laboratory and University of California, Berkeley, BERKELEY, United States of America
[3]University of California, BERKELEY, United States of America

On-road motor vehicles (MVs) in the United States (US) emit approximately $10^9$ kg/y of conserved (non-reactive and non-depositing) hazardous air pollutants (HAPs) to the atmosphere. There is a need to spatially resolve the population impacts associated with these HAP emissions. To address this need, we estimate population impacts using the intake fraction (iF)--the ratio of the chemical mass taken in by a population to the mass released. The population iF [ppm] is estimated from the on-road MV source-receptor relationships derived from the US Environmental Protection Agnecy's AERMOD model, which was employed in the latest (2005) National Air Toxics Assessment (NATA). AERMOD is an advanced local-scale air quality model that provides S-R relationships ($\chi$/Q), in mg/m$^3$ per ton/y emitted, for the roughly 65,000 census tracts in the continental US.

With AERMOD, we estimate iF for within county receptors, and separately for extra-county receptors. In our California case study, the resulting population iF ranges between 0.5 to 328 ppm--four orders of magnitude. We also compare the within county AERMOD iFs with a county-level iF derived from a box model, based on breathing rate, population, mixing height, wind speed and county area. The box-model iF tracks the lower range of the within-county AERMOD iF. The AERMOD extra-county iFs are generally 1-2 orders of magnitude lower than the range of the within-county iFs. Exceptions are counties with smaller land area and high population density. We are expanding our approach to characterize the within-county and extra-county iF for every county in the continental US. Additionally, we are introducing persistence (reaction and degradation) of each on-road-MV-emitted HAP to the box-model derived iF. Results can be easily incorporated in health impact assessments of on-road MVs at various spatial scales, such as county, regional, and national scales.

**WT 349**

**A population-based modeling framework to assess health impacts from indoor pollutants emitted from gas cooking burners**

B Lobscheid[1], NE Klepeis[2], TE McKone[3], BC Singer[1]
[1]Lawrence Berkeley National Laboratory, BERKELEY, United States of America
[2]Stanford University, PALO ALTO, United States of America
[3]Lawrence Berkeley National Laboratory and University of California, Berkeley, BERKELEY, United States of America

Natural gas cooking burners - including cooktop, oven and broiler burners - emit substantial quantities of air pollutants, such as CO, NOx, and HCHO, that can affect residential indoor air quality, pollutant exposures, and related health risks. To characterize health impacts from gas cooking burners we use a physics-based, data-driven simulation model to build virtual cohorts of homes that are representative of residences in the state of California. Time dependent indoor pollutant concentrations are calculated for each residence, taking into account emissions, dilution, deposition to surfaces, removal by air exchange, as well as pollutants entering with outdoor air. Household and building characteristics influencing these processes are drawn from several data sources, including a representative statewide residential appliance use survey of over 10,000 anonymous households, the US Environmental Protection Agency's (EPA's) National Human Activity Patterns Survey, and a web-based cooking activity survey we conducted to gather additional data on household cooking activity patterns. By linking household specific cooking activity data and residential characteristics we account for the co-variances between the inputs. Based on a literature review, source-proximity effects to the "cooker"and to young children are also incorporated in the model.

Health impacts can be assessed at various spatial scales (county to regional). Impacts are quantified based on modeled peak and time-averaged concentrations in residences and for individual occupants, and the frequency at which health-protective exposure limits are exceeded. Results from a recent model application suggest that nearly 40% of all households in Southern California that use gas cooking burners exceed the US EPA's 1-hr ambient NO2 standard (190 μg/m$^3$) at least once during a typical week in winter. The model is ultimately intended to inform and guide public health policy related to changing gas supplies in California.

**WT 350**

**Validation of the deterministic indoor air model SprayExpo**

S Hahn, A Bitsch, K Schröder, E Berger-Preiss, H Kock, S Gerling, W Behnke, W Koch
Fraunhofer ITEM, HANNOVER, Germany

The deterministic indoor air model "SprayExpo"calculating inhalation exposure to aerosols released during professional liquid spraying processes and containing non-evaporable active components has been validated. The model calculates the concentrations of spray related non-volatile aerosols in various health-relevant particle size fractions independent from the room volume. It takes into account turbulent diffusion, droplet evaporation, and gravitational settling.

Sensitivity analysis has been performed to reveal the most influencing parameters. For validation, modelled values have been compared with measured values carried out at real workplaces in the fields of antifouling treatment and stored-product protection. The exposure concentrations of the active substances used were determined by time-resolved and particle size-segregated personal sampling and subsequent chemical analysis. In addition, the modelling results of SprayExpo have been compared with similar modelling using ConsExpo and BG-Spray.

SprayExpo was found to be an appropriate model for assessing exposures during indoor spraying processes and especially suited for large room volumes. The sensitivity analysis confirmed the assumption that besides the substance release rate, the droplet spectrum of the spraying device is the process parameter which decisively influences the exposure.

Validation of SprayExpo is of relevance for acceptance of this tool to assess the exposure to hazardous substances in indoor air. For regulatory purposes such as the Biocidal Products Directive 98/8/EC, an improved validated model is now available to estimate inhalation exposure to non-evaporable active substances during spray applications.

**A mechanistically-based model for estimating exposure to volatile insecticides from a solid resin matrix ('pest strip')**

JM Verhaar[1], SH Youngren[2], TB Starr[3]
[1]Environ Netherlands BV, DEN DOLDER, The Netherlands
[2]Bergeson & Campbell, P.C., WASHINGTON, DC, United States of America
[3]TBS Associates, RALEIGH, NC, United States of America

A variety of pesticides and other chemicals are formulated in solid resin matrices (e.g., flea and tick collars, pest strips, air fresheners and cleaners, etc.), which permit a controlled release of the active substance from the resin. Controlled-release formulations are very important drug delivery vehicles in pharmacology, but also in other areas, such as chemical synthesis, agricultural fertilizers, pheromone dispersal, and pest control. Controlled-release of a solute from a solid matrix can be governed by diffusion of the solute through the matrix, 'degradation' of the matrix, or both. This poster describes a mathematical model that can accurately predict the release of chemicals contained in such resin formulations. The model incorporates the diffusion-based slow release mechanism, with parameters estimated using experimental chamber data, and it is independently validated against a large database of measured room concentrations for one of the most common applications of chemical-laden resins, i.e., dichlorvos (DDVP) contained in commercially available "Pest Strips". This poster also outlines an exposure assessment that combines reliable monitoring data for long-term ambient dichlorvos concentrations in relevant indoor situations with mathematical simulation modeling of other situations for which monitoring data are lacking. The exposure assessment demonstrates the accuracy of the model predictions compared to the existing monitoring data.

**WT 352**

**Perfluorinated Compounds in Human Blood, Freshwater Fish and Seafood from China: Regional and Global Implications for Human Exposure**

T ZHANG[1], H Sun[1], L Yan[1], K Kannan[2]
[1]Nankai University, TIANJIN, China
[2]Wadsworth Center, New York State Department of Health, ALBANY, United States of America

Despite the growing public interest in perfluorinated compounds (PFCs), very few studies have reported the sources and pathways of human exposure to these compounds. In this study, concentrations of PFCs were measured in human blood (n=93) and freshwater fish and seafood (n=73) samples collected from China to determine residue levels, dietary intakes, regional differences in human exposures, and risk associated with ingestion of PFCs from a primary food source for the Chinese population. The highest mean perfluorooctane sulfonate (PFOS) concentration in human blood was 12.5 ng/mL (from Tianjin), and 25.4 ng/g wet wt (or 0.92 ng/g wet wt after excluding an outlier value) in freshwater fish and seafood. An anomalously high concentration of PFOS was found in a crucian carp collected from Wuhan at 1610 ng/g wet wt. The daily intake of PFOS, perfluorooctanoic acid (PFOA), and perfluoroundecanoic acid (PFUnDA) via fish and seafood consumption (EDIfish&seafood) ranged from 0.10 to 2.51, 0.13 to 0.38, and 0.16 to 0.32 ng/kg bw/d, respectively, for different age groups (i.e., toddlers, adolescents and children, and adults) from selected locations (i.e., Tianjin, Nanchang, Wuhan, Shenyang). The daily dietary PFC intake values increased ($p < 0.05$) with age. Comparison of EDIfish&seafood values with the modeled total dietary intake (TDI) of PFCs by adults from Tianjin, Nanchang, Wuhan and Shenyang, showed that contributions of fish and seafood to TDI of PFOS varied depending on the location. Fish and seafood accounted for 6%, 25%, 80%, and 85% of PFOS intake in Nanchang, Shenyang, Wuhan and Tianjin, respectively, suggesting regional difference in human exposure to PFOS. Based on the export of fish and fishery products from China in 2009, the outflow of PFCs was estimated to range from 0.22 (perfluorohexane sulfonate, PFHxS) to 3.42 kg (PFOS); the outflow of PFOA, PFUnDA and sum of PFCs was 0.87, 0.84, and 6.59 kg, respectively.

**WT 354**

**Human biomonitoring to assess exposure of Norwegian infants to perfluorinated compounds**

G Becher, LS Haug, A Sabaredzovic, KB Gutzkow, G Brunborg, C Thomsen
Norwegian Institute of Public Health, OSLO, Norway

Perfluoroalkyl compounds (PFCs) comprise a large group of man-made fluorinated organic compounds used in numerous consumer products and industrial applications. Several PFCs have been shown to be persistent and bioaccumulative and have been found widespread in the environment and in humans. Animal studies have demonstrated hepatotoxicity, developmental toxicity, immunotoxicity as well as hormonal effects. In order to explore pre- and postnatal exposure to PFCs, we have initiated several studies.

Up to 7 PFCs were detected in the 123 paired samples of maternal and umbilical cord blood plasma. The maternal and fetal levels were significantly correlated for perfluorohexane sulfonate (PFHxS), perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA) and perfluoroundecanoic acid (PFUnDA). The relative proportion of PFHxS was higher than that of PFOS in cord blood compared to maternal blood, and it was higher for PFOA than for PFNA and PFUnDA. This indicates that the chain length of the fluorinated compound is an important determinant for placental passage. Mean PFC concentrations in cord blood were 34 to 84% of the maternal concentrations.

Concentrations of PFOS and PFOA were determined in paired samples of serum and breast milk from 19 Norwegian mothers. Breast milk concentrations were only 1.4 and 3.8% of the serum concentrations, respectively, and the relationships were linear. Assuming a consumption of 700 ml breast milk/day the intakes from breast milk are 61 for PFOS and 29 ng/day for PFOA. In comparison, a dietary intake of 113 and 44 ng/day has been estimated for the adult Norwegian population.

Finally, to study rates of elimination through breastfeeding, 9 primiparous mothers collected breast milk samples monthly from about two weeks after birth and up to 12 months. Using linear mixed effect models, the depuration rates for PFOS and PFOA were calculated to be 3.1 and 7.7% per month, respectively.

**WT 355**

**PBDEs, HBCDs and TBBPA internal level in blood serum from Neonates-Mother paired samples in Korean population and estimating various parameters on internal accumulation of 3 BFRs in human serum**

U.-J. Kim Un-Jung[1], Y-H, Hong Yong-Hee[2], W-J Sim Won-Jin[1], D-H Lee Dong-Hwan[2], J-E Oh Jeong-Eun[1]
[1]Pusan National University, BUSAN, South-Korea (Rep)
[2]Soonchunhyang University Hospital, SOEUL, South-Korea (Rep)

This study investigated three brominated flame retardants compromising 23 tri- to deca- BDEs, TBBPA, alpha-, beta- and gamma- HBCDs in 38 pair blood serum samples of mother and neonates pair samples from Korea population. Also, the effect of environmental factors or impact to health status like thyroid function on internal accumulation of BFRs with 76 blood serum samples were analyzed statistically. Total PBDE concentration in blood serum was ranged from 1.559 to 50.85 ng/g lipid (mean: 17.72 ng/g-lipid) in normal group mothers and from 0.829 to 252.9 ng/g lipid (mean: 46.29 ng/g-lipid) in normal group neonates. In case of patient group, Σ3-7 BDEs concentration was detected from 3.692 to 1563 ng/g lipid (mean: 83.58 ng/g-lipid) for mothers and from 2.216 to 860.2 ng/g lipid (58.25 ng/g-lipid) for neonates. Total HBCDs concentration in normal mothers was ranged from 0.450 to 99.79 ng/g lipid (mean: 12.72 ng/g-lipid) and in normal neonates was ranged from <LOQ to 165.6 ng/g lipid (mean: 17.47 ng/g-lipid). In patient group, total HBCDs concentration was detected from <LOQ to 14.15 ng/g lipid (mean: 3.164 ng/g-lipid) for mothers and from <LOQ to 69.96 ng/g lipid (mean: 7.884 ng/g-lipid) for neonates. Total HBCDs were possessed less than 20% among 3 BFRs in four groups of in this study but relatively highly observed in normal mothers as 31%. TBBPA was analyzed for 76 blood samples and ranged from below LOQ to 73.96 ng/g-lipid (mean: 10.93 ng/g-lipid) in normal group mothers and from below LOQ to 457.4 ng/g lipid (mean: 77.65 ng/g-lipid) in normal group neonates. In case of patient group, TBBPA concentration was detected from <LOQ to 48.25 ng/g lipid (mean: 8.888 ng/g-lipid) for mothers and from <LOQ to 713.6 ng/g lipid (mean: 83.42 ng/g-lipid) for neonates. Among various environmental factors-BDEs with computer use hours and chemical substances or industrial chemicals, HBCDs with production year of car, TBBPA with coffee intake frequency was shown the highest correlation.

**WT 356**

**A biomonitoring study designed to estimate human exposures to pyrethroid pesticides in residential settings using an exposure reconstruction framework**

MK Morgan[1], SR Sobus[2], J Starr[1], D MacMillan[3], D Barr[4], Y Tan[2], L.S. Sheldon[2]
[1]USEPA, RESEARCH TRIANGLE PARK, United States of America
[2]USEPA/NERL, RESEARCH TRIANGLE PARK, United States of America
[3]USEPA/NHEERL, RESEARCH TRIANGLE PARK, United States of America
[4]Emory University, ATLANTA, United States of America

Biomonitoring is an important tool for understanding the linkages between external chemical exposures, internal doses and potential health outcomes in humans. In recent years, there has been an explosion of available urinary biomonitoring data. However, urinary biomarkers by themselves cannot be used to quantitatively reconstruct human exposures to non-persistent chemicals (e.g., pyrethroids). Exposure reconstruction is a process of estimating an external exposure that is consistent with biomonitoring data and requires modeling tools and other key data such as environmental and biomarker measurements, activity pattern, and chemical toxicokinetics. To aid in identifying critical research components and parameters to improve biomarker-based exposure assessments for non-persistent chemicals, we have designed an exposure reconstruction framework. Using the framework, we identified the major data gaps and modeling inputs that were likely needed to improve exposure estimates for the pyrethroid insecticides. 'The Pilot Study to Estimate Human Exposures to Pyrethroids Using An Exposure Reconstruction Approach' was designed to collect these specific types of data including the temporal variability of pyrethroids and their metabolites in environmental media, cumulative oral intake estimates of pyrethroids/metabolites, temporal variability of urinary pyrethroid metabolites, and temporal food, pesticide-use, and activity pattern data. Adults collect their own environmental (food, water, dust, and surface wipes) and biological (urine) samples and diaries at their homes in North Carolina with repeated sample collection for a total of three weeks over a six-week monitoring period. Current-use pyrethroids and their metabolites (environmentally-occurring and urinary) are being measured in the environmental and/or urine samples. This study will assess the feasibility of using an exposure reconstruction approach to estimate 50 adult exposures to pyrethroids using urinary biomarkers.

**Community Duplicate Diet Methodology: A New Tool for Estimating Dietary Intakes of Pesticides**

Jo Melnyk[1], M McCombs[2], GG Brown[2], M Nishioka[3], LC Michael[2]
[1]USEPA, CINCINNATI, United States of America
[2]RTI International, RESEARCH TRIANGLE PARK, United States of America
[3]Battelle Memorial Institute, COLUMBUS, United States of America

True dietary exposure to pesticides is determined by collection and analysis of food samples. Participant responses to questionnaires about acceptability during a recent field study showed the Community Duplicate Diet approach to be feasible as a dietary collection strategy while maintaining low participant burden. The calculation of dietary intake of selected pesticides was accomplished using food samples collected from individual representatives of a defined demographic community. Successfully determining the intake of pesticides through the dietary route will allow for an accurate assessment of the potential exposures to individuals within the community; thereby significantly enhancing the research conducted under large scale epidemiological studies.

For nine participants selected from among a community in Apopka, Fl, intakes of organophosphate (OP) and pyrethroid pesticides were 140 - 1335 ng and 1017 - 24,282 ng, respectively, based on analysis of individual samples collected over one week. Individual samples were collected for breakfast, lunch, dinner, and snack; although not all individuals collected samples at each event. Utilizing individual samples, a community intake was calculated to be 1650 ng for OPs and 37,746 ng for pyrethroid pesticides.

The results showed higher measured levels of pyrethroid pesticides than for OPs, which is consistent with their decreased usage. The diversity of the pyrethroid pesticides detected in food samples was greater than expected. Bifenthrin was detected in several samples, indicating an increase in its use compared to permethrin. Continually changing pesticide usage patterns need to be considered when determining the analytes of interest for large scale epidemiology studies. The Community Duplicate Diet Methodology is a tool for researchers to meet emerging exposure measurement needs that will lead to a more accurate assessment of intake which may in turn enhance decisions for chemical regulation.

**WT 358**

**Estimating the number of Canadian agricultural workers exposed to pesticides**

AP McKenzie[1], NA Garzia[2], K Poplawski[3], AM Nicol[3], PA Demers[4]
[1]Carex Canada, VANCOUVER, Canada
[2]School of Population and Public Health, University of British Columbia, VANCOUVER, Canada
[3]School of Environmental Health, University of British Columbia, VANCOUVER, Canada
[4]Occupational Cancer Research Centre, Cancer Care Ontario, TORONTO, Canada

Introduction

Pesticide exposure surveillance for Canadian agricultural workers is challenging due to a lack of detailed occupational data. Large amounts of pesticides that are classified as "possible"human carcinogens by the International Agency for Research on Cancer (IARC) are used for agriculture. Using a single province (Alberta) as a prototype, the objective is to estimate the number of agricultural workers at risk of carcinogenic pesticide exposure and to geographically characterize exposure by region.

Methods

Canadian Labour Force Survey (LFS, 2006) data on number of Alberta (AB) workers by job title (NOCS - 2006) is combined with regional (ecodistrict) estimates of annual pesticide use (APU). APU's are derived using data from the Interpolated Census of Agriculture (2006) and pesticide use information from the Ministry of Agriculture and Pesticide Management Regulatory Agency. Ecodistricts are categorized into four exposure groups based on APU quartiles, and mapped using a Geographic Information System (GIS).

Results

LFS reports 18,030 agricultural workers in AB broken down by NOCS titles: 'farmers and farm managers' (n=11,510), 'agricultural and related service contractors and managers' (n=20), 'farm supervisors and specialized livestock workers' (n=635), general farm workers (n=5,715), and 'harvesting labourers' (n=150). Agriculture occurs in 110 of 150 (73%) AB ecodistricts. APU estimates (tonnes) were derived for 2,4-D (mean 111; range 0-61) and Chlorothalonil (mean 100; range 0-1029). Using GIS, ecodistricts were mapped by exposure group to visually identify high risk exposure regions for agricultural workers.

Conclusions

Information on the number of agricultural workers at risk of exposure to IARC "possibly"carcinogenic pesticides is necessary to understand the impact of these pesticides. This work is limited by only having access to occupational data at the provincial level, when estimates of pesticide use are most useful at the sub-provincial level.

**WT 359**

**Estimated Dietary intake of Bifenthrin and Indoxacarb in Leaf Mustard**

SW Shim[1], SS Yun[1], SK Oh[1], CW Jin[1], KI Kim[1], MS Ahn[1], YJ Kim[1], EA Park[1], NY Lee[1], ST Kim[1], KS Kyung[2]
[1]National agricultural products quality management service Chungbuk office, CHEONGJU, South-Korea
[2]Chungbuk national university, CHEONGJU, South-Korea

This study was carried out to estimate the dietary intakes of pesticide residues of commonly used insecticides, bifenthrin and indoxacarb in leaf mustard. The pesticides were sprayed onto the leaf mustard at recommended and double doses at the 14 days before the harvest and then sampling was done at 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 and 14 days after spraying under greenhouse conditions. The amounts of pesticides residues in the crop were analyzed with GC-ECD. Limites of detection(LODs) of both bifenthrin and indoxacarb were 0.008 mg $kg^{-1}$. Mean of the recoveries were from 110.1 to 112.9% in case of bifethrin and from 102.8 to 111.0% in case of indoxacarb, respectively. Biological half-lives of bifenthrin and indoxacarb were 6.390 and 6.211 days at the recommended dose and 5.158 and 4.716 days at the double dose, respectively. The estimated daily intakes (EDIs) of the pesticides in the crop harvested at 14days after spraying were less than 0.05% of their acceptable daily intakes (ADIs), representing that risk of the pesticides were generally low.

**WT 360**

**Human dietary exposure to Uranium in Catalonia, Spain**

V Linares Vidal[1], M Belles Mateu[2], G Perelló i Berenguer[2], L Vilavert Castellà[2], B Millan Mainar[2], JL Domingo Roig[2]
[1]Universitat Rovira i Virgili, REUS, Spain
[2]Laboratory of Toxicology and Environmental Health, Universitat Rovira i Virgili, REUS, Spain

Uranium (U) is a health concern as a potential carcinogen and as a causal agent of kidney dysfunction. Human exposure to U can be through dermal contact, inhalation, or ingestion through water or food. In natural environments, uranium isotopes include 238U (99.3%), 235U (0.71%), and 234U (0.006%).

At the moment, we had no information on the concentrations of U in foodstuffs. The main purpose of this study was to establish the temporal trend in the daily dietary intake of U by the population of Catalonia, Spain. Fish and seafood, vegetables, fruits, and rice, were randomly acquired in 12 localities of the zone under evaluation between March and June. U levels were determined by high-resolution gas chromatography-high-resolution mass spectrometry. The dietary intake of U was subsequently estimated for the population of Catalonia, and the results will be the basis for a future survey. The highest U concentrations were found in fish and seafood, dairy products, meat and meat products and bakery products, with mean levels of 0.0199, 0.0105, 0.0061 and 0.0053 ng/g of fresh weight. U intake was estimated for four population groups: children, adolescents, adults, and seniors (aged >65 years). The highest and lowest U intake corresponded to children and senior, respectively. All the intakes are considerably lower than the World Health Organization tolerable daily intake, which is 0.5μg and 5μg per kg of body weight per day in humans of soluble and insoluble DU respectively. In summary, the results of this study indicate that, currently, the dietary intakes of U should not mean additional health risks for the consumers.

**WT 361**

**Consumer exposure to food chemicals: using probabilistic modelling to determine aggregate exposure and assess susceptible human subpopulations.**

CM O' Mahony
Creme Software, DUBLIN, Ireland

The outlined approach is to use a combination of Monte Carlo simulations, large data sets, and probabilistic modelling to create a software tool that can determine the exposure in consumers to chemicals in food. Sources of exposure that are considered include (but are not limited to) pesticides, Food Contact Materials (FCMs), additives, flavourings, contaminants, and food ingredients. In order to accurately determine exposure to a food chemical for a population, an extensive diary of food consumption events needs to be combined with the appropriate chemical concentration data for each food. This concentration data may be may uncertain, have known variability, be the output of a model, or be at a greatly aggregated level. In order to adequately determine the risk to consumers, thousands of simulations are required. These simulations can then be collated to determine susceptible subpopulations by determining e.g. the high consumers, the high percentiles, and the main drivers of exposure. This is also the approach currently being taken in FACET (Flavourings, Additives and Food Contact Materials Exposure Task, a four year EU FP7 project).

**WT 362**

**Evaluating different approaches to uncertainty in fugacity-based multimedia modeling: Probabilistic and non-probabilistic method**

T Öberg, MS Iqbal
Linnaeus University, KALMAR, Sweden

Multimedia environmental fate models are used for evaluating the fate and distributions of organic chemicals in the environment. Uncertainty is associated with the input parameters used in these models and will thus influence the assessment of exposure and risk. Monte Carlo-simulations using assumed parametric distributions have been applied previously, but suffer from the problem of capturing true knowledge uncertainty, for example regarding the choice of distribution or uncertainty in its parameters. Uncertainty can also be described by fuzzy numbers or in combination with distributions as probability boxes. Here we report preliminary results from applying these three different approaches (fuzzy arithmetic, probability bounds analysis and parametric distributions) to characterize uncertainty in a fugacity-based equilibrium criterion level-I mass balance model in an evaluative environment. The uncertainty analysis was performed for three test compounds: benzene, pyrene, and DDT. Experimental data to characterize uncertainty in the Henry's law constant, the organic-carbon water partition coefficient, and bioconcentration factors for fish were collected from literature. Both the measurement uncertainty and the availability of data were substantially different between investigated properties and test compounds, directly influencing the description and modeling of uncertainty. The connection between possibility theory and probability theory was used to implement similar constraints for the fuzzy arithmetic and probability bounds analysis. These calculations were subsequently compared with a description of uncertainty assuming log-normal distribution. The results demonstrate a considerable uncertainty in the estimated uptake in biota, while the general distribution in the environment seems to agree well with a traditional deterministic calculation. The evaluation also highlights some of the possibilities and constraints in the assessment and description of uncertainty.

**WT 363**

**European Solvents Industry Group Consumer Generic Exposure Scenario Tool**

RT Zaleski[1], H Qian[1], MP Zelenka[1], A George-Ares[1], C Money[2]
[1]ExxonMobil Biomedical Sciences, Inc., ANNNANDALE, NEW JERSEY, United States of America
[2]ExxonMobil Petroleum & Chemical, MACHELEN, Belgium

The European Solvents Industry Group (ESIG) has developed a novel tool to undertake an evaluation of the safety of consumer uses of solvents, as required by the Registration, Evaluation and Authorization of Chemicals (REACH) Regulation. This tool builds upon the consumer portion of the European Center for Ecotoxicology and Toxicology of Chemicals Targeted Risk Assessment tool (ECETOC - TRA, a recommended lower tier tool under REACH) by implementing refinements described in Appendix F of ECETOC technical report 107, while accounting for the application hierarchy described in Chapter R15 of the REACH Technical Guidance. The technical enhancements include utilization of additional data to refine scenario defaults and the ability to include the impact of indoor ventilation rates. When appropriate, additional exposure scenarios were developed to cover those not currently contained within the TRA. Via the inclusion of substance-specific Derived No Effect Levels, vapor pressure, and molecular weight information, the TRA tool structure was also modified to automatically determine conditions necessary for safe use (Risk Characterization Ratio <1). Using specific standard phrases, this information is then automatically reported for relevant exposure scenarios, in order that the outputs can be readily assimilated within Material Safety Data Sheet and other similar information technology systems. Transparency within the tool is maintained by including all original defaults and associated exposure predictions, as well as the refined defaults and exposure predictions.

**WT 364**

**REACT - REACH Exposure Assessment for Consumers Tool**

NONE Rodriguez[1], E Deag[2], N Corea[3]
[1]Procter & Gamble, STROMBEEK BEVER, Belgium
[2]Unilever, SHARNBROOK, United Kingdom
[3]SC Johnson, CAMBERLEY, United Kingdom

REACH, the EU chemical legislation, implies the principle 'no safe use - no market'. This means that the safe use of chemicals must be demonstrated and requires that exposure assessments be performed as part of the risk assessment process. For consumer products such as cleaning and maintenance products, human exposure resulting from the domestic use of such products has to be assessed. Chapter R15 of the REACH guidance on Data requirements and Chemical Safety Assessment outlines the basis for tier-1 exposure assessments for consumers. A.I.S.E., the international association of the manufacturers of cleaning and maintenance products, concluded that the current tier-1 exposure assessment methodology results in significant over prediction of consumer exposure. Consequently, to refine exposure assessments for chemicals used in cleaning and maintenance products, A.I.S.E developed its significant habits and practices database for these products and built REACT, a dedicated consumer exposure assessment tool. REACT covers the full range of consumer products marketed by A.I.S.E. member companies. It is based on simple, transparent algorithms and has a similar structure to that of the consumer ECETOC TRA tool. REACT has been used in the 2010 registrations for raw materials by A.I.S.E. member companies.

**WT 365**

**Evaluation of intake fraction for near and far field exposure using Computational Fluid Dynamics models**

GG Giannopoulos, JBM Barrero-Moreno, DK Kotzias
Joint Research Centre, ISPRA, Italy

Inhalation exposure can be represented through Intake Fraction (IF) which is defined as the mass of pollutant inhaled by an individual over a given time per total mass of pollution emitted in the environment in which the individual resides. This term has been proposed by a number of researchers as a robust tool in order to establish the link between emission sources and health effects without applying full chain modeling including mechanistic models. However, the estimation based on the Intake Fraction may contain significant errors, especially when based on the assumption of homogenous concentration in indoor environments. This is mostly the case in environments where emission sources are strongly localized and thus indoor concentrations may vary significantly even within a small distance from the source.
Various analytical models have been developed in order to assess the near and far field exposure for indoor environments, where multiple zones are considered. Among the disadvantages of such an approach is that the division of the internal environment into various zones has to take place before the analysis, thus influencing the final assessment. In the present work the use of CFD techniques is proposed in order to evaluate more accurately the near and far field exposure and thus create a more detailed map of the indoor pollutants concentration close to the occupant. The comparison of the CFD model with the available analytical multi-zone models can help to create a guide for the applicability of simplified analytical models for near and far field exposure assessments. A typical indoor office environment has been chosen for performing the case study and comparing the analytical multi-zone models with the CFD approach.

**WT 366**

**Refined REACH consumer exposure assessment for adhesives**

D Keller[1], H Onusseit[1], A Hollander[2], G Schilling[1], B Schoettmer[1]
[1]Henkel AG & Co KGaA, DUESSELDORF, Germany
[2]Radboud University, NIJMEGEN, The Netherlands

REACH, the EU chemical legislation implements the principle 'no safe use - no market'. This implies that the safe use of dangerous chemicals be demonstrated and requires that exposure assessments be performed. For adhesives and sealants intended for consumer use the exposure resulting from the domestic use of such products has to be assessed. Chapter R15 of the REACH guidance on Data requirements and Chemical Safety Assessment outlines the basis for tier-1 exposure assessments for consumers. FEICA, the international association of the manufacturers of adhesives and sealants concluded that the tier-1 exposure assessment methodology results in significant overprediction of consumer exposure. Consequently, to refine exposure assessments, FEICA developed its knowledge base on the consumer use of adhesives and sealants into a dedicated exposure assessment tool. As a dedicated tool for adhesives, it covers the major categories of adhesives and sealants in consumer use. It is structurally similar to the consumer ECETOC TRA tool and based on simple, transparent algorithms. The tool has been widely used in the 2010 registrations for raw materials of FEICA member companies.

**WT 367**

**Connectivity: causal web for exposure and risk assessment of combined exposure to chemicals**

DA Sarigiannis[1], A Gotti[2], SP Karakitsios[2], G Cimino Reale[3]
[1]Aristotle University of Thessaloniki, THESSALONIKI, Greece
[2]CERTH, THERMI, Greece
[3]Fondazione IRCCS Istituto Nazionale Tumori, MILAN, Italy

This article presents an exposure biology approach to mechanistically-based exposure and risk assessment of environmental chemical mixtures comprising the following steps:
a) Characterization of exposure factors quantifying the parameters that affect human exposure to environmental chemicals, such as time-activity relationships, seasonal and climatic variation, and consumer choice. These exposure factors can be used to derive aggregate and cumulative exposure models, leading in probabilistic exposure assessments.
b) Current toxicological state of the art combines estimations of biologically effective dose with early biological events to derive dose-effect models, which can be used in combination with the probabilistic exposure estimates to derive biomarkers of exposure and/or effect. Combined use of epidemiological, clinical and genetic analysis data may shed light on the effect of risk modifying factors such as lifestyle choices and DNA polymorphisms. Observation of real clinical data and / or results of biomonitoring, if coupled with the exposure/effect biomarker discovery systems, can produce biomarkers of individual susceptibility and thus allow estimations of individual response to toxic insults. Toxicogenomics (transcriptomics, proteomics, metabolomics) is key to this kind of analytical and data interpretation process.
c) The integrated analysis of the biomarker data (including results on biomarkers of exposure, effects and individual susceptibility) results in the integrated assessment of risk factors. Use of information on risk factors with molecular dosimetry data (i.e. estimation of the actual internal and biologically effective dose of xenobiotic substance found in the target organ and, indeed, perturbing cellular response) enables population risk studies to be done, by converting generic exposure profiles into population risk metrics having taken into account inter-individual variability of response and exposure uncertainty.

**WT 368**

**Tiered aggregate exposure assessment methodology and toolbox: the TAGS approach**

DA Sarigiannis[1], C Cornelis[2], M Van Tongeren[3], SP Karakitsios[4], K De Brouwere[2], J Cherrie[3], R Torfs[2]
[1]Aristotle University of Thessaloniki, THESSALONIKI, Greece
[2]VITO, MOL, Belgium
[3]IOM, EDINBURGH, United Kingdom
[4]CERTH, THERMI, Greece

The objective of the TAGS project is the development of a tiered approach to aggregate exposure assessment and the compilation of a computational platform, able to perform quantitative aggregate exposure assessments for environmental and consumer products following a full chain approach (including emission-migration, media concentrations, exposure and internal dosimetry). The use of biomarkers to verify model predictions, to reconstruct population exposure and allocate to apportion exposure to sources (reverse modeling) constitutes a part of the tiered approach and the accompanying guidance. The tiered approach guides the user through the preparation of the exposure assessment. It is foressen to make use of qualitative and quantitative information to evaluate the need for an aggregate assessment and will allow delineation of the assessment to its relevant aspects. Clear criteria for the advancement from Tier 0 (qualitative assessment) to Tier 2 (fully quantitative assessment, coupling probabilistic and deterministic information) have been defined for use in the frame of EU chemical and consumer product safety legislation.
The methodology for quantitative aggregate exposure assessment has been implemented into a proof-of-concept computational platform, the core of which is a synthetic dynamic modeling environment able to track and describe in mathematical terms all the steps of the full chain approach, implementing both mechanistic (e.g. dispersion models, Physiology Based ToxicoKinetic Models) and probabilistic methodologies (Markov Chain Monte Carlo or maximum likelihood

estimates) based on outcome optimization and the current status of knowledge and data availability. The tool provide not only "forward"mode of analysis, but it also describe in a more interactive way the procedure from the source to the target tissue in a way that all intermediate stages can be estimated when needed, with a well defined level of uncertainty.

**WT 369**

**The GExFRAME: IT reflections of the Global Risk Assessment Dialogue**

A Arvanitis[1], S Kephalopoulos[1], G Giannopoulos[1], V Reina[1], D Kotzias[1], G Scotto di Marco[2], M Jantunen[3]
[1]European Commission Joint Research Centre, ISPRA, Italy
[2]GSM, BARASSO, Italy
[3]Institute for Health and Welfare, Department of Environmental Health, KUOPIO, Finland

Since 2008 the European Commission through DG SANCO supports the Global Risk Assessment Dialogue, a Forum to discuss and collaborate on harmonising risk assessment of chemical substances among the OECD member countries.

One of the main common issues dealt with in the Forum is Exposure Assessment. Key issues of Exposure Assessment identified include reviewing and comparing existing approaches worldwide, facilitating the dissemination and sharing of exposure data and assessment methodologies and exposure training. Model credibility and uncertainty, systemic exposure scenarios development (via the establishment of collaborative case studies) and applicability of models in various tiers of assessment are specific issues to focus on.

The GExFRAME is a web-based platform developed by the Joint Research Centre (JRC) of the European Commission and designed to host exposure assessment models for inter-comparison and harmonisation purposes that includes also scenario and new model building capabilities. It allows exposure assessors to apply different, new or existing, low or high tier assessment approaches, under the same model and data management system and compare input assumptions and output results. As such, it provides the technology to tangibly address the key issues identified in the Global Dialogue on Exposure assessment using a central, reference platform.

**WT 370**

**Potential Screening Approaches for Identifying Indicator Compounds at Land affected by Contamination in the UK**

K J L Baker, J D C White, K M Borthwick, H M Hayward
ARCADIS (UK) Ltd, NEWMARKET, United Kingdom

The assessment of land affected by contamination in the UK follows a risk-based framework, relying on the early identification of source-pathway-receptor (SPR) linkages, which could present unacceptable risk. Both qualitative and quantitative methods are used routinely, allowing refinement of the conceptual site model as site-specific data are gathered and eliminating SPR linkages from further assessment. However, there are multiple examples of global semi-quantitative methods that can be used to support discounting SPR linkages without having to undertake a full quantitative assessment. These methods are less commonly used in the UK, resulting in either qualitative assessments that are not robust, or quantitative assessments that are more complicated than is needed. Examples of these semi-quantitative methods which can be used include (1) source-receptor off-set criteria, used in the United States, (2) volatility and toxicity screening criteria used in the United States and promoted in good practice guidance in the UK, and (3) an in-house system to rank contaminants based on their toxicological characteristics and behavior in the environment. Each of the three forms of semi-quantitative is described in detail, highlighting the background to how each approach was first developed, and examples scenarios where they have been applied successfully in the UK.

If applied early in the process, these semi-quantitative assessment approaches would allow UK risk assessment practitioners to more successfully identify indicator compounds, negating the requirement to undertake a detailed quantitative assessment for multiple contaminants.

**WT 372**

**The European Exposure Factors (ExpoFacts) Sourcebook**

IA Zenié, VR Reina, DK Kotzias
EU Commission - DG JRC, ISPRA, Italy

The ExpoFacts database is a unique European tool for exposure assessors and risk managers involved in health and environmental issues, particularly in the areas of indoor air quality, dietary exposures and safety of consumer articles. It implies risk scientists as well. The database contains information on exposure factors and population data covering 30 European countries with extensive links and references.

European exposure factor data have been scattered around national and international institutes, in scientific articles and reports. The ExpoFacts team reviewed available sources, collected reliable exposure factors and evaluated the quality of the data. They classified them into seven main categories: countries, housing, dietary ingestion, non-dietary ingestion, physiology, population and time activity. Two main and complementary search interfaces are made available: either by guided procedure or by free text search. ExpoFacts is accessible through the website http://expofacts.jrc.ec.europa.eu and does not require any registration.

ExpoFacts Sourcebook, financed by CEFIC was developed by THL and JRC, with a steering group composed of key EU academic and regulatory experts as well as opinion formers and supporting peer review process. The database was placed on the JRC web server on 15th January 2007.

The ExpoFacts follow up project started in 2009 and aims to collect, maintain, and provide the most updated reference data on exposure factors specific to European populations. Following its second meeting, the expert group of the ExpoFacts follow up project (including BfR, THL, InVS, LIGA.NRW, ANSES and VWA in addition to HETUS and RefXP ambassadors and ExxonMobil) evaluated new datasets and recommended the dissemination of its use as well as its mutual link with the U.S. Exposure Factors Handbook. The new datasets will be available starting the second trimester 2011.

**WT 373**

**Children exposure to mixtures: Parameters, Scenarios and exposure estimates**

E. STEENHOUT
Université Libre de Bruxelles, BRUXELLES, Belgium

Exposure to a variety of chemicals occurs since conception and then at all stages of age. It varies in intensity as well as in the multiple combinations of many determinants of exposure. Adverse health effects may result from, some effects showing up during the same life stage at which the exposure has occurred while others being delayed until later. There are determinants and parameters that, per se or in combination with other factors, contribute to the occurrence of windows of vulnerability to chemicals. This paper deals with a body of information covering several temporal intervals and with a series of situations involving the inhalation route and dust ingestion. Respiratory volume has been measured in children from 5 to 12 years old, depending on physical activity. Time budget have also been recorded at various ages. An assessment of ingested dust is obtained in another part of the study. These data are used in exposure scenarios involving exposure to mixtures. Children exposure estimates to dust, to ambient and indoor air pollutants are provided for the case of cumulative exposure to lead and organic compounds.

**WT 374**

**PAHs, Nitro-PAHs and Diesel Exhaust Toxins in the North American Great Lakes**

SA Batterman, SM Chernyak, SV Bohac, H Elsaad, J-Y Chin, L Huang
University of Michigan, ANN ARBOR, MI, United States of America

This study investigates the composition and selected sources of polycyclic aromatic hydrocarbons (PAHs), nitro-PAHs, and hopanes and steranes used as diesel exhaust markers in several compartments in the North American Great Lakes region. While concentrations of nitro-PAH compounds are generally well below those of PAHs, their greater toxicity may result in greater ecological and human health risks. Several types of samples were collected and analyzed: diesel exhaust emissions sampled as particulate matter (PM) from engines combusting both conventional diesel and biodiesel fuels; atmospheric deposition samples obtained along transects of major roadways and at urban and remote locations; and biological samples including predator fish (whole sample) and birds (livers) from the Great Lakes. Diesel exhaust emissions showed many PAHs and nitro-PAHs, with levels and compositions that depended on emission control technology, fuel type, and load, e.g., the use of biodiesel fuels significantly lowered both PAH and nitro-PAH emissions as compared to conventional diesel. Graidents in the deposition samples helped to confirm the importance of highway emissions. Concentrations of individual PAH and nitro-PAH compounds in fish and bird samples were detected in the 1 to 100 ng/g range, indicating a need to enhance monitoring, examine trends, assess risks, and apportion emission sources. The development and application of source profiles that can help to identify sources and quantify emissions of these toxic compounds is discussed.

**WT 375**

**Time Trends of Brominated Flame Retardents in Fish from German Water Bodies**

A Würtz, L Windmüller, G Sawal, C Schröter-Kermani, P Lepom
Federal Environment Agency, BERLIN, Germany

Brominated Flame retardents (BFR) are mainly added to plastics to prevent them from catching fire and hence, contribute to consumer product safety. However, they may be released into the environment during use and after disposal of those products and have been found as ubiquitous pollutants in all environmental compartments.

We analyzed muscle tissue homogenates of bream (*Abramis brama*) sampled from six German river systems (Rhine, Elbe, Danube, Mulde, Saale and Saar) for 23 PBDE congeners, five brominated benzene derivates, DBDPE, BTBPE, and HBCD. Samples were taken in biennial intervals in the period 1995-2009 within regular sampling campaigns of the German Environmental Specimen Bank.

Tissue samples were extracted with toluene by PLE, followed by a cleanup using GPC and multilayer silica gel column chromatography. All analytes were quantified by GC-ECNI-MS except HBCD which was analyzed by LC-MS/MS.

Being banned in the EU, many PBDEs are currently no longer in use. Nevertheless, they can still be detected in environmental samples. For the period 1995 to 2009, we found declining PBDE concentrations for most of the congeners while coincidentally concentrations of other BFR, in particular of HBCD were increasing. BFR levels at different sampling sites showed significant differences with lowest concentrations seen in breams from the reference site, Lake Belau, and highest concentrations in those from the River Saar, an area characterized by a high degree of industrialization. Our study clearly indicates that since regulatory actions to limit the use and marketing of PBDEs were taken, their levels in fish from German Rivers declined. However, they were still detected in all fish samples.

Other BFR like HBCD and DBDPE, used as substitutes for banned PBDEs, are of growing concern as their concentrations in biota are on the rise.

**WT 376**

**Environmental toxicology and carcinogenesis**

T Jindal
Amity University, NOIDA, India

In today's scenario of increasing industrialization, different factors including indiscriminate use of various agrochemicals for the protection of crops; release of toxic chemicals and other industrial and automobile exhausts into air, soil and water; have been responsible for imbalance in ecosystem. Accumulation of residues of these environmental pollutants produce adverse effect on various body functions, immune system in particular, making man and animals more vulnerable and susceptible to diseases. The incidence of cancer is on the rise, with multiple risk factors that involve interplay between genetic and environmental components. In India, the annual estimate of cancer was 0.98 million (2001).

Recently PAHs in the environment have become serious concern worldwide since the exposure to high concentrations has been linked to carcinogenic risk. The International Agency for Research on Cancer (IARC) has classified 48 PAH compounds likely to be carcinogenic to humans. Presently in India, light duty diesel cars are selling in large numbers due to the fuel economy. Levels of PAHs such as fluoranthene, pyrene, chrysene, benzo[a]pyrene etc. are higher in emissions of diesel cars than petrol versions. Widespread dieselization of light duty cars and commercial vehicles might further exacerbate the health risks of the urban people of India. According to CPCB, ambient air PAH in Delhi ranged between 9.4-60.9 ng/m3 during 1999-2000 with higher values recorded in winter.

Environmental toxicants have been responsible for the rise in breast cancer cases in females in India. The general population is exposed to organochlorines through food chain but water, ambient and indoor air, dust, and soil are also thought to be involved. As a result, several organochlorines are commonly detected in serum, adipose and breast milk of human origin (Aronson K.J. et.al. 2000). Pollution due to heavy metals is also a big threat to the plant and animal communities, including the human race. Saha (1983) made an extensive survey from 61 villages of 7 districts of West Bengal. He detected 1214 cases of chronic arsenical dermatoses, having skin cancer in 6 cases.

Thus the paper highlights the role of environmental toxicants in rapidly increasing cancer cases, cardiovascular mortality and several other health abnormalities in the current Indian scenario.

Key Words: Cancer; Environmental toxicants; Carcinogenic; Industrialization

**Evaluation of specific Environmental Release Categories (spERCs) developed by industry associations**

D Sättler[1], N Aust[1], A Reihlen[2]
[1]Umweltbundesamt, DESSAU-ROβLAU, Germany
[2]Oekopol GmbH - Institut für Oekologie und Politik, HAMBURG, Germany
At an early stage of RIP 3.2 members of industry associations claimed that the emission factors listed in the guidance documents often are excessive when compared with real emission data. Therefore different industry sectors developed specific environmental release categories (spERCs) with corresponding fact sheets documenting the derivation of the spERCs.
Together with Oekopol GmbH, the Federal Environment Agency Germany analyzed several spERCs at a general level to examine how they were derived and documentated. Additional questions were how existing guidance for the development of spERCs was used, and how different actors in the REACH process understand the role and scope of spERCs. Industry understands spERCs as specification of ERCs. However, according to industry associations who developed the spERCs it is not intended that spERCs are used by registrants directly and without adaptation to his (a single registrants) specific situation. This intention differs from the general expectations of other REACH actors (registrants, downstream user, authorities etc.) not involved in the development of spERCs.
It became clear that conditions of use assumed for a spERC are described at a very general level in most of the fact sheets. The covered uses are frequently rather broadly defined, respective descriptions are spread over several sections in the fact sheets and are partly inconsistent. The default values of the spERCs are derived using different methods and different information sources. In many cases the documentation of the justification of values is regarded as not sufficient.
An essential aspect of the further development of spERCs is the clear and precise information whether or not release factors apply before or after risk management measures. This is necessary for downstream users and evaluators because this information gives indication on reliability and accuracy of the exposure assessment and avoids an underestimation of risks in the Chemical Safety Assessment.

[5]BASF SE, LUDWIGSHAFEN, Germany
[6]European Chemicals Agency, HELSINKI, Finland
[7]Unilever, SHARNBROOK, United Kingdom
REACH, the EU chemical legislation implements the principle 'no safe use - no market'. This implies that the safe use of dangerous chemicals be demonstrated and requires that exposure assessments be performed. The emission estimation constitutes the starting point for environmental exposure assessment. Chapter R16 of the REACH guidance on Data requirements and Chemical Safety Assessment provides the environmental release categories (ERC). They provide very broadly applicable first-tier emission estimates which often lead to significant overprediction of environmental exposure. Consequently, a considerable number of sector groups of chemical industry and their downstream customer industries refined the emission estimates by introducing so-called specific ERCs (SPERCs). This poster presents the outcome of a workshop involving representatives of national competent authorities, European Chemicals Agency, OECD and industry. The workshop is held on April 14. It addresses the current state of emission assessment under REACH, the future development needs for emission assessment under REACH (and elsewhere) with a focus on SPERCs, options for communcation on SPERCs and other emission assessment approaches in order to improving the general level of knowledge and adapting generic emission assessments to specific local conditions.

**WT 379**
**Development of release classes for chemicals used during their various life-cycle stages**
Y Bruinen de Bruin, J Bakker, J De Knecht, E Hogendoorn, T Traas
RIVM, BILTHOVEN, The Netherlands
Under REACH, the safety of chemicals needs to be demonstrated by industry by means of the preparation of chemical safety assessments. A crucial step is to estimate the environmental releases of chemicals during the chemicals' life-cycle stages. To facilitate these estimations, the concept of Environmental Release Categories (ERCs) has been developed. ERCs do not assume any Risk Management Measures (RMMs) and are not based on the chemical's properties. To facilitate more detailed release estimates, they can be considered as blueprints to start building emission scenarios applicable to numerous applications covering the entire life-cycle of a chemical. In total, 24 ERCs have been developed each covering different parts of industrial processes, applications in products and in articles with corresponding assumed emission fractions to air, water and soil. ERCs were intentionally designed to provide very conservative (high) release estimates of substances.
In cases when there is a need for more refined emission information under REACH, the design of specific ERCs (SPERCs) defined and used by industry is optional. SPERCs contain release factors that are based on more process-specific knowledge, including information on implemented RMMs and operational conditions. Hence, SPERCs will be less conservative and, therefore, more useful in attaining realistic release estimates of substances. A source of information for making a SPERC is release information from existing Emission Scenario Documents (ESDs).
Based on two existing OECD ESDs, the potential of ESDs to transform ERCs into SPERCs was investigated. The feasibility of this approach as well as the observed shortcomings in the information requirements will be presented in this poster.

**WT 380**
**A decision tree for Exposure Based Waiving of toxicological studies under REACH**
H Marquart[1], T Meijster[2], M Van de Bovenkamp[3], W Ter Burg[3], S Spaan[2], J Van Engelen[3]
[1]TNO Triskelion, ZEIST, The Netherlands
[2]TNO, ZEIST, The Netherlands
[3]RIVM, BILTHOVEN, The Netherlands
The EU 6th Framework Project OSIRIS (Optimized StrategIes for Risk assessment of Industrial chemicalS through integration of non-test and test information) aims to improve integrated testing strategies for REACH to increase the use of non-testing information for regulatory decision making, and thus to minimize animal testing. A decision tree on the possibilities of Exposure Based Waiving (EBW) for human health endpoints has been developed and will be presented in this poster. The regulatory requirements of REACH determine the legal possibilities for waiving toxicological studies. Waiving is legally possible for repeated dose, reproductive toxicity and carcinogenicity studies, but it has to be adequately justified. In general this requires sound argumentation that exposure levels are already so low that more knowledge on the hazards will not trigger further reduction. Therefore the decision tree focuses on parameters of substance, product, process, conditions and risk management measures that will ensure these very low exposure levels. The following factors are taken into account:
- Substance concentration in products
- Encapsulation
- High integrity closed systems
- Personal Protective Equipment
- Process and product characteristics
- Absorption, distribution, metabolism and excretion
- Frequency and duration of exposure

For some of the factors, e.g. frequency of exposure and process characteristics an expert elicitation process delivered input to specify criteria or examples.
A further option is to compare quantified exposure estimates to so-called 'Thresholds of Toxicological Concern"(TTC), which are general thresholds for groups of substances below which the chance of any of these substances exerting an effect is very low. Proposals for TTC's for inhalation exposure and for dermal exposure have been made within OSIRIS.
The final decision tree is included in the OSIRIS Integrated Testing Strategy Tool at http://osiris.simpple.com.

**WT 382**
**The protection of groundwater and drinking water within the REACH-system**
M Neumann, A Klein
Federal Environment Agency (UBA), DESSAU-ROSSLAU, Germany
Chemicals and uses that fall within the scope of the REACH regulation (1907/2006 EG) have to be registered at ECHA in Helsinki. By doing so, industry guarantees the safe use of chemicals throughout the whole life cycle. Registrants are requested to ensure a high level of protection of human health and the environment. It is common sense for the public and beyond controversy between industry and authorities that groundwater and drinking water need the highest level of protection. The conservation of clean drinking water is one the most prominent examples where the precautionary principle in our society should be applied.
In Europe drinking water is obtained mainly from groundwater, reservoirs or rivers by bank filtration. If these environmental compartments are contaminated by chemicals a contamination of the drinking water itself is possible. As a result society as a whole - and not the polluter - would have to pay for the costs of water treatment. These are often considerably higher than the costs of precautionary action. Thus the protection of groundwater and drinking water gives reasons for a sound assessment of the physico-/chemical substance properties and the exposure of the environment in the registration under REACH.
Here we present an inventory of exposure pathways to be considered and a review of guidance available. We indicate and discuss gaps and offer a definition of the exposure path "men via the environment"in relation to drinking water. The Federal Environmental Agency (UBA) has the aim to support industry to fulfil their responsibility by providing support and guidance. In addition our aim is to identify chemicals for which regulatory action may be necessary. For the protection of drinking water we focus on those combinations of physico-chemical properties and uses that cause a potential contamination. Consequently we also discuss here the key physico-chemical properties, the key uses as well as the regulatory action that should be envisaged.

**WT 383**
**Past, Present and Future - Human Health and Ecological Exposure Assessment under Canada's Chemical Management Plan**
B Zidek[1], Don W Gutzman[2], D Delage[2], L MacKinnon[1]
[1]Health Canada, OTTAWA, Canada
[2]Environment Canada, GATINEAU, Canada
Assessing risk as part of Canada's global commitment to address legacy chemicals by 2020 is implemented through the Chemicals Management Plan. In 2006, Canada categorized approximately 23,000 existing commercial substances through a priority-setting exercise using available data, QSAR modelling, and simple tools that ranked substances based on a number of parameters including their potential for human exposure. Since 2007, Health Canada and Environment Canada have addressed the highest priorities from this exercise by jointly conducting screening assessments on approximately 200 substances as part of its 'Challenge' initiative. Exposure was characterized using empirical data and exposure models to estimate environmental concentrations in air, water, soil, sediments, food and dust, as well as exposure resulting from use of consumer products. Rapid screening approaches were also developed for lower priorities. An overview is presented of both human and ecological exposure tools and methods used to estimate environmental releases and assess ambient environmental exposure, and approaches to assess exposures in indoor environments (personal care products, toys, building materials, etc.). Moving forward, it is recognized that novel approaches to complete the assessment of approximately 3000 remaining prioritised substances and that enhancements to exposure tools available to regulators are needed. Understanding where and how chemicals are used throughout their life cycle is a crucial step in exposure assessment and continued efforts, be it through international initiatives (OECD, WHO, Transatlantic Risk Assessment Dialogue) or stakeholder engagement, are key to improving the quality of exposure assessments. This poster will highlight strengths and limitations from past exposure-based prioritization exercises, exposure-based lessons learned from the 'Challenge' initiative, and current data and exposure tool needs moving forward within the context of chemical regulation.

**WT 384**
**Metabolomic study of rat exposed to pentabromodiphenyl ether**
JJ Seo, Eunjung Bang, Eun Ok Kim
Korea Basic Science Institute, SEOUL, South-Korea
Polybrominated diphenyl ethers (PBDEs) are a group of brominated flame retardants, which have been manufactured in large quantities and widely used in a variety of consumer goods. They spread ubiquitously as environmental contaminants and have been detected in a wide range of environmental samples and humans.
Although tetra- to hexa-brominated congeners tend to dominate the patterns observed in wildlife, the penta-BDE product, which contains mainly tetra- and pentabrominated congeners, is a minor portion of the commercial PBDE flame retardant market.
PBDEs may leach or volatilize from products and have been shown to bioaccumulate in the environment. Bioaccumulation of PBDEs has been extensively studied several decades ago. But little information is available about the metabolic characterization of PBDEs in animal models. In this work, we investigate the metabolic changes in rat force-fed with pentabromodiphenyl ether(PeBDE) by NMR-based metabolomics. 1H-NMR spectra obtained from rat urine and

liver tissue samples.
In order to examine the bioavailability and bioaccumulation of PBDEs at low exposure levels, we have performed a mass balance study in rats fed a low dose of a penta-BDE for 7 days. Suitable extraction and analytical methods were developed to achieve the chromatographic separation of pentabromodiphenyl ether metabolites formed in vivo and to study their structure.
The identification of the OH-PBDE metabolites was also supported by full scan electron ionization mass spectra and MS/MS spectra of LC-orbitrap mass spectrometer.
Six biomarkers were candidate from NMR analysis of urine metabolites isolated from rat dosed with BDE119.
This study provided the valuable information of metabolic difference between treatment and control group by using multivariate analysis and could be applied for understanding the toxicity of PBDEs.

## CS01 - Climate changes, biological invasions and pollution

**TH 002**

**Life under climate and pesticide conundrum: can the plethora of life below-ground endure concomitant stresses part 1 - functional response in terrestrial model ecosystems**

EL Ng[1], C Bandow[2], C Silva[1], R Guilherme[3], J Römbke[2], JP Sousa[1]
[1]IMAR-CMA, COIMBRA, Portugal
[2]ECT Ökotoxikologie GmbH, FLÖRSHEIM AM MAIN, Germany
[3]Escola Superior Agrária, COIMBRA, Portugal

Soil microorganisms are key drivers of many important ecosystem services, including those that support agricultural production. However, climate change may pose a threat, directly through its impact on soil properties (especially temperature and moisture content) and indirectly through the shifts in soil communities. We hypothesise that pesticide risks to microorganisms may change as a result of climate change. The key question is how the plethora of soil inhabitants will endure simultaneous stresses. Aiming to study the interaction of climatic and pesticide stressors on soil microbial activity and function, a Terrestrial Model Ecosystem experiment was conducted under two climatic conditions - Mediterranean (Portugal) and Continental (Germany). The fungicide pyrimethanil (PYR) was used as chemical stressor and extreme rain events (drought and flooding events) were used as climatic stressors. We measured enzyme activities (dehydrogenase, β-glucosidase, phosphatase, potential nitrification) and carbon metabolism profile (BIOLOG). In Portugal, enzyme activities related to C and P cyclings shifted significantly at the maximum application rate (MAR) of PYR (1kg a.i./ha) and so was overall enzyme activity (dehydrogenase) while those related to N and S cyclings were unaffected by PYR. Extremes in precipitation elicited few effects in the measured parameters. The interaction between the two factors did not alter pesticide risks to soil microbial function in long term (8 weeks after treatment) although a short-term (2 weeks after treatment) shift in metabolic profile was observed as a result of the interaction between the extremes in precipitation and pesticide. Biotic and abiotic factors beyond soil moisture seemed to interweave to produce the observed patterns. For German data, where a wider gradient of PYR concentration were used (from 0 to 1400X above MAR), we were able to determine stronger PYR effects and stronger interactions between factors, even for a short period of time, causing irreversible shifts. Such a shift was observed for N cycling.
These findings suggested that microorganisms are sensitive to the interaction between climate change and pesticides even in short-term for low concentration and at high concentration, the effect can be persistent. These changes indicate potential shifts in nutrient cycling in the future. Whether these changes represent a risk or opportunity to ecosystem health will depend on the biotic legacy and immediate pressures.

**TH 003**

**Life under climate and pesticide conundrum: can the plethora of life below-ground endure concomitant stresses part 2 - structural response in terrestrial model ecosystems**

EL Ng[1], C Bandow[2], S Santos[1], D Proença[1], J Römbke[2], JP Sousa[1], PV Morais[1]
[1]IMAR-CMA, COIMBRA, Portugal
[2]ECT Ökotoxikologie GmbH, FLÖRSHEIM AM MAIN, Germany

As the primary chemical pollution from agriculture, pesticide use imposes major stress to soil. Climate on the other hand, has an overriding influence on landuse, particularly agriculture. In Portugal, the Intergovernmental Panel on Climate Change foresee greater risks of flash floods and droughts that will start earlier and last longer, while Germany will see hotter summers with lower rainfall together with wetter and warmer winters. In face of the confounding effects of pesticide and climate change, we hypothesised that microbial community may respond with a shift in its community structure. We used terrestrial model ecosystem to examine the interaction between these factors under two climatic conditions - Mediterranean (Portugal) and Continental (Germany). The fungicide pyrimethanil (PYR) was used as chemical stressor and extreme rain events (drought and flooding events) were used as climatic stressors. We examined the response of bacteria community structure via PCR-DGGE.
PYR was found to be the dominant factor driving bacterial diversity in Portugal, with increasing bacterial diversity up from 0X PYR to 5X PYR (whereby maximum application rate (MAR) of PYR = 1kg a.i./ha). Climatic extremes were not significant at all times and a significant interaction was observed only for a short time (2 weeks after pesticide application), with no lasting impact. Where climate is relevant in the interaction, a mixture of biotic and abiotic factors beyond soil moisture appeared to direct the trend of diversity. Similar short-term effects of PYR were found on bacterial diversity in Germany even though the highest PYR application was 1400X above MAR.
The findings of this study suggest that bacteria communities are sensitive to the interaction between climate change and pesticide in short-term even at low concentration although no long-term shifts in the bacterial diversity were observed even at concentration above 1400X MAR PYR. These changes indicate that microbial communities are resilient to simultaneous stresses.

**TH 004**

**Influence of drought and flood stress on carbaryl toxicity to the reproduction and survival of Folsomia candida (Collembola).**

M Lima, DN Cardoso, AM Soares, SM Loureiro
Aveiro University; CESAM, AVEIRO, Portugal

Edaphic organism can experience a large range of environmental fluctuations in the field and drought and flood stress can influence the life-traits of organisms, influencing their growth, reproduction and survival. Another source of stress is the presence of chemicals in the environment. The aim of this work is to study the effects of soil moisture on the chemical toxicity of carbaryl to a soil-dwelling collembolan Folsomia candida. The effects on survival and reproduction were investigated in single and combined exposures. The main conceptual model for mixture evaluation data, Independent Action, and deviations to synergism/antagonism, “dose ratio”and “dose level”dependency were used to predict the joint toxicity. The reproduction of F.candida was strongly affected by the water content in soil, decreasing the number of juveniles produced at extremely conditions of drought and flood stress. Carbaryl also induced changes on adult survival and number of juveniles produced. Regarding combined exposures, the observed effects were compared to the predicted effects considering stressors single effects and patterns for synergism or/and antagonism were observed.This study highlights the importance of including natural stressors as an extra source of stress that can occur in the environment and that conventional ecotoxicolgical studies with controlled and optimum conditions do not regarded these exposure scenarios.

**TH 005**

**Dose level dependent interactions of binary mixtures of Cd and Zn under different temperatures in the earthworm Eisenia andrei**

SA Reinecke, P Voua Otomo, AJ Reinecke
Stellenbosch University, STELLENBOSCH, South Africa

To investigate whether binary mixtures of heavy metals in soil would affect organisms differently from exposure to the metals sperately, earthworms (Eisenia andrei) was exposed to a fixed ratio (1:1) of mixture concentrations of Cd and Zn in artificial OECD soil for four weeks. As climatic conditions such as rising temperatures have recently become an increasing concern and to determine if different temperatures might affect these metal interactions, the exposures were conducted at three different temperatures (15oC, 20 oC and 25oC)
Selected adult specimens of E.fetida from a stock culture maintained at 20oC, were exposed to 0+0, 50+50,100+100; 250+250, 500+500, and 750+750 mg/kg Cd+Zn (these concentrations were later transformed to toxic units -TU). The experiments were conducted in triplicate and excecuted in incubators at the three temperatures mentioned. Soil moisture, pH and light were kept constant and food, in the form of dried cattle manure was added weekly to all replicates. Biomass change was monitored and the results were analised following a stepwise approach as suggested by Jonker et al (2005), using MixToxModules. The interactions between Cd and Zn at all three temperatures were antagonistic at the lower mixture concentrations but became synergistic at higher concentrations. Analysis parameters indicated that the type of interactions between Cd and Zn were dose level dependent rather than dose ratio dependent. It was also found that a change from antagonism to synergism occurred at higher dose levels than the EC50s measured at all three temperatures. These results showed that these temperatures had no direct effect on the type of interactions present.
Results obtained for interactions between these heavy metals in mixtures indicate that conclusions should always be made with caution, taking into account the concentrations used. Further, that the effects of mixtures on test organisms should preferably be assessed using a wide range of exposure concentrations. In binary mixtures of Cd and Zn the interactions between the metals vary from antagonism (at dose levels lower than the mixture EC50) to synergism (at dose levels higher than the mixture EC50). Thus, metal interactions in mixtures should always be assessed by using a wide range of doses.

**TH 006**

**Effect of freezing and thawing on the availability and elution of PAH in soils**

A Eschenbach[1], B Mahro[2], A Zschocke[1]
[1]University of Hamburg, HAMBURG, Germany
[2]University of Applied Science, BREMEN, Germany

The fate of organic contaminants in soil depends on soil related factors like carbon content, microbial activity as well as on intrinsic contaminant properties. However the impact of environmental conditions such as water content, freezing and thawing, occurrence of cations e.g. is of significance as well. Research on these effects is of high interest in the context of interactions of contaminated to climate conditions and climate change In different approaches - in parts with $^{14}C$ labeled PAH - the effect of freezing and thawing on the fate of PAH in soil samples was investigated. We conducted column experiments to study the elution, column experiments to study the dislocation during slow freezing processes and batch experiments to study the stability of non-extractable residues. In waste material the application of previous freezing and thawing cycles had an impact. The elution rate and availability of PAH was higher than in the untreated control experiments. However in soil material this effect was not detectable. The stability of not-extractable $^{14}C$-PAH bound residues was not significantly influenced by freezing and thawing cycles as well. The extractable fraction and the mineralization to $^{14}CO_2$ in treated samples were comparable to controls.
In soil columns slow freezing processes (4°C per day) which occur under field conditions were simulated and a possible dislocation of organic contaminants was investigated with respect to a differentiation in a frozen and an unfrozen part of the soil column. First experiments on this topic could not confirm expected effects of phase separation and squeezing process due to ice formation. The results of the different investigations will be discussed in comparison and with regard to conditions of permafrost soils.

**TH 007**

**The bait-lamina test as a tool to assess differences in soil activity caused by season, fire and invasion by alien grasses in Cerrado, Brazil**

C Musso[1], HS Miranda[2], AMVM Soares[1], S Loureiro[1]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Universidade de Brasília, BRASÍLIA, Brazil

The Cerrado is a Brazilian savanna recognized as a conservation hotspot. In this environment, the vegetation has to cope with several types of stress, either natural or originated by human activities as a) water-stress, caused by a marked seasonality of the rains, b) fire, which is a natural ecological feature but its frequency has been intensified by human activities, and c) invasion by exotic grass species, which can markedly change the natural environment by displacing natural grasses and increasing the total fuel biomass. It is known that changes in plant community can also affect soil health, since plant-species composition is a key factor in ecosystem nutrient cycling. In this context, a promising method for biological assessment in tropical soils is the Bait-Lamina test which provides a general overview on soil functioning, and can be performed under different conditions. Although it is mostly used to assess effects of chemicals on soil fauna, some studies also report a correlation between feeding activity in the soil and the existing vegetation. The aim of this study was to assess soil-feeding activity using the bait-lamina test in different environmental conditions. Four experiments were conducted in the National Park of Brasília (S 15º 47’ e W 47º 56’). Firstly, the sites, within a study area of 5.400 m2, where sites were classified according to vegetation cover: 1- Melinis minutiflora, an invasive species, 2 - Native grasses/dicots, 3- Andropogon gayanus, an invasive species. For each of the three groups, five replicates of 16 probes were placed in the soil, totalizing 256 probes, for each of the four experiments. The bait used in the experiment was composed by cellulose powder, oat flakes and agar (7:2:1), and the probes were maintained for 10 days in the soil. This procedure was conducted 1- before fire and during the dry season, 2- after a prescribed fire and during the dry season 3- in the same burned area in the beginning of the rainy season, and 4- in an equivalent adjacent unburned area in the beginning of the rainy season. Data was analyzed by Mann-Whitney ranking test, using the software R. Results suggest that both climate, fire and species composition may affect soil feeding activity.

### TH 008

**Does the altered thermal regime measured in the Cerrado soils after fires have a significant effect on germination of native and invasive grasses?**

C Musso[1], S Loureiro[1], AMVM Soares[1], HS Miranda[2]
[1]Universidade de Aveiro, AVEIRO, Portugal
[2]Universidade de Brasília, BRASÍLIA, Brazil

Fire is an important ecological factor in many ecosystems worldwide. In the Brazilian savanna, known as Cerrado, it has been occurring naturally for more than 30,000 years, being ignited by lightening during the rainy season from September to May. However, human activities have been changing fire regimes, and this ecological feature became more frequent during the dry season. This shift may generate losses of annual seed production and depletion of soil seed bank, especially of grass species, that correspond to the major part of the diversity (richness and biomass) of the herbaceous layer. Still, soil seed bank is not completely extinguished by fire, once soil works as a thermal isolator, protecting the seeds from lethal temperatures. It is also known that fires that occur in the dry season cause a significant change in soil thermal regime at 1cm of depth, where more than 90% of soil seed bank can be found. The normal amplitude of temperature is of 13°C (22°C-35°C), and it can reach almost 40°C (10°-50°C) in a burned area. The direct effect of peaks of high temperatures has been reported to cause little effect on germination of Poeaceae seeds. Nevertheless, the effect of different storage temperatures in soil is considered to affect germination of many seeds. Regarding the lack of information on this field and the importance of the Cerrado region as a tropical hotpost for conservation, the aim of this study was to assess the effect of the increased soil temperature, and the time of exposure to these conditions, to ability and mean time of germination of 10 grass species (nine native and one invasive). The post-fire soil conditions were simulated in a germination chamber, where seeds were kept dry in the dark in a oscillating temperature of 10ºC/45ºC, 14h/10h for 7, 15 of 30 days, simulating time between fire and the beginning of the rains. Each time of exposure was followed by a germination period of 30 days, in a photoperiod of 10h of light in 22ºC/37ºC 14h/10h, where seeds were kept watered and seed germination verified daily. Results suggest a species-specific response to these conditions. Germination ability was species and time of exposure dependent. Changes in time for germination were also verified, which can have a significant effect on site recolonization dynamics in post-fire environments and in competition between native and invasive species.

### TH 009

**What's up inside the reactor - biotests for risk assessment of biofuel fermentation**

S Heger[1], K Bluhm[1], M Brinkmann[1], K Winkens[1], A Schneider[1], M Wollenweber[1], S Maletz[1], MT Agler[2], LT Angenent[2], TB Seiler[1], H Hollert[1]
[1]RWTH Aachen University, AACHEN, Germany
[2]Department of Biological and Environmental Engineering, Cornell University, ITHACA, NY, United States of America

As a consequence of the increasing use of biofuels and bioenergy as alternative energy sources to replace fossil fuels, there is an urgent need for ecotoxicological evaluation, in particular within processes that are used to gain these alternative energies. Although research in the field of energy sciences was steadily growing during the last years, ecotoxicological data on the intermediates in the fermentation processes have not yet been sufficiently investigated.
Thus, a project was initiated to assess the pollutant development by microbial conversion from substrate to end product in cooperation between Cornell University and RWTH Aachen University. Cornell University works on the conversion of lignocellulosic wastes into n-butyrate, which can be further converted to the liquid biofuel n-butanol in a subsequent fermentation step. To ensure sufficient biological breakdown, lignocellulosic materials are pretreated with several different techniques, such as hot water acid and hot water base treatment. This process, however, has a known disadvantage of generating toxic compounds, which can inhibit microbial cultures that are grown in down-stream bioprocesses. Undefined mixed cultures may destroy the toxic compounds, which would prevent inhibition. However, if intermediates are not degraded they are assumed to be of ecotoxicological relevance due to possible release into the environment.
In this approach, we want to meet this hypothesis applying a battery of acute and mechanism specific in vitro biotests. Biological analysis will focus on different pretreated and untreated substrate samples, as well as on complementary effluent samples. In detail, cytotoxicity will be assessed using the neutral red retention assay, and Ah receptor agonist activity will be detected with the EROD assay, both using RTL-W1 cells. In addition endocrine activity will be determined in the yeast endocrine screen (YES) assay. Further biotests are considered. Finally, toxic impacts of effluents resulting from the production process will be assessed.

### TH 010

**Climate change damage functions in LCA - (2) data availability and selection of indicators**

I Callesen[1], C Beier[2], R Bagger Jørgensen[2], SI Olsen[1], MZ Hauschild[1]
[1]DTU Management Engineering, LYNGBY, Denmark
[2]Risø-DTU, ROSKILDE, Denmark

Emissions of greenhouse gases among other things lead to increasing atmospheric $CO_2$ concentrations, increasing temperatures, changed precipitation patterns and thus multi-factorial changes in the growth environment (1). Primary producers in both terrestrial and aquatic ecosystems and consumers in the food web will experience ecophysiological changes as a consequence of this. To date, only very few truly multi-factorial ecophysiological experiments at the field scale exist. Results from these suggest that the sensitivities of species and ecosystems towards a changing growth environment will be variable (2). Modeling exercises suggest large-scale range shifts of the major biomes of the world (1). The unknown magnitude of future GHG emissions and the complexity of the climate-carbon system induce large uncertainties in the projected changes. A changed climate may result in new interactions and new directions of ecosystem change due to differing adaptive capacities and new species assemblages.
Within the framework 'ecosystem services' both marketed and non-marketed utilities of the natural environment are formulated (3). Provisioning, cultural, supporting, and regulating ecosystem services have been described. How will these services be affected by the increasing atmospheric GHG concentrations ? How can the changes be expressed in a damage model for LCIA? For the area of protection 'Natural environment' both sensitive and robust responses to climate change may be foreseen for different species within ecosystems and between ecosystems. A common metric may thus show high variability. Plural metrics may be needed to adequately describe the variety of different ecosystem services in different regional settings.
By evaluation of available data from e.g. global monitoring initiatives of ecosystem services such as UN's Food and Agriculture Organisation (FAO), UN-REDD (reducing emissions from deforestation and forest degradation in developing countries), and other available sources (e.g. the Global Biodiversity Information Facility), we discuss the selection of indicators for different environmental services from the natural environment, how these can be related to life cycle inventory results for GHG emissions and what would be appropriate metrics for the resulting damage to the area of protection 'Natural environment'.

### TH 011

**Water temperature, ultraviolet radiation transparency, and motorized watercraft activity interact to control invasive warm-water fish in a Montane Lake**

JT Oris, AJ Tucker, AK Gevertz, CE Williamson
Miami University, OXFORD, United States of America

Montane lakes have been shown to be good sentinels of and are sensitive to the impacts of climate change. In addition, because they are typically oligotrophic and located in aesthetically desirable surroundings easily reached by humans, montane lakes are under increasing pressures due to the impacts of climate change and human recreational activities. The purpose of this study was to determine how multiple stressors affect both non-native and native fish species in Lake Tahoe, a montane lake located at an elevation of 1,900m in the Sierra Nevada mountain range of western United States. Lake Tahoe is a large, ultra-oligotrophic lake that has a history of impacts due to recreational activity and introduced species, including recent introductions of warmwater fish such as bluegill sunfish. Warm-water fish must spawn in shallow littoral waters because of adult requirements for warmer spawning temperatures. In transparent lakes this potentially exposes eggs and larvae to high levels of ultraviolet radiation (UVR). We examined how water temperature, transparency to UVR, and polycyclic aromatic hydrocarbons (PAH) from motorized watercraft activity influence the suitability of nearshore habitats for invasive warm-water fish in Lake Tahoe. Due to climate change and human development, nearshore temperature, UVR attenuation, and PAH levels are increasing, affecting natural processes of the lake. Responses to these changes in the native Lahontan Redside minnow (*Richardsonius egregius*) and the non-native warm-water Bluegill sunfish (*Lepomis macrochirus*) were compared in *in situ* exposures and in controlled outdoor exposures. These results were combined with UVR transparency data from monthly profiles to predict fish survival in each nearshore site as a function of UVR exposure. Our results suggest that current UVR transparency and water temperature limit establishment of non-native fish in most, though not all, nearshore sites in Lake Tahoe. PAH increased the level of UVR toxicity in both species and added an additional stressor to nearshore areas. Determination of the effects of these multiple stressors clarifies an understanding of the invasive success of bluegill and similar species in Lake Tahoe and other oligotrophic, montane lakes that are susceptible to climate change, habitat alteration, nutrient inputs, and recreational activity.

### TH 012

**Combined effects of UV radiation and triclosan in zebrafish early life stages**

R Almeida, I Domingues, S Loureiro, AMVM Soares
CESAM & University of Aveiro, AVEIRO, Portugal

Climate change is an imperative problem compromising human and nature well-being. At ecosystems level, environmental parameters such as temperature, pH, dissolved oxygen concentration and intensity of UV radiation have an important role on the efficiency of organisms' physiological and behavioural performances and consequently on the capacity of response to contaminants. Insignificant alterations of these parameters may compromise this response; thus, toxicity of pollutants is not only conditioned by its concentration and bioavailability but also by possible interactions with abiotic factors. Understanding the combinatory effects of chemicals and environmental parameters is absolutely necessary for an adequate prediction of risk in aquatic environments.
This work aims at studying the combined toxicity of UV radiation and triclosan, a biocide commonly used in personal care, acrylic, plastic, and textiles products. Zebrafish (Danio rerio) newly fertilized eggs were used and the draft OECD guideline on Fish Embryo Toxicity Test was followed. Embryos were exposed to nominal concentrations of 0.1, 0.3, 0.5 and 0.7 mg/l of triclosan, plus a control, under 5 different UV intensities for 8 hours. After this period, embryos were exposed to visible light until the end of the test (96h). Embryos/larvae were daily inspected for mortality, developmental anomalies and development delay. A general Morphology Score (GMS) (based on tail detachment, somite formation, pigmentation, eye development, heartbeat, movement, blood circulation, pectoral fin, mouth and hatching) was used to quantify development delay. Observed results were compared to the ones predicted by the Independent Action (IA) model, usually used in chemical mixture toxicity assessment, considering effects induced by single exposures. It was observed that for the parameters chosen patterns for synergism and/or antagonism were observed as deviations from the IA model. Results will contribute to the understanding of possible interactions of UV radiation and triclosan at lethal and sublethal levels to zebrafish embryos.

### TH 013

**Ultraviolet radiation increases sensitivity to pesticides - Synergistic effects on population growth rate of Daphnia magna at low concentrations**

MA Beketov, A Speranza, M Liess
UFZ - Helmholtz Centre for Environmental Research, LEIPZIG, Germany

Ozone depletion and climate change have resulted in increased UV exposure within both terrestrial and aquatic habitats. These processes highlight the need for improved consideration of UV and other environmental stressors in ecological risk assessment of toxicants. However, the combined effects of UV and contaminants on organisms remain poorly understood, and such effects have not been studied for pesticides. In the study reported herein, we aimed to investigate whether UV"ðB radiation and three selected pesticides at environmentally realistic sublethal doses/concentrations had additive or synergistic effects on the survival, reproduction, and population growth rate of the standard test species *Daphnia magna*. We observed synergistic effects of UV and pesticides on both cumulative reproduction and population growth rate for fenoxycarb and pirimicarb, but a less"ðthan-additive effect for tebufenpyrad. The results indicate explicitly that concentrations of toxicants that are nontoxic in standard tests can cause harmful population"ðlevel effects when combined with UV.

**TH 014**

**Effects of parasitism and pesticide exposure on life-history and biochemical traits in two Daphnia magna clones**

IM de Coninck[1], KAC de Schamphelaere[1], M Jansen[2], L de Meester[2], CR Janssen[1]
[1]Ghent University, GENT, Belgium
[2]KULeuven, LEUVEN, Belgium

In nature multiple chemical stressors occur and interact, however, also other environmental stressors (biotic as well as abiotic) can have an influence on the environmental effects of a pollutant. In this study, the influence of the gram-positive bacterial parasite *Pasteuria ramosa* on the toxicity of the insecticide carbaryl to the waterflea *Daphnia magna* was studied. In a three-way full factorial design two different *D. magna* clones were exposed to carbaryl, the parasite and the combination of both. Several key life-history (growth, survival, reproduction, filtration- and castration rate) and biochemical traits (energy reserves, electron transport system, acethylcholinesterase- and phenoloxidase activity) were measured. The two selected *D. magna* clones differed in the presence (clone P) or absence (clone A) of a previously detected synergistic effect of the combination of both stressors on the castration rate.

The insecticide carbaryl had a direct effect on reproduction in both clones. No effect on any of the other measured traits was detected for clone A. In contrast, a significant decrease in filtration rate, growth and survival were observed for clone P. Exposure to *P. ramosa* initiated a shift in energy reserves in both clones: protein reserves decreased while lipid- and carbohydrate reserves increased. This suggests a shift from lipid- and carbohydrate metabolism to protein metabolism. Although the previously detected synergistic effect on the castration rate was not confirmed, the above results clearly demonstrate clonal sensitivity differences towards carbaryl toxicity and enhance knowledge on the biochemical mode of action of the parasite *P. ramosa*.

**TH 015**

**The use of biomarkers to assess effects of binary combinations of chemical and natural stressors to Daphnia magna**

MD Pavlaki, NGC Ferreira, AMV Soares, S Loureiro
University of Aveiro, AVEIRO, Portugal

In aquatic ecosystems several stressors may act together and affect the life traits of organisms. Pesticide runoffs are usually associated with high inputs of organic matter and depletion of oxygen in aquatic systems. This study aimed to use biomarkers (eg. AChE, LDH, CAT and GST) to assess the single and combine effects of imidacloprid and thiacloprid and imidacloprid and low food levels to the life traits of Daphnia magna. Biomarkers were measured after a 96h exposure period showing that chemical stress impaired the activity of several biomarkers used (e.g. related with nervous system). Whenever possible, the two conceptual models, Independent action and Concentration Addition, usually used for assessing response patterns in binary combinations of chemical and natural stressors, were used to fit our data.

Our results showed that biomarkers can be used as useful tools to understand the physiological processes that undergo detoxification processes or to understand stressors mode of action.

**TH 016**

**Multiple stressor effects of predation and chemical pollution in green algae**

BB Fischer, S Roffler, RIL Eggen
Eawag, DÜBENDORF, Switzerland

To investigate the toxicity of chemicals for environmental risk assessment, standard toxicity tests were established which are conducted with single species under controlled and reproducible exposure conditions. In nature, however, species do not live isolated or under constant conditions, but due to changing environmental factors they are permanently challenged with abiotic and biotic stressors such as extreme temperature, nutrient limitation or predation stress. Still, little is known about the effect of the combined stress condition caused by changing environmental factors and chemical pollutants, and how the tolerance to such multiple stressor conditions correlates with the tolerance to the individual stressors. In order to investigate the effect of predation stress in combination with the exposure to toxic chemicals in algae, we tested the sensitivity of eight different natural isolates of the green alga *Chlamydomonas reinhardtii* to grazing stress by the rotifer *Brachionus calyciflorus* and to various herbicides with different modes of action. First, dose-response relationships of individual single stressor were measured to determine 50% effective concentrations for each strain. Based on these experiments, several strains with different susceptibilities to grazing stress and the individual herbicides were selected for combined exposure experiments. The results of these combined exposure conditions will be presented and interpreted in order to determine the role of individual stress factor on the susceptibility of the selected strains to the combined stressors.

**TH 017**

**Effects of temperature variation on the acute toxicity of florfenicol to Daphnia magna and Chlorella vulgaris**

AS Martins[1], LM Guimarães[2], LM Guilhermino[1]
[1]ICBAS/CIIMAR, PORTO, Portugal
[2]CIIMAR, PORTO, Portugal

In the last decade veterinary pharmaceuticals have been increasingly found in aquatic ecosystems raising concern on their possible adverse effects on non target species. Florfenicol is an antibiotic widely used in animal production, including in aquaculture, which has been detected in freshwater ecosystems. The aim of the present study was to investigate the effects of temperature variation on the toxicity of florfenicol to the freshwater producer Chlorella vulgaris and its grazer Daphnia magna. Standard acute bioassays with C. vulgaris and D. magna were carried out in accordance to OCDE guidelines at three different temperatures: 15, 20 and 25 ºC. Test concentrations ranged from 31 to 750 mg/L for C. vulgaris bioassays and from 300 to 1000 mg/L for D. magna bioassays. Six different treatments were prepared for each bioassay and two control groups were used: (i) test medium and (ii) solvent - control. The results indicate that temperature changes the acute toxicity of florfenicol both to the algae and to the water flea, with increased toxicity at 25 ºC relatively to lower temperatures, raising concern on effects at the ecosystem level due to possible disruption of phytoplankton-first consumers balance in freshwater systems contaminated with florfenicol and experiencing water temperature increase as a result of global warming. This may be a factor acting in favour of non-native invasive species (NIS) in their competition with native species, especially in the case of NIS with sub-tropical or tropical origins.

This work was supported by EU-FEDER and national MCTES funds through a PhD grant from the Portuguese Foundation for the Science and Technology (FCT) to Alexandra Martins (SFRH/BD/65436/2009).

**TH 018**

**Does temperature acclimation alters cadmium sensitivity in the green alga Pseudokirchneriella subcapitata ?**

BTA Muyssen, CR Janssen
Ghent University, GHENT, Belgium

Growing attention in environmental toxicology is directed towards the effects of combined - abiotic and biotic - stressors. In aquatic (ectotherm) animals it is frequently observed that metal sensitivity is temperature dependent. Similar research for phytoplankton is limited. In the present study we have cultured the green alga *Pseudokirchneriella subcapitata* for 8 weeks at 12, 20 and 25°C. At the beginning (week 1) and the end (week 8) of this period the algae were exposed to a Cd range (0-320 µg/L Cd) at the respective temperatures. Cd tolerance ($72hE_rC50$), Cd accumulation (internal and adsorbed) and pigment ratios (chlorophyll a and b, carotenoids) were used as endpoints to investigate if temperature alters Cd sensitivity and if changes in Cd sensitivity occurred due to temperature acclimation. At week 1, it was demonstrated that the Cd toxicity at 20 and 25°C was significantly higher than at 12°C with $72hE_rC50$ values of 159 (95% CI=140-181), 157 (139-178) and 197 (172-227) µg/L Cd, respectively. Similarly, Cd accumulation was significantly higher at 20 and 25°C compared to 12°C. At week 8, only at 25°C the $72hE_rC50$ was significantly different from 12°C. Cd accumulation was significantly higher than at week 1 but in general no significant differences between temperature treatments were observed. For the pigment ratios it was shown that temperature did not influence the effect of Cd on pigment ratios, although differences were observed between week 1 and week 8. As a conclusion for this species of green algae we can state that temperature in the range of 12 to 25°C does affect Cd sensitivity and that the effect of temperature can be modified by temperature acclimation.

**TH 019**

**Genetic adaptation potential of Chironomus populations to temperature stress**

SC Nemec[1], J Barateiro[1], B Streit[2], C Nowak[3]
[1]Senckenberg Research Institute, GELNHAUSEN, Germany
[2]Goethe University, FRANKFURT, Germany
[3]Biodiversity and Climate Research Centre (BiK-F), FRANKFURT, Germany

The evolutionary potential of natural populations to environmental stress, is virtually unknown for most species. Under rapid anthropogenic modifications, such as water pollution and Global Climate Change the potential of populations to adapt to environmental changes is of increasing importance. In order to test, if populations of the freshwater model organism *Chironomus riparius* are adapted to local water temperatures we performed common garden life history experiments and used measures of genetic diversity and differentiation. Six populations of *C. riparius* from a climatic gradient in Europe were subjected to three different temperatures (20, 24, 28 °C). While we found significant life history differences among populations and a significant reduction in fecundity in all populations under temperature stress, there was no clear overall sign of genetic adaptation for most parameters investigated. In contrast to southern populations, for instance, midges from northern sampling sites produced egg masses of significantly reduced size under temperature stress. We correlate life history traits with several other factors, such as geographic origin, local climate differences, genetic variation, and differentiation among populations. Our results clearly show that genetic factors have to be considered in assessments of organismal stress sensitivity.

**TH 020**

**Effects of short-term exposure to pyrene on mussels (Mytilus galloprovincialis)**

M Oliveira[1], C Gravato[2], L Guilhermino[1]
[1]University of Porto, ICBAS & CIIMAR, PORTO, Portugal
[2]University of Porto, CIIMAR, PORTO, Portugal

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitously distributed environmental pollutants that pose a potential risk to aquatic organisms. Pyrene is one of the priority PAHs, widespread distributed in estuarine and marine ecosystems that has demonstrated its toxicity in several species. According to some climate changes scenarios, the pH of sea water is expected to decrease in the future and this may interfere with the toxicity of PAHs. Thus, the objective of this study was to investigate the effects of pyrene at different pH values on *Mytilus galloprovincialis*, a mussel that has been commonly used as a sentinel species in the marine environment. Mussels were exposed for 96 hours to a range of sub-lethal pyrene concentrations at three different pH values. At the end of the bioassay, several biomarkers involved in energy production, neurotransmission, biotransformation, antioxidant defences and indicative of oxidative damage were determined. Furthermore, the accumulation of pyrene metabolites was also investigated. Significant effects of pyrene on biomarkers were found and pH variation was able to change the response of some biomarkers to pyrene. This study highlights the importance of investigating combined effects of chemicals and abiotic factors variation on marine organisms.

This work was conducted in the scope of the project RAMOCS (ERA-AMPERA/0001/2007) supported by the Portuguese Foundation for the Science and Technology and FEDER funds in the framework of the EU AMPERA ERA-NET (ERAC-CT2005-016165) and by FCT (European Social Fund and Portuguese "Ministério para a Ciência e Ensino Superior") through a postdoctoral research grant to Miguel Oliveira (SFRH/BPD/65188/2009).

**TH 021**

**May pollution act as limiting factor of the invasive behaviour of the Asian clam (Corbicula fluminea) by decreasing its capability to face chemical stress?**

CA Oliveira, CA Gravato, LM Guilhermino
CIIMAR, PORTO, Portugal

The Asian clam Corbicula fluminea is one of the most important non-indigenous invasive species (NIS) in aquatic ecosystems that has been causing considerable negative ecological and economic impacts, especially in Europe and North America. In the present study, the effects of the reference compound aniline on C. fluminea populations from two adjacent estuaries of the Portuguese NW coast with similar hydromorphological characteristics but different types and levels of pollution were compared as a first step to investigate if chemical pollution may act as limiting factor of the invasive behaviour of this species. Advantage was taken from the comparison between a population inhabiting a low polluted estuary (Minho River estuary) that colonized all the freshwater tidal area and has at the present extremely high densities and a population living in a more polluted estuary (Lima estuary) where it is restricted to small area for years in the vicinity of a paper mill. The hypotheses to be tested is that pollution is decreasing the health status of the population inhabiting the most contaminated estuary, decreasing its capability to face chemical stress and thus the population is not able to spread. Animals were collected in both Lima and Minho estuaries and were separately exposed to the reference compound aniline for 96h, individually, in semi-static conditions with appropriate medium renewal to prevent toxicant degradation. At the end of the assay, several biomarkers involved in functions determinant for survival and performance of the animals were determined (e.g. neurotransmission, energy production,

biotransformation and anti-oxidative stress defenses). The results are discussed in relation to field data on the invasive behaviour of the species and health status.
This study was done in the scope of the project NISTRAKS (PTDC/AAC-AMB/102121/2008) funded by the Portuguese Foundation for the Science and the Technology (FCT) and COMPETE funds

**TH 022**

**Forecasting the effects of global change on bioaccumulation patterns in Great Lakes species**

CA Ng[1], KA Gray[2]
[1]ETH Zurich, ZURICH, Switzerland
[2]Northwestern University, EVANSTON, United States of America

Climate change will have substantial impacts on biodiversity, particularly for aquatic species. Warming temperatures and changing weather patterns will also remobilize and modify chemical partitioning. Holding millions of cubic yards of sediments contaminated with persistent legacy chemicals such as polychlorinated biphenyls (PCBs) and dioxins, the Laurentian Great Lakes are a laboratory for observing interactions between biological and chemical responses to climate change. They provide a wide range of habitat to a variety of species, from littoral forage fish to deep-water predators. In this paper, we couple bioenergetic and bioaccumulation models to investigate the biological and chemical effects of climate change in the Great Lakes. We consider three species: round goby, a warm-water invasive forage fish; mottled sculpin, a cool-water native forage fish; and lake trout, a cold-water native predator. Using our coupled models, we calculate the accumulation of a representative persistent chemical, PCB-77, under four climate scenarios for Lake Erie and Lake Superior. Predator-prey (lake trout-round goby) interactions and food availability (high-low) are incorporated into our simulations. For cool- to cold-water species (sculpin, lake trout) we find that warm temperatures limit growth. For warm-water species (round goby) cold temperatures limit growth. The impact of climate warming on growth depends on the winter lows as well as the summer highs of the scenario, in combination with the species' critical upper and lower thermal limits. We find conditions for high growth and consumption rates generally lead to high bioaccumulation. However, this can be confounded by predator-prey dynamics, as mismatches in the temperature preferences of predator and prey can lead to mismatches in relative growth and uptake rates. As predator-prey dynamics are expected to undergo substantial shifts with changing climate, these relative thermal sensitivities will be key in determining the implications of climate change for bioaccumulation, particularly in top predator species.

**TH 023**

**The impact of climate change related events on water quality**

T Hamers[1], E Simon[1], M Lamoree[2], B van Hattum[1]
[1]Institute for Environmental Studies (IVM), Vrije Universiteit, AMSTERDAM, The Netherlands
[2]Institute for Environmental Studies, VU University, AMSTERDAM, The Netherlands

Climate change may not only affect river water discharges in terms of water quantity, but also in terms of water quality. During flooding periods, for instance, higher water discharges may cause a dilution of normal pollution levels while increased transport of suspended particulate matter (SPM) may strongly reduce the bioavailability of contaminants. On the other hand, higher discharges may cause increased mobilization of polluted sediments and surface run-off from possibly polluted flood plains and inundated urban areas. To study the impact of climate change on the quality of urban and coastal waters, a battery of in vitro bioassays was applied to determine the toxicity profiles of environmental samples collected during climate change related events. SPM samples were collected in rivers from Norway, Sweden, Denmark, Germany, and The Netherlands during periods of dryness, flooding and extreme run-off. In addition, passive sampling was performed using silicone rubber sheets during 4 to 6 weeks periods with different river discharges. Extracts from SPM and passive samples were tested for respiratory toxicity, dioxin-like activities, (anti )androgenic, (anti )estrogenic, and thyroid hormone-like activities, and for mutagenicity. At the time of submission of this abstract, sample collection has been completed and toxicity profiling is subsequently executed. Results will be presented in the context of the sampling events. The work described is performed within the context of the DiPol (Diffuse Pollution) project, which is funded by the Interreg IVB North Sea Region Programme.

**TH 024**

**Impact of climate change on the drinking water resource - focus on emerging substances on the Vilaine's basin**

SL Piel[1], E Baurès[1], S Masclet[2], J Pérot[2], O Thomas[1]
[1]LERES,EHESP, RENNES CEDEX, France
[2]SAUR, GUYANCOURT, France

The Vilaine's basin is located in Brittany, the first agricultural and food industry region of France. This watershed covers two thirds of the region (10,500 km$^2$). Its main river named the Vilaine is about 220 km long and crosses Rennes, which is the main city in this area (approximately 210,000 inhabitants).
All these activities (urban, industrial and agricultural ones) could have an impact on the water quality of this river and its tributaries. Heavy rains could otherwise play a role. This region is often facing significant rainfall events, it rained approximately 170 days and 730 millimetres in 2009 in Rennes.
The DWTP located in Ferel (close to the mouth of the Vilaine) is the biggest facility in Brittany and it is operated by Saur company. So this study aims at following the evolution of the water quality under different hydrological conditions from the source of the Vilaine to the entrance of the DWTP. According to the resource characteristics this study could help optimize the different treatment steps on the DWTP.
Thirty one strategic sampling points have been identified with a preliminary study of land use. To assess the global quality of the watershed, three sampling campaigns on the Vilaine and its tributaries are planned during dry periods. Another one, related to the impact of climate change on water quality, is planned after a rainfall event (preceded by a long dry period).
After analyzing the global physicochemical characteristics of these samples, pesticides and human and veterinary pharmaceutical products will be looked for by developing adapted and robust analytical methods.
Results consist on the description of amounts of all these emerging substances along the Vilaine's basin. Furthermore the main objectives are the comparison of data under dry weather and rainfall events to provide information about the consequences on the drinking water resource quality. Finally the better understanding of the river basin quality could assist the water treatment companies in managing their plants in responses to a sudden climate change, particularly by modulating the quantity of consumables to implement.

**TH 025**

**Predicting the effect of climate change on agricultural insecticide exposure and risk for freshwater communities**

M Kattwinkel, K Foit, M Liess
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

Climate change exerts direct effects on ecosystems but has additional indirect effects due to changes in agricultural practice. These include the increased use of pesticides, changes in the areas that are cultivated, and changes in the crops cultivated. It is well known that pesticides, and in particular insecticides, affect aquatic ecosystems adversely. To implement effective mitigation measures it is necessary to identify areas that are affected currently and those that will be affected in the future. As a consequence, we predicted potential exposure to insecticide (runoff potential, RP) under current conditions (1990) and under a model scenario of future climate and land use (2090) using a spatially explicit model on a continental scale, with a focus on Europe. Space-for-time substitution was used to predict future levels of insecticide application, intensity of agricultural land use, and cultivated crops. To assess the indirect effects of climate change, evaluation of the risk of insecticide exposure was based on a trait-based, climate-insensitive indicator system (SPEAR - SPEcies At Risk). To this end, RP and landscape characteristics that are relevant for the recovery of affected populations were combined to estimate the ecological risk (ER) of insecticides for freshwater communities. We predicted a strong increase in the application of, and aquatic exposure to, insecticides under the future scenario, especially in Central and Northern Europe. This will result in a severe increase in ER in these regions. Hence, the proportion of stream sites adjacent to arable land that do not meet the requirements for good ecological status as defined by the EU Water Framework Directive will increase (from 33% to 39% for the EU-25 countries), in particular in the Scandinavian and Baltic countries (from 6% to 19%). In the most affected regions adaptation and mitigation strategies including vegetated buffer strips and recolonization zones along streams should be fostered.

**TH 026**

**May results of aquatic microcosm and mesocosm experiments with pesticides be extrapolated between climate zones in Europe?**

MA Daam[1], MJ Cerejeira[1], PJ van den Brink[2], TCM Brock[3]
[1]ISA/UTL, LISBON, Portugal
[2]Alterra and Wageningen University, WAGENINGEN, The Netherlands
[3]Alterra, Wageningen University and Research Centre, WAGENINGEN, The Netherlands

Higher tier studies to assess the environmental risks of pesticides have been performed mainly in Atlantic Central Europe and North America and results of such studies have been extrapolated to other climatic regions such as South Europe. Since climate (e.g., sun hours, rainfall, temperature), agroecosystems (e.g., crop rotation, field size), and edge-of-field surface waters (e.g., hydrology, ecology) in those regions are quite different, it may be expected that exposure profiles and effects of pesticides in surface waters are also different. To account for the lack of studies in the South zone, a research project was initiated that started with the set up of an outdoor microcosm facility in Lisbon (Portugal). One of the aims of this facility is to study the possibilities and limitations in the spatial extrapolation of regulatory acceptable concentrations (RACs) derived from outdoor micro-/mesocosm experiments between European climate zones. As a preliminary evaluation, differences in (1) ecology of edge-of field surface waters, (2) exposure conditions to pesticides, (3) direct and indirect effects, and (4) recovery potential in pesticide stressed (semi-) field freshwater ecosystems under South zone compared to Central zone conditions that a priori may be anticipated, will be discussed.

**TH 027**

**Ecological assessment of situation in Shirvan region of Azerbaijan**

TE Gasimzade
Institute of Botany and Institute of Soilscience and Agrochemistry of ANAS, BAKU, Azerbaijan

The total area of flat and mountain part of Shirvan makes 748 thousand in hectares. Anthropogenous factors influensis on changes of biogeocenosisare are drainage and flooding of territories, agricultural land development, set of agrotechnical actions for increase of soils fertility, cutting down of woods and bushes, building of roads and industrial targets. The region climate is non-uniform: climate is damp in high-mountainous and middle- mountainous parts, in foothill-hilly - droughty, warm, in low-flat - dry and warm. The mountain zone of area is rich by mineral waters of medical and resort value. 7 basic rivers proceeding in region: Kur, Goycaychay, Turyanchay, Girdimanchay, Agsuchay, Pirsakhatchay, Gozluchay, their chemical, bacteriological structure influences an ecological condition of a soil-vegetative cover of Shirvan. Pollution of the rivers occurs both superficial and sewage where get a waste and products of live ability of the person. The springs rich basically by sulphur and hydrocarbonates are used as a source of medical and potable water. The mountain part is located at height of 700-3000 m over level of s.l. Soil resources of region differ by variety. Deterioration of physical and chemical properties of soils are observed, has amplified water and wind erosion. It inseparably linked with a soil erosion, salification, chemical pollution and as a whole soil degradation. Development of degradation processes of the soils depends on an overexploitation, unstable agriculture and irrigation, destruction of woods, biodiversity pauperization. These processes are caused by factors of political, economic character, absents of special knowledge, internal both regional conflicts and natural factors. The basic industries of region are food-processing industry, processing local agricultural production (winemaking, fruit growing) and light industry (sewing, carpet weaving). Besides, wood-working enterprises functions in Ismayilli district, stone open-cast mines, brick-works, the enterprises for agricultural machinery repair in Shamakhi and Gobustan districts. Instability of Shirvan ecosystems negatively affects on it biogeocenose and there is actual a working out of measures on its preservation. Constant monitoring of a soil and vegetative cover gives the chance monitoring of an ecological condition of region. The full and all-round information is necessary for decision-making on protection of Shirvan environment.

## EC02 - Atmospheric chemistry, transport and deposition

**Dioxin-like pollutants in sub-alpine Northern Italy: results from 1 year of monitoring at the EMEP Ispra Station**

J Castro-Jiménez[1], SJ Eisenreich[2], G Mariani[3], H Skejo[3], G Umlauf[3]
[1]Ecole des Mines d'Alés, ALES, France
[2]European Commission, Joint Research Centre - Directorate of Programmes, BRUSSELS, Belgium
[3]European Commission - Joint Research Centre - IES, ISPRA, Italy

Dioxin-like pollutants (i.e. polychlorinated dibenzo-p-dioxins and dibenzofurans, PCDD/Fs

and dioxin-like polychlorinated biphenyls, DL-PCBs ) are considered potent toxicants capable of producing a wide spectrum of adverse health effects in biota and humans. There are still some areas in Europe for which none or little information is available on atmospheric ambient levels, occurrence and deposition of these contaminants. Such is the case with Southern-Western Europe for example. Moreover, the scarcity of consistent experimental data sets on atmospheric concentrations poses a problem for proper validation of models. The objective of this study was to initiate POPs atmospheric measurements (weekly resolution) in order to assess air concentrations, seasonal variations and atmospheric deposition of PCDD/Fs and DL-PCBS in a sub-alpine location where little information is available on POPs ambient levels. To achieve this goal, a monitoring and research station was set up at the Joint Research Centre EMEP site (Ispra, Italy). A one year data set (2005-2006) on PCDD/Fs and DL-PCB air concentrations (gas and particulate phases) is presented and discussed.
∑2,3,7,8-PCDD/Fs and ∑DL-PCB total (gas + particulate) atmospheric concentrations ranged from 70 to 3000 fg m-3 (4 to 215 WHO98-TEQ fg m-3) and 3 to 16 pg m-3 (2 to 6 WHO98-TEQ fg m-3), respectively. Both POPs families exhibited different seasonal patterns, PCDD/Fs presenting higher concentrations in the cold season and DL-PCB in hot season. Atmospheric deposition fluxes are under calculation and will help to complete the picture.

**TH 037**
**Levels of PCDD/Fs and PCBs in ambient air from an highly industrialized city of North of Italy**
A Colombo[1], DG Baderna[1], GR Rotella[1], ML Lodi[1], SGB Bugatti[1], EB Benfenati[1], G Ziemacki[2]
[1]Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy
[2]Istituto Superiore di Sanita' (ISS), ROME, Italy
In the present study ambient air samples around a polychlorobiphenyls (PCBs) production plant placed in Brescia, an highly industrialized city in north of Italy, were collected. This plant was the sole Italian PCBs producer and it operated from 1930 to 1984. Previous investigations demonstrate that in the surrounding areas soil levels of polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (PCDD/Fs) and PCBs were higher than limits of the law. The most contaminated area was of particular interest because it may affect several farms producing milk and meat. The first aim of this work is to complete the information rising from the previous studies with an air monitoring in the city of Brescia. PCDD/Fs were measured and expressed as TEQ concentrations according to the international (I-TEF), and World Health Organization toxicity equivalent factors (WHO-TEQ) schemes were calculated. However ambient air may be affected by several emission sources, thus the second aim of this study to understand if there are other potential PCDD/F and PCB emission sources affecting the atmospheric concentrations. Principal component analysis (PCA) was used to compare the "fingerprint"of the air data obtained on the city of Brescia with some source-related data selected from experimental and published data. Finally all the data collected were included in risk assessment analysis applying the Italian guidelines in order to estimate the possible adverse effects induced by the pollutants levels on human and ecological targets.

**TH 038**
**Bulk atmospheric deposition of legacy and current-used persistent bioaccumulative toxic pollutants to remote regions of Europe**
MP Fernandez[1], L Arellano[1], JO Grimalt[1], M Bacardi[2], L Camarero[2], H Thies[3], U Nickus[3], N Rose[4], D Hardekopf[5], E Stuchlik[5]
[1]Institute of Environmental Assessment and Water Research, BARCELONA, Spain
[2]Centre for Advanced Studies of Blanes, GIRONA, Spain
[3]Institute of Meteorology and Geophysics, INNSBRUCK, Austria
[4]Environmental Change Research Centre, LONDON, United Kingdom
[5]Institute for Environmental Studies, PRAGUE, Czech Republic
Persistent bioaccumulative toxic substances (PBTs) cover a wide range of chemical with different physico-chemical properties which pose serious concern for human and environmental health, not only for their toxicity but also because they remain in the environment for long periods of time. In addition, some of these chemicals have high environmental mobility being detected in Polar Regions on they were never produced nor used. Terms like global distillation or selective trapping have been used for describing the processes responsible of the global distribution of these compounds base on their physico-chemical properties and ambient temperature.
Remote mountain regions have been considered as the more pristine areas at temperate and tropical latitudes; however several studies have shown that, as Polar Regions, mountains can act as a cold trap for persistent organic pollutants or even for those chemicals with a limited atmospheric transport, like current-use pesticides.
Moreover, mountain regions represent pronounced gradients of environmental conditions at small scale, which allows studying transport and distribution processes of contaminants that can be representative of the mechanisms operating at global scale.
In order to gain insight into these mechanisms, PBT substances have been determined in bulk atmospheric deposition samples collected in four mountain areas throughout Europe from 2004 to 2006. Sampling sites cover from the south (Pyrenees), to central (Alps), east (Tatra Mts), and west Europe (the Grampians Mts).
Compounds determined encompass both legacy (PCBs, HCHs and HCB) and current-use (endosulfans and PBDEs) pollutants.
Significant spatial differences have been found for all studied compounds, being Tatra Mts the site with the highest deposition fluxes and Pyrenees with the lowest. Interestingly, similar deposition fluxes were found for light BDE congeners between sites, while decaBDE deposition shows the above-mentioned spatial distribution. In general, higher fluxes are found during warmer seasons except for PBDEs. Comparison of the total deposition levels found in this study with fluxes determined in the Pyrenees and the Alps in the late 90s reveals a marked decrease of HCHs and endosulfans deposition to these remote sites while levels of PCBs have increased.

**TH 039**
**Linking polycyclic aromatic hydrocarbons in alpine lake sediments from the High Tatras with atmospheric deposition**
BL van Drooge[1], J Lopez[2], P Fernandez[2], E Stuchlik[3], JO Grimalt[2]
[1]Institute of Environmental Assessment and Water Research, BARCELONA, Spain
[2]IDAEA-CSIC, BARCELONA, Spain
[3]Charles University, PRAGUE, Czech Republic
European alpine lake systems are used as indicators of air quality over the continent. Preliminary data showed high polycyclic aromatic hydrocarbons (PAH) loads in the High Tatras (Eastern Europe) in comparison to other mountain regions (1, 2). Here, insight on the spatial distribution of PAH is provided from analysis of top-core sediments of 27 alpine lakes distributed along the High Tatras mountain range.
Top-core sediment concentrations were higher than those in deep-cores, and they were higher than those observed in other European high mountain regions. The PAH profiles were uniform and comparable to those observed in aerosols and snow, indicating that atmospheric deposition was the predominant PAH input pathway to the lakes. Good agreement between estimated atmospheric deposition and sedimentation fluxes was observed. However, in several lakes in the western mountain range higher sediment fluxes may respond to induced PAH deposition. These higher concentrations may also reflect inputs from potential emission source areas west of the mountain range.

**Influence of residential wood combustion on the air quality (PM10 and its chemical composition) in Bremen, Germany**
A Dreyer[1], T Springwald[1], C Temme[1], K Berger[1], A Schemmel[2]
[1]Eurofins GfA, HAMBURG, Germany
[2]Free Hanseatic City of Bremen Senate Department for Environment, Construction, T, BREMEN, Germany
The recent price development of fossil fuels increased the attractiveness of wood firing for residential heating. Therefore, many people decide using wood as sustainable and renewable energy source. However, wood firing, particularly using old furnaces, results in enhanced particle emissions leading to an impairment of the air quality. In this study, the impact of residential wood firing on air quality in an urban area of Bremen, Germany was investigated in winter time 2009/2010. PM10 samples were taken in 1 day intervals from October 2009 until March 2010 and analysed for arsenic (As), lead (Pb), cadmium (Cd), nickel (Ni) as well as polycyclic aromatic hydrocarbons (PAH), including the 3-ring PAH retene. PM10 concentrations ranged from <4 $\mu g/m^3$ to 89 $\mu g/m^3$ in periods of low temperatures and inversion and were higher than those of comparable measurements at other locations in Bremen. Concentrations of As, Cd, Ni, and Pb were between <0.2 and 4.1, 0.05 and 6.3, <1 and 3.6, and 2.4 and 38 $ng/m^3$, respectively and were always below regulatory limits. ð'__PAH+retene concentrations were between 17 and 335 $ng/m^3$. PAH profiles clearly revealed the presence of wood firing at the investigated site which was possibly caused by the individual wood combustion used for residential heating.

**TH 041**
**Air quality assessment by tree barks biomonitoring in urban, industrial and rural environments of the Rhine Valley: PCDD/Fs, PCBs and trace metal evidence**
M Millet[1], FG Gueguen[2], PS Stille[1]
[1]University of Strasbourg / CNRS, STRASBOURG CEDEX, France
[2]LHyGeS (UMR 7515)/LMSPC (UMR 7515), STRASBOURG, France
Tree barks have been used as passive samplers to evaluate past atmospheric pollutions because they accumulate organic and trace metal compounds in their structure. The studied sites were the urban areas of Strasbourg (France) and Kehl (Germany) near the Rhine river and a remote forested environment in the Vosges mountains. The urban zone is situated close to an important industrial harbour with steel plant, waste incinerators, thermal power plant and others. Tree barks have been collected in spring 2008, 2009 and 2010 in this industrial area, but also in the urban and remote areas. One tree bark sample was collected in the forested part of the Vosges Mountains. Dioxins (PCDDs), furans (PCDFs) and polychlorinated biphenyls (PCBs) were analyzed in barks, as they own to Persistent Organic Pollutant (POP) group. These pollutants are emitted by industries and human activities. Trace metals were also analyzed to quantify the toxic metal concentrations in bark, and identify the emitters.
PCDD/Fs concentrations in the industrial area (509-1420ng/kg dw) were in the range of variation usually found in this type of zone. 22 PCB congeners were analyzed in bark by GC-2ECD on a range of concentration between 15±4 and 270±40 ng/g. Median level of PCB were found to be close to industries and highways (40-60 ng/g) while low level were observed in rural and forested zone. An important concentration was measured in the urban environment (170-270 ng/g) close to a former landfill. At this place, not only organic but also inorganic pollutants were enriched in tree bark.
High trace element (Cd, Sb, As, Sn, Co, Cr and Ni) concentrations were found close to the steel plant. Waste incinerators also appear to be important emitters of trace metall enriched particulate matter. Barks still have high Pb concentrations close to traffic but also Sn, Sb, Mo, and Ni (280 ppm, 7 ppm, 4 ppm, 3 ppm and 10 ppm respectively). In this study organic and inorganic pollution were not necessarily coupled. However a strong relationship exists between barium and PCB concentrations ($r^2$=0.85) in tree bark. Barium could be associated with sulphate in the atmosphere and has halogenated affinities.

[5]National Agricultural Research Laboratories - Kawanda, KAMPALA, Uganda
As part of the global monitoring plan under the Stockholm Convention on persistent organic pollutants (POPS), member states are called upon to regularly take record and report atmospheric POPs data. There remains severe shortage of general data on POPs, especially from atmospheric measurements, from the region of Africa. The results presented here are part of the first and, so far, the longest study to measure atmospheric prevalence of POPS and currently used pesticides (CUPs) in the East African region. We present data from measurements of PCBs, Organochlorine Pesticides (OCPs), PBDEs, PAHs and CUPs. High volume active samples (taken weekly at Entebbe, Uganda) and passive samples (taken quarterly at Entebbe and Bukasa Island in Lake Victoria, Uganda) were taken between November 2008 and March 2010 and analysed for the above chemicals at the Environment Canada laboratories (PCBs, OCPs, PBDEs and CUPs) and AirZOne Inc. (PAHs) in Burlington and Mississauga, ON respectively. Samples were extracted by accelerated solvent exraction (Dionex ASE 200) using hexane: acetone 70:30 v/v and analysed by GC/MSD. PBDEs and endosulfan were determined in negative chemical ioniza-

tion mode (GCMS-NCI). PCBs and OCs were determined by GC-μECD. Preliminary PAH results show a mean of 27.97 ng/m3 (51 samples and a range of 4.05 - 58.97 ng/m3) with high PAHs from combustion of biomass. We will present further analysis of the PAHs data by source. Preliminary PBDE (18 congeners) partial results show a mean of 25.74 pg/m3 (20 samples and a range of 7.40 - 53.94 pg/m3) with a relatively high abundance of BDE 47, 99, 183 and 153 congeners. Partial and preliminary ð'-PCBs data show a range 29-159 pg/m3 and average ð'-DDT concentration of 40pg/m3. Preliminary partial data for CUPs shows a predominance of Chlorpyrifos with a mean of 33.42 ng/m3 (20 samples and a range of 0.08 - 161.87 ng/m3) and ∑- endosulfan with a mean of 126.85 pg/m3 (20 samples and a range of 0.40 - 340.70 pg/m3) with the α-endosulfan isomer being the major isomer at a mean concentration of 109.85 pg/m3 (20 samples and a range of 0.4 - 295.99 pg/m3). More data from all the samples will be presented. Analysis of all the data against rainfall and air mass flow will be presented.

### TH 043

**Assessing legacy and current-use pesticide levels in air from an agricultural region of Valle del Cauca, Colombia**

J Banguera[1], KP Pozo[2], VE Estellano[2], TH Harner[3], SF Focardi[2], MP Paez[1]
[1]Universidad del Valle, CALI, Colombia
[2]Universidad de Siena, SIENA, Italy
[3]Metereological Service of Canada, TORONTO, Canada

Passive air sampler (PAS) consisting of polyurethane foam (PUF) disk, were deployed over three month period from August to October 2010 in three different areas of the agricultural center (CORPOICA), in the city of Palmira, Valle del Cauca Region - Colombia. The purpose of the study was to assess the gas-phase concentrations of current use pesticides (CUPs) and legacy (OCPs) pesticides. PUF disk samples were extracted with 300 ml of petroleum ether for 20 hours in soxhlet system and analyzed by gas chromatography and mass spectrometry (GC-MS). Target compounds that were regularly detected include Chlorpyrifos ethyl and Trifluralin for CUPs and Endosulfan and chlordanes for OCPs. Air concentrations (ng/m3) of CUPs were very high ranging from 50 to 95 (74 ± 13) for Chlorpyrifos ethyl and from 17 to 26 (22 ± 49) for trifluralin. However, OCPs air concentrations (pg/m3) were one order of magnitude lower than CUPs with Endosulfan showing air concentrations (pg/m3) that ranged from 190 to 1990 (770 ± 70) and for CC ranged from 42 to 136 (88 ± 63). In the case of CUPs these results are much higher than those reported in other agricultural areas of the world suggesting an intensive use of this pesticides in the agricultural activities in the Valle del Cauca region of Colombia.

### TH 044

**Sources of and temporal trends in occurrence of Legacy Pesticides in atmosphere of eastern United States**

A Goel[1], LL Mcconnell[2], A Torrents[3], C Hapeman[2]
[1]Indian Institute of Technology, Kanpur, KANPUR, India
[2]EMBUL - US Department of Agriculture-ARS, BELTSVILLE MD, United States of America
[3]University of Maryland, COLLEGE PARK MD, United States of America

Legacy Pesticides, mostly Organochlorines, are pesticides whose use in most countries has been banned or severely restricted. To elucidate the atmospheric sources and temporal trends in concentrations of these chemicals in the mid-Atlantic region of USA, weekly air (n= 265) were collected over 2000 to 2003 from three locations in the Delmarva Peninsula, part of the Chesapeake Bay watershed, USA. Legacy Pesticides (n = 15; from four pesticide groups: chlordanes, HCHs, DDTs and Diels-Alders related) were consistently present in the gas phase with infrequent detection in the particle phase. Patterns in gas phase concentrations at all three locations indicated that cis- and trans-chlordane and both HCH isomers are present continuously (95-100% detection) in the region at low levels averaging 20 to 50 pg/m3. Other pesticides including oxychlordane, heptachlor, dieldrin, and 4, 4'-DDE were also detected frequently. The highest mean air concentrations were for dieldrin (60-84 pg/m3), g-HCH (37-83 pg/m3), and 4, 4'-DDE (16-80 pg/m3).
Multiple regression analyses of air concentrations with temperature and wind conditions using modified Clausius-Clapeyron equations explained only 30 to 60% of the variability in concentration for most chemicals. Combining the data for mid-Atlantic (this study) with Central America, the southern United States (U.S.), and the Great Lakes region, reveals a general decrease in concentration with increasing latitude for cis- and trans-chlordane, indicating the Southern U.S. and areas of Central America remain source areas. However, examination of chlordane isomer ratios indicates some local and regional contributions. Spatial comparison of concentrations at the three Delmarva sites and the enthalpy of phase transfer indicates that the sources of chlordanes, HCHs, and heptachlor are primarily long range transport and that 4, 4'-DDE and dieldrin have substantial local sources at some sites. Results of this work indicate that soils on the Delmarva Peninsula are contaminated with dieldrin, g-HCH, and persistent pesticide degradation products (4, 4'-DDE, oxychlordane, and heptachlor epoxide).
Dissipation half-lives in air were well below 10 years for all chemicals and below published values for the Great Lakes except dieldrin, which did not decline during the sample period. The concentrations of most legacy pesticides are likely to decrease to below 10% of today's values over the next 30 to 40 years.

### TH 045

**High sea to air fluxes of aliphatic hydrocarbons and implications for formation of marine secondary organic aerosol**

J Dachs, C Encinar, C Galbán, J Zúñiga, N Berrojalbiz
IDAEA-CSIC, BARCELONA, Spain

Aliphatic hydrocarbons such as n-alkanes, branched alkanes, other hydrocarbons and the unresolved complex mixture (UCM) are among the most abundant semivolatile organic compounds in seawater and the atmosphere. Here we report the concentrations of aliphatic hydrocarbons in seawater and gas phase samples from the Mediterranean sea. The samples were taken in two East-West sampling cruises covering all the major Mediterranean regions. The concentrations of individual alkanes in seawater are in the order of tens of ng/L, but the UCM concentrations are two orders of magnitude higher. The estimation of air-water diffusive fluxes show an ubiquitous sea to air volatilization flux in all the Mediterranean Basin. Most of this flux is due to the contribution of the unresolved complex mixture. In fact, the UCM fluxes are higher than dimethylsulfur and isoprene fluxes, two well known precursors of sulfphate aerosol and marine secondary organic aerosol. Implications of these fluxes are discussed.

### TH 047

**Pollution of atmospheric precipitation and predict of their acidification at agricultural ecosystem**

I Klymenko[1], E Klymenko[1], F Beneskriptova[2]
[1]Nikita botanical gardens, SIMFEROPOL, Ukraine
[2]Center of soil fertility protecting, SIMFEROPOL, Ukraine

The pollution of an atmosphere by sulfur and nitrogen oxides can cause acid deposits, which can put significant harm to agricultural cultures dropping out in agricultural areas and rivers' basins. In this connection monitoring of atmospheric precipitation chemical compositions is necessary. Such 12 years monitoring (1994-2005) was carried out in agricultural area of Crimea (Ukraine). It was determined ions $SO4^{2-}$, $NO_3^-$, $Cl^-$ and $NH_4^+$ and pH value. The annual mean atmospheric precipitation pH was 5.43 with range of 3.82-7.63. In the first 6 years period (1994-1999) deposits with pH less than 4 met only in the cold period of year, but in 2001 the precipitation with such pH values dropped out in June. The ion $SO_4^{2-}$ prevailed in deposits for all years. It was marked a negative trend its concentration during time basically at the expense of decrease it in a cold season. The contents of anion $NO_3^-$ in atmospheric precipitation was high enough. The concentration was increased in time and was higher in the cold period of year in comparison with warm. The relation two basic acidification ions ($SO_4^{2-}$ : $NO_3^-$) was 2.8 with significant fluctuations on years. A tendency to decrease of this ratio in time was marked The annual mean concentration of Cl- was 60 μeq l-1. In the cold period of year chloride ions were more than in warm. The increasing of $Cl^-$ concentration from year to year is marked. The content of an ion $NH_4^+$ in deposits was rather high, and accrued with current of time. Concentration of Cl- ion in summer deposits was more, than in winter that is characteristic for agricultural area of Salgir river basin. The pH value of deposits depends on their content and was defined in the basic concentrations of ions SO42-, NO3- and Cl-. In warm period of year the pH in the greater measure depends on concentration of anion $NO_3^-$, in cold - $SO_4^{2-}$. The ions $SO_4^{2-}$ and $NO_3^-$ participated in acidification of precipitation in the warm period of first 6 year period. In the second 6 years (2000-2005) in a cold season ions $SO_4^{2-}$ and $NO_3^-$ is authentic, Cl- insignificant influence to deposits acidity. Closest and significant (1 % level) connection of pH values and sum of ions $SO_4^{2-}$, $NO_3^-$ and Cl- is found out in the cold period (r = - 0.74). Thus, if we know the content of acidifying ions in the certain periods of year, it is possible to predict acidification of atmospheric precipitation in concrete territory.

### TH 048

**Study of the reentry interval and worker exposure after applying granular type pesticide formulation on soil in greenhouse**

PBJ Park, SKA Son, HSM Hong, IGJ Im, HMK Hong
National Academy of Agricultural Sciences, Rural Development Administration, SUWON,GYEONGGI, South-Korea

This study carried out to establish reentry interval after applying granular type pesticide formulation on soil in greenhouse for preventing farmer's pesticide intoxication.
The recovery of pesticide, cadusafos, ethoprophos and probenazole on absorbent in air were ranged 80.9~121.1% in charcoal and 90.6~99.0% in XAD-4, respectively. Emission rate of pesticides from top soil added water in lysimeter was higher 3~5 times than that of pesticides from top soil not added water at 35ðð plot after applying a mixture of granular formulation and soil. The ethoprophos concetration in air, 50cm high from soil surface at greenhouse, was reached the highest 186.4 $\mu g/m^3$ within 13 hours and were ranged 17.8~186.4 $\mu g/m^3$ during 46 hours after applying granular formulation at dose rate 150 g a.i./245$m^2$. The cadusafos concetration in air at greenhouse was reached the highest 37.3 $\mu g/m^3$ within 39 hours and were ranged 10.0~37.3 $\mu g/m^3$ during 46 hours after applying granular formulation at dose rate 180 g a.i./245$m^2$. The probenazole concetration in air at greenhouse was reached the highest 1.45 $\mu g/m^3$ within 37 hours and were ranged 0.23~1.45 $\mu g/m^3$ during 46 hours after applying granular formulation at dose rate 144 g a.i./245$m^2$.
The pesticide exposure in air was measured in actual site generally using pesticides. The result of the reentry interval study demonstrated that reentry intervals for ethoprophos and cadusafos are longer than 48 hours.

### TH 049

**Seasonal trends of airborne VOCs and microbiological pollution in the vicinity of mechanical-biological plant. Human health risks.**

L Vilavert, M Nadal, M Schuhmacher, JL Domingo
Rovira i Virgili University, REUS, Spain

Although composting may be, in principle, a good alternative for the treatment of organic waste, adverse health effects related to this practice are not entirely known. The important accumulation of chemical and microbial agents released during the process may pose a risk for populations living close to composting facilities. Therefore, it is crucial to update information on health risks in non-occupationally exposed people before enhancing the active regulation to develop composting and similar waste treatment methodologies as the basis to manage organic residues. The aim of this study was to analyze the environmental concentrations of volatile organic compounds (VOCs) and bioaerosols (bacteria, fungi, and specifically Aspergillus fumigatus) in the vicinity of an organic waste treatment facility (Ecoparc-2) located in Montcada i Reixac (Catalonia, Spain), as well as to determine seasonal trends in their levels. The human health risks associated to the exposure to those pollutants were also characterized. Air samples were collected at 12 sampling sites around the plant. Mean VOC concentrations showed values of 32.4 and 15.7 μg/m3 in winter and summer respectively, although seasonal differences were not statistically significant. In addition, non-significantly higher concentrations of most microbiological contaminants (total bacteria, Gram negative bacteria, and fungi at 37ºC) were found in summer, with the only exception of fungi at 25ºC and A. fumigatus at 37ºC. The concentrations of both groups of agents, VOCs and bioaerosols, were slightly higher than those previously found in reference sites where no composting plants are operating. Anyhow, the current levels detected around the Ecoparc-2 do not pose an important carcinogenic or non-carcinogenic additional risk for the population living nearby.

### TH 050

**VOC emissions in offset printing plants**

D Adamovic, J Kiurski, M Djogo, S Adamovic, D Milovanovic, M Vojinovic Miloradov
Faculty of Technical Sciences, NOVI SAD, Serbia

Volatile organic compounds (VOCs) are organic chemical compounds that have high enough vapor pressures under normal conditions to significantly vaporize and enter the atmosphere. Printing inks and coatings used in the commercial graphic printing industry contain VOCs in varying amounts, depending on the type of ink, the drying and printing processes, substrates and end-use application requirements. Mean VOC concentrations in four different printing plants that use distinct types of vegetable based and water based inks and solvents were monitored for the purpose of quantifying the various VOCs in these areas and to relate the results with conventional printing processes. In each site VOCs were monitored during one workweek. They were sampled and analysed by mobile GC Voyager Photovac. Concentration levels of BTEX were often below limit of detection. Concentration levels of isopropanol and acetone were in range 232 - 4630 ppb and 144 - 1813 ppb, respectively. BTEX concentrations and concentrations of the other VOCs founded in printing work environments of "ecological"printing plants were below the limits considered by the Serbian law and recommendations prescribed by NIOSH (National Institute for Occupational Safety and Health).

**TH 051**

**Ozone and volatile organic compounds as prominent pollutants of printing indoor**

JS Kiurski, DLj Adamovic, IB Oros, JD Krstic, SZ Adamovic
Faculty of Technical Sciences, NOVI SAD, Serbia

In the present work we investigated the concentration levels of ozone and total volatile organic compounds (TVOCs) measured during working time in a screen printing facility of Novi Sad. Our objective is to report a detailed analysis of TVOCs and ozone data exceeding the thresholds established by the air quality guidelines in order to investigate the workers exposure level of TVOCs and ozone and to identify correlation between ozone and TVOCs in a printing environment.

The air sampling was conducted in press department, including two different types of screen printing machines: semi-automatic and automatic. Air samples were collected and analyzed in situ for 4 times, once per 2 hour, during working time of 8 hour by ozonometer, Aeroqual Series 200, Aeroqual Ltd. and mobile gas chromatograph Voyager, Photovac, Inc. Results were obtained promptly, registering current situation and status of the working environment, which enables swift and adequate reaction in case of accidents and abnormal activities. The ozone concentrations were from 0.18 to 0.33 ppm for semi-automatic printing machine and 0.69 to 0.81 ppm for automatic screen printing machine. The TVOC concentrations were from 27.21 to 36.74 ppm for semi-automatic and 8.05 to 12.17 ppm for automatic screen printing machine.

The experimental data showed that ambient ozone concentration slowly increases with increasing of TVOCs concentration and illumination intensity during screen printing process. The ozone concentration levels were above the permissible exposure limit (PEL) for 8-hour TWA (time-weighted average) recommended by the OSHA (Occupational Safety and Health Administration), while the TVOCs concentrations were much below the PEL prescribed by the OSHA. In the Republic of Serbia, the Regulation of permitted concentration levels of TVOCs and ozone until now has not adopted.

Keywords: Ozone, total volatile organic compounds (TVOCs), exposure level, printing

**Contribution of surface/air exchange to deposition potential for cyclic methylsiloxanes: a modeling assessment**

S Xu
Dow Corning Corporation, MIDLAND, United States of America

Partition of airborne contaminants to surface media such as soil, plant and aquatic suspended particulates have been identified as significant contributors to deposition potential for known persistent organic pollutants (POPs) such as PCBs and pesticides. In this study, the effects of partitioning of airborne cyclic volatile methylsiloxanes (cVMS) to soil, plant biomass and suspended particles in the remote region on the deposition potential of cVMS were estimated by equilibrium modeling. For each process, partitioning equilibrium between surface medium and air was assumed and the partitioning coefficients were estimated based on available data and approaches reported in literature. It was found that cVMS have surface media/air partition coefficients 3 to 6 orders of magnitude lower than those of the most volatile POP reference materials such as hexachlorobenzene (HCB) and PCB 28 congener. This is especially true for octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5). Consequently, gas absorption via soil/air, plant/air or suspended particulates/air partitioning contributes minimally (< 1% of total airborne D4 or D5) to the deposition potential of D4 and D5 in the remote region. For dodecamethylcyclohexasiloxane (D6), plant/air and suspended particulates/air partitioning should contribute minimally to the deposition of airborne D6 to surface media, while soil/air partitioning may account for a small fraction (e.g., 3%) of airborne D6 transferred from air to soil under the low temperatures (e.g., -20 °C) in the remote region.

**TH 053**

**Sorption behaviors of octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5) on various atmospheric aerosols**

J Kim, S Xu
Dow Corning Corporation, AUBURN, United States of America

The study investigated sorption and desorption behaviors of octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5) with nine major atmospheric aerosols including both primary and secondary aerosols. Sorption and desorption took place via an initial rapid and a rather slow processes. The initial rapid processes were favored especially at low concentrations. Both distribution coefficients and irreversible sorption fractions of D4 and D5 on the aerosols were determined based on isotherms of sorption and desorption. Distribution coefficients of D4 and D5 varied in a range of 8.32[GREEKX]$10^{-5}$ ~ 4.17[GREEKX]$10^{-2}$ $m^3/m^2$ and 1.47[GREEKX]$10^{-3}$ ~ 1.52[GREEKX]$10^{-1}$ $m^3/m^2$, respectively, depending on aerosol types due to unique interactions between D4 & D5 and each type of the aerosols tested. Kaolinite and sulfate aerosols showed high irreversible sorption for D4 and D5 whereas carbon black and sea salt aerosols reversibly interacted with the adsorbates. It was discovered that the irreversible sorption was caused by surface catalytic hydrolysis on the reactive aerosols. After the ring of the cyclic siloxanes was opened in the first step, consecutive surface reactions took place resulting in further cleavage of siloxane bonds. The degree of partitioning and transformation vary so widely that it is impossible to deal with the mixture of atmospheric aerosols as a single entity. Thus, atmospheric aerosols can play two major roles on volatile siloxanes: to remove airborne cVMS by sorption and to transform sorbed molecules to less volatile compounds such as silanols.

**TH 054**

**Filtration performance characteristics of depth filter media using KCl particles**

P Youngok[1], B Kim[2], N Hasolli[1], Y Rhee[3]
[1]Korea Institute odf Energy Research, DEAJEON, South-Korea
[2]Institute od DAEWOO E&C Co. Ltd, SUWON, South-Korea
[3]Chungnam University, DEAJEON, South-Korea

Initial filtration performance of the filter media is usually evaluated by measuring two of the most significant parameters: the initial pressure drop and fractional collection efficiency. In the literature [1,2,3] these parameters are described as indicators weather the filter media is suitable for their intended application. Initial pressure drop is tested and usually regarded as the pressure difference (DP) measured up- and downstream of the filter media specie. Since the initial condition tests are conducted in a very short testing time, the loading of the filter media and thus its effect on pressure loss is usually neglected. For the purpose of filter media particle collection efficiency, test particles injected in the upstream of the test filter media can be of poly- or monodisperse nature. The test with monodisperse particle has been conducted and results are reported In our previous work [4]. In case of polydisperse test particles it is possible to evaluate the most penetrating particle size (MPPS) by comparing the concentration of particles of that particular size in the up- and downstream. This parameter is considered as of great interest by some testing standards available today [5,6]. These test standards specify the use of the KCl particles to determine the particle collection efficiency. Two depth filter media samples are used for this study to evaluate the filtration performance of depth filter media. During this study, the interest is to evaluate the above mentioned parameters by varying the face velocity

Due to the inconsistency of the data from the measurements for particles of the range 20 to 46 nm were not taken in consideration. From the initial KCl-water solution we could achieve a high particle concentration which in return had some slight effect on the pressure difference between two runs. The two media tested during this study have shown different results, having the media TFM1 which exhibits a more or less constant particle collection efficiency for the whole particle range while TFM2 media exhibits an increasing efficiency with the increase of particle size. Further test are required to confirm the behaviour of the filter media media during the test with submicron particles and the effect of particle loading. .

**A novel process to remove SO2 in internal circulating fluidized bed reactor**

Y Park
Korea Institute of Energy Research, DEAJEON, South-Korea

Currently, reducing SO2 emission from power plants is a main issue for the environmental protection. Accordingly, fine powder based semi-dry FGD was proposed for higher SO2 removal efficiency which was accomplished by interacting flue gas and powder sorbent to be adhered on to the surface of particle1. The aim of the present research is to study a semi-dry FGD in fluidized bed reactor to be appropriate in the one-body cleaning process, evaluating the effects of water injection flow rate, Ca/S and NaHCO3/SO2 molar ratio, superficial gas velocity and specific water volume on SO2 removal efficiency.

Study of SO2 removal was carried out using fine powder of Ca(OH)2 and NaHCO3 as sorbents to achieve high desulfurization (>98%) with continuously fed water. The effect of operating variables such as water injection flow rate, Ca/S and NaHCO3/SO2 molar ratio, superficial gas velocity, and specific water volume on SO2 removal was investigated.

The target efficiency (>98%) was achieved by specific water volume of 0.035 liter-water/Nm3-gas as optimum operating condition at Ca/S molar ratio of 1.3 and gas flow rate of 20 Nm3/min. It was observed that the required specific water volume increases with the increase in superficial gas velocity or decrease in Ca/S molar ratio. SO2 removal efficiency of about 50~60% was achieved using NaHCO3 as sorbent in dry-FGD test and SO2 removal efficiency used with Ca(OH)2 was higher it used with NaHCO3 in semi-dry flue gas desulfurization.

**FT-IR as promising method for rapid determination of adulteration of gasoline with kerosene**

N Mayora[1], N Murago[2], K Kiptoo[2]
[1]Narok University College, NAROK, Kenya
[2]JOMO Kenyatta University, NAIROBI, Kenya

ABSTRACT
Adulteration of automotive gasoline is widespread throughout the world and Kenya is not left out. Adulteration takes its toll both in terms of the air quality and loss in tax revenue. Increase in prices of fuels and fuel intermediates is often cited as a cause for adulteration. Adulterated fuels deprive the consumers of assured quality fuels and lead to increased tail pipe emissions. In this study a method, using FTIR, has been developed to provides an alternative rapid analysis of adulteration of gasoline with kerosene using a peak at 1380.9cm-1. This method has been found to be economical in terms of amount of gasoline used ( 2µl ) and the time for a single scan which is less than 1 minute.

Key words: (1) Adulteration (2) Gasoline (3) FTIR (4) Kerosene

**A novel approach to assess exposure for pollinators**

S Stefania, A Ippolito, C Vaj, M Vighi
University of Milano-Bicocca, MILANO, Italy

One of the main drawbacks in ecotoxicological risk assessment for terrestrial ecosystems is the lack of suitable methods for assessing exposure to plant protection products (PPPs) for epigean communities (bird, insects). This has particular relevance in risk assessment for organisms with a large foraging area like pollinators. At this stage, pollinator risk assessment is based on a procedure specifically addressed to *Apis mellifera*, comprehending a preliminary risk assessment with the Hazard Quotient, calculated as the ratio between the application rate of the PPP and a toxicological end point, refined by cage, semi-field and field studies. Therefore, any exposure assessment is not included in this kind of approach. In this work a procedure to assess exposure for pollinators was fully developed and applied. Starting from exposure models developed for the small scale, specific equations to evaluate the distribution of pesticides outside the field, as a function of the distribution of the treated crop, were obtained. The small scale approach was than adapted to the large scale; a semi quantitative index to determine the concentration of pesticides on non target vegetation was therefore elaborated. The input data of this approach are the application rate and land use. The developed approached was applied and experimentally validated in different field sites of 4x4 km located on NE Italy. A good agreement between predicted and measured concentrations was observed. Generally, the ratio between predicted and measured data was within a factor of about 2. The main results of this work are here presented.

**Relevance of an Integrated Pest Management approach towards understanding the possible causes in decline of honeybee population in the State of Punjab, India**

V Saini
Sunrakshan Foundation, FARIDABAD ( HARYANA ), India

India has been popularizing the concept of Integrated Pest Management through out the country since early 1980's, having a whole division dedicated to it under the Directorate of Plant protection, Quarantine and Storage. The Ministry of Agriculture, Government of India has been encouraging the promotion of bio-pesticides and bio-fertilizers in this regard. However, the ignorance of the farmer in understanding the hazard linked implications of the indiscriminate use of pesticides they practice, are not only resulting in having its impact on the environment and human health, but also are having an impact on the honey bees population existing naturally or commercial breed bee hives. The current practice of agriculture, indiscriminate use of pesticides and plant growth regulator's, have given rise to the reduction of the honey bee populations and other beneficial insects of pollination importance. We tend to highlight our field experience and survey information collected in assessing the causes of decline in insect pollinators in Indian Agriculture, in the State of Punjab.

**Honeybee brood development: automated evaluation with the help of image analysis**

S Kimmel, L Jeker, JP Magyar, S Höger
Harlan Laboratories Ltd., ITINGEN, Switzerland

Adverse effects of plant protection products on development of the honeybee (Apis mellifera) brood under conditions close to the open environment are assessed according to the OECD guidance document 75. This evaluation requires assessment and correlation of the developmental stages in a large number of cells in several treatments and replicates at several time points. Manual counting of such systems is time consuming, of limited reproducibility and difficult to verify. These deficits can be resolved by purpose-built computerised image analysis tools.
Optimized computer-assisted digital image acquisition was conducted in order to deliver high resolution images with maximal contrast and minimal reflections. For the analysis of the images, customized macros of the freeware program "ImageJ"were created, providing automatic identification of the combs and an optimal interface to assess the developmental stage of the larvae. The features include:
1) jumping from comb to comb at optimal magnification,
2) non-destructive user-defined labelling of the staging of individual eggs, larvae or pupae,
3) galleries of the same comb on consecutive images of the same frame at different time points,
4) results of individual combs to facilitate data evaluation.
Ongoing development is aimed to implement pattern recognition of the combs' content, allowing the completely automated assessment of entire bee brood studies in a batch mode and also enabling the measurement of additional morphometric parameter (e.g. size, shape, staging).
The digital evaluation significantly accelerates the assessment of honeybee brood studies and allows full documentation of these studies with possibility of control and revision at the individual comb level.

**The value of using ecological models in the ecosystem service approach within ERA**

N Galic[1], A Schmolke[2], V Forbes[3], V Grimm[2], H Baveco[4], P van den Brink[1]
[1]Wageningen University, WAGENINGEN, The Netherlands
[2]Helmholtz-Zentrum für Umweltforschung - UFZ, LEIPZIG, Germany
[3]Roskilde University, ROSKILDE, Denmark
[4]Alterra, WAGENINGEN, The Netherlands

From theoretical concepts to applied conservational and management studies, ecological models have been proven to be useful on many levels. Recently, they started gaining popularity in chemical, mainly pesticide, ecological risk assessment (ERA). Their first and foremost advantage is gaining deeper insight into and understanding of ecological processes and mechanisms. Of special value for the risk assessment sector is the possibility of quantifying and extrapolating effects across spatial, temporal and biological scales, e.g. relevance of impact on individuals for the whole population, extrapolate from the local to the landscape scale etc. Moreover, they offer ample opportunities for extensive scenario testing and comparison without accompanying high costs of experimental setups or field-surveys. Finally, if well tested and validated, they can also have predictive potential.
The ecosystem services (ES) concept offers a new currency for discussing protection goals, evaluating and mitigating environmental issues, of course not only restricted to chemicals. The drivers behind different types of services are ecosystem processes, structures and functions, which can be described by the use of ecological models. First to identify the exact driver, or a service providing unit, (can be a local population, functional group, community etc.), then for quantifying the service provided, for testing and comparing different usage scenarios, and, if necessary, for identifying possible trade-offs between different services. Putting an economic value to a specific service, or a part of it, makes cost-benefit analyses much more feasible. This makes ecological-economical models very useful in quantifying and negotiating trade-offs between services.
In this poster, we discuss advantages and caveats of using ecological models for ERA, using protection goals defined through the ecosystem service framework and especially focusing on how ecological models can link the ES with ERA. We provide examples of the usefulness of models developed for other purposes and models developed for the specific purpose of service trade-off analyses, and propose future steps for involving the knowledge obtained with applying ecological models into a more meaningful and protection goal relevant risk assessment process.

**Understanding ecosystem services provided by rice fields**

T Moore[1], MA Locke[1], R Kroger[2]
[1]USDA Agricultural Research Service, OXFORD, MISSISSIPPI, United States of America
[2]Mississippi State University, MISSISSIPPI STATE, MS, United States of America

While the concept of ecosystem services is not new, there is revived interest in how these services should be measured, monitored, and valued. Focused research over the last four years has provided insight into the mitigation capabilities of rice fields in the lower Mississippi River Valley of the United States. In an effort to assign an ecosystem value to this mitigation capacity, two field studies were evaluated for their effectiveness at decreasing concentrations and loads of various pesticides. In the large scale study (0.19-0.27 ha), aqueous diazinon concentrations decreased 81±18% from inflow to outflow after passing through a rice field. Given assumptions of the mean rice production in the state of Mississippi and current rice commodity prices, this area would have produced \$355 - \$507 worth of rice crop for a farmer. However, using ecosystem services values in published literature, the waste treatment value alone of these fields ranged from \$1176 - \$1670. A second, smaller scale study (0.02 ha) found similar results, with rice fields able to decrease aqueous atrazine and diazinon concentrations 77±20% and 82±15%, respectively, from inflow to outflow. Given the same assumptions above, \$47 worth of rice could have been produced from this research plot, with approximately \$150 worth of waste treatment achieved by the same system. Although these ecosystem service values are estimates, these studies demonstrate the potential for a 3-fold benefit in environmental services versus traditional crop production revenue. There are many additional issues to consider, including maintenance and other costs, but environmental practitioners must begin placing values on such systems to promote global sustainability.

**TH 069**

**Soil invertebrate communities and urban pollution**

L Santorufo[1], CAM van Gestel[2], G Maisto[1]
[1]University of Napoli "Federico II", NAPOLI, Italy
[2]Vrije University, AMSTERDAM, The Netherlands

Soil invertebrates play an important role in the functioning of soil ecosystems. So far, focus has been mainly on natural systems. Little is known about urban soil and the impact of urban activities on soil invertebrate communities. This study investigated the functioning of urban soils with different characteristics, through the evaluation of the diversity and abundance of invertebrate communities. Final aim was to identify key species and their functional role in the urban soil ecosystem. Five sites with different grades of human impact were sampled in the urban area of Naples (Southern Italy). Soils were analyzed for physico-chemical properties (pH, granular composition, organic matter content, etc.) and Cu, Fe, Pb and Zn concentrations. To assess the abundance and diversity of the enchytraeid and microarthropod communities, soil samples were extracted using wet or dry Tullgren methods. Species richness varied among the sampled soils, and community composition differed, with certain taxa being present only in some soils. Four taxa (Collembola, Diplopoda, Chilopoda and Acarina) were extremely widespread and abundant. The study revealed that the sharply differentiated soil invertebrate community structure seems closely linked to soil properties, with the abundance and species richness of the soil invertebrate community decreasing with decreasing pH and organic matter contents and increasing metal concentrations. Further investigations are done to evaluate the effect of metals on the structure of the soil invertebrate community. For this purpose, bioassays with Collembola (Folsomia candida), earthworms (Eisenia andrei) and enchytraeids (Enchytraeus albidus) will be performed to assess toxicity of the different soils. These bioassays will follow the standard test guidelines (ISO, OECD) and focus on effects on survival and reproduction. In addition, metal uptake by the test organisms will be evaluated.

**Decision analysis for a sustainable environment, economy & society**

TJ Canfield[1], TS Stockton[2], AV Vega[1], BD Dyson[1], MS Small[3], JC Carriger[1], AR Rehr[3], BF Faulkner[1], PB Bradley[1], SY Yee[1], MT ten Brink[1], WB Berry[1], KB Black[2], WF Fisher[1], VH Hansen[1]
[1]U.S. Environmental Protection Agency, ADA, United States of America
[2]Neptune and Company, LOS ALAMOS, United States of America
[3]Carnegie Mellon University, PITTSBURGH, United States of America

Environmental decisions are often made without consideration of the roles that ecosystem services play. Most decision-makers do not currently have access to useful or usable methods and approaches when they are presented with choices that will have significant ecosystem impacts. The goal of the Ecosystem Services Research Program (ESRP) Decision Support Framework (DSF) Team is to help provide that access by identifying or developing effective and user-friendly decision methods and approaches that empower decision-makers to explicitly and routinely incorporate ecosystem services into their decision-making. To this end the ESRP DSF team is developing an open-source, web-based decision analysis framework called DASEES: Decision Analysis for a Sustainable Environment, Economy and Society. DASEES integrates guidance and decision support tools to implement a five step iterative Bayesian decision process:
Step 1 - Understand Content
Step 2 - Define Objectives
Step 3 - Develop Options
Step 4 - Evaluate Options
Step 5 - Take Action
DASEES will be developed with stakeholder and decision-maker input, through case studies, to ensure the guidance, tools, and templates meet user needs and facilitate the incorporation of ecosystem services in the decision-making process.

**TH 071**

**Ecosystem service models for balancing nature protection and wind energy development**

KM Suedkamp Wells, G Reub, RJ Wenning, M Matt
ENVIRON International Corporation, ANN ARBOR, MI, United States of America

Renewable energy development has been the focus of energy policy development in many countries worldwide, particularly among European Union Member States who have agreed to obtain national targets in support of multiple Directives. However, renewable energy development is often associated with fundamental conflicts between policies that mandate environmental protection and policies that mandate energy independence and sustainability. In October 2010, the European Union released guidance on wind energy development that is specifically designed to balance prior nature conservation legislation with renewable energy development and siting policies. The resulting guidance proposes a development framework to guide assessment of potential impacts and resulting measures to mitigation stressors while balancing the need to provide the renewable energy development and financing community with predictable processes and mechanisms to implement wind generation projects. Successful implementation of such an approach will ultimately involve identification of the suite of stressors that may be associated with wind energy development, properly describing their relationship to ecosystem or nature protection services, and quantifying the value of ecosystem or nature protection services affected to properly mitigate for environmental impacts. Examples from related technical fields and regulatory frameworks in the U.S. and other countries such as Natural Resource Damage Assessment, Ecological Risk Assessment, and Environmental Impact Assessment provide ideal opportunities to describe the stressors associated with wind energy development, capture their relationship to ecosystem services, and appropriately quantify mitigation to compensate for potential environmental impacts. This presentation will draw upon approaches currently used in the U.S. to quantify stressor impacts and develop mitigation measures to protect biodiversity such as federally threatened or endangered species and their habitats. The model will demonstrate the utility and inclusiveness of an ecosystem service approach for evaluating wind energy development projects that balances the need to protect nature with the need for sustainable energy sources consistent with current environmental directives in the European Union and comparable regulatory requirements in the U.S. and other countries.

**TH 072**

**Quantifying ecosystem service considerations during restoration of contaminated lands and waterways**

J Wenning[1], S Deacon[2], G Reub[1], K Suedkamp-Wells[1], E Bizzotto[3], F Colombo[3], G Quadri[3]

[1]ENVIRON, EMERYVILLE, United States of America
[2]ENVIRON UK, BATH, United Kingdom
[3]ENVIRON Italy, MILAN, Italy
While a significant part of regulatory decision making has focused on the protection of human health, regulatory agencies and international non-governmental organizations have re-emphasized their mandate to protect the environment by encouraging long-term sustainable practices and an increased focus on the ecological benefits of environmental policies and actions. This renewed effort reflects recognition by business, government, and other institutions of the need for more rigorous and comprehensive accounting of the ecosystem impacts of their activities. As such, an understanding of ecosystem services, how services are quantified, and how the values of different types of services are ascertained and evaluated has become of paramount importance. Several models and methods for quantifying ecosystem services and evaluating tradeoffs between different policy or management alternatives have emerged that enable decision makers to assess the implications of decision alternatives on preservation, enhancement, or reduction of different types of services. These tools make clear the ways in which regulatory policy and management choices affect the type, quality, and magnitude of services we receive from ecosystems - such as air, water, productive soils, food, timber, and other resources and processes that sustain humans and biota alike. This presentation will show example results of tool applications, including a framework for screening and cataloguing ecosystem attributes and the application of tools such as Habitat Equivalency Analysis (HEA) and Net Environmental Benefits Analysis (NEBA) to quantify and aggregate ecological service flows (both detrimental and beneficial) of various restoration actions on resources and ecosystem attributes. A weighting scheme for compiling net changes in habitat value and ecosystem services, and approaches to monetize the relative changes in habitat value and ecosystem services between restoration alternatives will be demonstrated. It is evident from the environmental directives in Europe and environmental policy changes occurring in the U.S. and elsewhere that business and government can both benefit - financially, as well as in terms of stewardship and reputation - by incorporating ecosystem service considerations into the management strategies guiding their environmental obligations.

**TH 073**

**A comparative analysis to select the best remedial alternatives for the Ecosystem of the Pallanza Bay (Lake Maggiore)**

G Quadri[1], J Nicolette[2], FI Colombo[1]
[1]ENVIRON Italy, MILAN, Italy
[2]ENVIRON, ATLANTA, United States of America
Authors: Joe Nicolette PhD; Fabio Colombo PhD and Giorgia Quadri PhD

In the context of site remediation, a Comparative Analysis is an approach that provides a formal quantification of the change in ecosystem service values (ecological and human use) that would be associated with the implementation of a remedial action and compares those changes to costs and predicted changes in risk. The goal of a CA is to provide the necessary information to support the selection of remedial alternatives that maximize benefits to the public, while managing site risks and remedial costs.
A CA is typically conducted to evaluate if the potential exists for a remedial action to create more natural resource harm and/or risk than that predicted by the risk assessment that drove the remedial action in the first place (i.e., create or increase natural resource liability) or provide a marginal benefit compared to the effort expended.
In this study four main remedial alternatives for the Pallanza Bay in the Lake Maggiore were identified for evaluation: monitored natural recovery (MNR) of Pallanza Bay; MNR of Pallanza Bay combined with riparian enhancement along the Toce River(tributary of the Pallanza Bay); capping of Pallanza Bay, and dredging of Pallanza Bay.
The CA required the:
1. Quantification of the ecological service losses and gains with the Habitat Equivalent Analysis, associated with implementation of each remedial alternative;
2. Quantification of the human use service values relying on tools used in benefit-cost analysis (e.g., benefits transfer methodology) associated with implementation of each remedial alternative;
3. Evaluation of how the human health and ecological risk profiles would change given implementation of each remedial alternative;
4. Development of order-of-magnitude cost estimates for each remedial alternative.
Based on the results of the Comparative Analysis it is recommended that the engineered remedial alternatives (capping and dredging) not be considered as viable options for Pallanza Bay. Capping and dredging appear to provide no benefit associated with overall ecological and human health risk, result in substantial detrimental effect on both ecological and human use service values and are characterized by costs that appear disproportionate to incremental benefits derived.

**TH 074**

**Implications of the European Commission's September 2010 decision on measuring 'Good Environmental Status' in marine waters**

J Wenning[1], S Deacon[2], E Bizzotto[3], G Quadri[3], F Colombo[3]
[1]ENVIRON, EMERYVILLE, United States of America
[2]ENVIRON UK, BATH, United Kingdom
[3]ENVIRON Italy, MILAN, Italy

On 1 September 2010, the European Commission released a "Decision"providing the clearest explanation, to date, of what precisely is required to achieve "Good Environmental Status"(GES) in the different environmental directives arising from European Union environmental legislation during the past 10- years. According to the "Decision", achieving good environmental status requires that all relevant human activities are carried out in coherence with the requirement of protecting and preserving the [marine] environment and the concept of sustainable use of [marine] goods and services by present and future generations. The "Decision"provides the first indications of what constitutes applicable and acceptable quantitative metrics for judging environmental quality in the marine environment, though several of the metrics are likely applicable to freshwater, soil, air, and biodiversity considerations as well. The "Decision"also points to areas where further scientific work is needed to improve the understanding of certain environmental metrics or to develop tools that are either absent or inadequate. Recognition of the limitations of the current state of knowledge and ability to collect meaningful measurements represents a significant acknowledgement that much work remains to be done to achieve the environmental quality goals envisioned in European Union environmental legislation. These same limitations are evident in North America and elsewhere; thus suggesting a possible path forward for future environmental and ecological research not only in Europe but also around the world. The "Decision"is particularly relevant to two concepts of environmental management evolving rapidly in both Europe and North America - preserving, restoring, and/or enhancing ecosystem services; and, adaptive environmental management. This presentation explores further the implications of the "Decision"on environmental management in the European Union and elsewhere. Additional insight on the limitations of the current state of monitoring practices and knowledge of ecosystem services and quality are discussed by reviewing the Part A annex, which addresses general conditions governing application of criteria and related environmental indicators, and the Part B annex, which specifies criteria for assessing the extent to which GES is achieved and lists related indicators and applicable methodological standards, where available, to make such criteria operational.

**The 'Green Liver System' - using single ecosystem function of aquatic macrophytes for sustainable water purification**

S Pflugmacher, CS Romero-Olivera, A Peuthert
Berlin Institute of Technology, BERLIN, Germany

The aquatic ecosystem must face a large input of xenobiotics, which are affecting organisms, populations and whole ecosystems. But not only anthropogenic substances is one cause of stress in aquatic ecosystems, also compounds synthesized by organisms within the ecosystem is another cause. To have clean water and stable aquatic ecosystems is the main goal for the future, as water is a limited resource in this world. Water purification could be one of the most expensive techniques, so methods cheaper and more sustainable must be developed to secure clean water for stable ecosystems and also for human use.
The ecosystem has many ways for selfpurification and stabilization and the river Tiete in Sao Paulo (Brasil) is a famous example for that. Crossing the city of Sao Paulo, the river is one of the most polluted water bodies with nearly no life concerning fish, plants etc, inside. But a few hundred kilometer after the city of Sao Paulo the river looks nice and clean with fish and plants in a nearly perfect ecosystem.
In the last years we developed the "Green Liver System"which is based on several basic ecosystem function using aquatic macrophytes. One of these basic function is the ability of aquatic plants to take up and bioaccumulate xenobiotics as well as natural toxins. Comparing the metabolic possibilities of plants with human liver , a lot of similar pathways could be detected.

**Perfluorooctanoic acid induces peroxisome proliferation-associated activities in the liver of Japanese medaka**

G Lee, J Yang
Catholic University of Daegu, DAEGU, South-Korea

Widespread contamination of perfluorooctanoic acid (PFOA) in the marine environment draws a great concern over its ecotoxicological impact on marine mammals and wildlife. In the present study, the male Japanese medaka (Oryzias latipes) was adapted to the seawater to mimic the marine environment and was then exposed to the nominal concentrations of 10, 50, 100 mg L-1 PFOA for 7 d. There were no impact on survival, relative liver and gonad size, and condition factor (measure of growth) at any concentration tested. Peroxisomal acyl-CoA oxidase (ACO) activity was elevated at the highest dose with a marginal significance ($P = 0.06$). The increase of ACO activity was paralleled by the significant upregulation of PPAR-$\alpha$ expression at the same dose. PFOA induced a significant inhibition of catalase (CAT) activity at high doses with no changes of superoxide dismutase (SOD) or glutathione peroxidase (GPx) activities in the liver. These results strongly suggest that PFOA may induce peroxisomal fatty acid oxidation and impose the oxidative stress through the alteration of cellular oxidative homeostasis in the liver. PFOA increased the mRNA levels of proinflammatory cytokines such as IL-6, TNF-$\alpha$ and IL-1β, suggesting that it may be involved in inflammation and tissue injury. This study may contribute to understanding the mechanism of PFOA-induced hepatic toxicity in Japanese medaka and assessing the potential risk of PFOA in marine fish and wildlife. In addition, the present results obtained at the high concentrations may provide important biological endpoints relevant to situations such as environmental spills.

**TH 080**

**Sexually dimorphic behavior to characterize hormone-dependent effects of non-dioxin-like PCBs in rats**

H Lilienthal[1], P Heikkinen[2], P Andersson[3], M Viluksela[2]
[1]Institute for Prevention and Occupational Medicine, BOCHUM, Germany
[2]National Institute for Health and Welfare, KUOPIO, Finland
[3]Umea University, UMEA, Sweden

Neurodevelopment and sexual differentiation of the brain are dependent on intrinsically formed sex steroids. We previously demonstrated that developmental exposure to a PCB-mixture which was reconstituted according to the pattern found in breast milk caused decreases in aromatase activity in newborn male rats and feminization of sweet preference (SP) as a sexually dimorphic behavior in adult males. This outcome may be due to dioxin-like (Ah receptor-active) or non-dioxin-like PCB congeners (NDL-PCBs). The aim of the present experiments was to determine if exposure to highly purified NDL-PCBs (to avoid any Ah receptor activity) also results in alteration of SP. Pregnant rats were orally exposed to PCB52 (6 dose groups, total doses of 0-3000 mg/kg bwt) or PCB180 (6 dose groups, total doses of 0-1000 mg/kg bwt). In another experiment, rat dams were treated with equimolar doses of PCB74 or PCB95 (total dose, 760 µmol/kg bwt - PCB74: 222 mg/kg or PCB95: 248 mg/kg). For the determination of SP, adult male and female offspring learned to drink from two bottles in the week prior to testing. Basal water intake was determined during this period. Thereafter, rats were given a choice between a bottle of saccharin solution (0.25%) and a bottle of tap water on 5 consecutive days. Amounts consumed of either fluid were measured daily. Control females consumed twice as much sweetened solution than control males, thus, demonstrating sexual dimorphism of this behavior. Signs of supernormal behavior were observed in female rats exposed to PCB180, with increased saccharin consumption at medium dose levels and dose-dependent increases in the percentage of saccharin to total fluid intake. PCB180 males were unaffected. Exposure to PCB52 caused an increase in the ratio of saccharin consumption (male to female intake) only at the highest dose level (3000 mg/kg), due to diminished saccharin intake in females of this group, while saccharin consumption was not changed in males. A similar result was obtained in rats exposed to PCB74. However, developmental PCB95 led to an increased ratio of saccharin intake in males to females, due to elevated saccharin consumption in males. This result indicates feminization of SP in males exposed to PCB95. It further demonstrates that feminization of sexually dimorphic behavior occurs in the absence of Ah receptor activity, but different NDL-PCBs exhibit differential effects on this behavior. (Supported by the EU; ATHON, FOOD-CT-2005-022923).

**Effects of solution chemistry on the interaction between triclosan and humic acid**

P Scherpenisse, J Haftka, J Hermens
Utrecht University, UTRECHT, The Netherlands

Increasing levels of dissolved organic matter (DOM) are produced in peat catchments due to climate change. These high levels of DOM in surface water can form a problem in the preparation of drinking water. The presence of DOM in the production of drinking water can cause the formation of toxic disinfection by-products and can mobilize polar organic contaminants such as pharmaceuticals, endocrine disrupting compounds, herbicides and other industrial chemicals. The sorption of polar organic contaminants in the aquatic environment is generally not predicted well from hydrophobicity parameters. The polarity and the charge also influence the degree of partitioning of these contaminants towards DOM and their removal by adsorption to activated carbon. A different mechanistic view is therefore required regarding sorption of polar organic contaminants to environmental sorbents. This research is focused on studying the sorption of different polar organic contaminants to DOM from different origins. The biocide triclosan is considered as an emerging contaminant in the environment and has been selected here as a representative compound for polar organic contaminants. Preliminary experiments with triclosan ($pK_a = 7.9$) show an effect of pH on the partitioning of triclosan to solid-phase micro-extraction (SPME) fibers and Aldrich humic acid. The experiments were performed in 25 mM phosphate buffer. Concentrations ranging from 1 to 100 mM of phosphate buffer did not affect partitioning of triclosan to SPME fibers. The logarithm of the fiber-water partitioning coefficients decreased from $\log K_f = 3.39$ to 2.62 by increasing pH from 6 to 9. Likewise, association of triclosan with Aldrich humic acid decreased from $\log K_{doc} = 4.05$ to 3.59. These results show that solution chemistry is an important variable that determines the freely dissolved concentration of triclosan. Further research is aimed at determining the relevant parameters to predict sorption of polar organic contaminants to DOM and activated carbon. The results of this research will be used in a joint coordinated effort to predict the removal efficiency of organic contaminants in the different treatment processes of drinking water production.

### TH 082
**Bioactivity of synergized neem (Azadirachta indica.A.Juss) and potentiated insecticides for the control of Culex quinquefasciatus Mosquito larvae**

IH Ahmed[1], SA Siddig[2]
[1]Khartoum College of Medical Sciences, KHARTOUM, Sudan
[2]2University of Khartoum, Faculty of Science, Department of Zoology,P.O.Box 321, KHARTOUM, Sudan

Environmental pollution, poisoning accidents and insecticides resistance beside the high cost; had been the most emerging problems that restrict the continuous use of chemical insecticides for pests and vectors control. The use of plant extracts as alternatives for chemical insecticides has been a sustainable and ecofriendly approach for managing these problems. The neem tree (Azadirachta indica.A.Juss) proved to be one of the most promising among plant species.

The present work was set to test synergism in neem extracts against Culex quinquefasciatus larvae by mixing them with sesame oil and potentiation when mixing neem formulations with lower doses of standard insecticides to reduce the cost.

Results of experiments revealed that neem oil (No) was the most effective against Cx. quinquefasciatus. 3rd instar larvae than neem seeds water extract (NSWE). On the other hand mixing sesame oil with both (NSWE) and (No) produced synergistic effect significantly increasing the larval mortality of Cx. quinquefasciatus. Furthermore the synergized (No) was more effective than the synergized (NSWE).

Results also showed significant potentiation of standard mosquito insecticides Abate (temephos) and malation when mixed with NO and NSWE. Abate at half the concentration (0.0002%) + NSWE (0.0002%) and malathion at half the concentration (0.0002%) + NSWE (0.0002%) were equally effective against the tested animals as the insecticides alone at full dose (0.0004%). Similarly NO potentiated abate and malathion using half the concentration of each and produced an effect similar to that of the insecticides at full conc. (0.0004%) (reduction of cost).

The relative toxicity of neem oil, neem oil/sesame oil and Abate/neem oil mixtures was assessed in terms of LC50 and LC95 values.

### TH 083
**Interactive toxicity of alum and polyDADMAC to Newsealand rabbits**

AB Medani[1], SMA El Badwi[2], AE Amin[2]

Interactive toxicity of alum and polyDADMAC to Newsealand rabbits
Medani, A. B.; El Badwi, S. M. A. and Amin, A. E.

Abstract
Six heads of Newzealand rabbits were divided into 2 groups. Group 1 animals were the undosed controls. The test group was given 1% alum and 1% polydadmac at 1:2 for a period of 10 weeks after an adaptation period of two weeks during which the animals were under ideal experimental conditions.

Clinical signs were closely observed with postmortem and histopathological examinations. Chemical investigations included enzymatic concentrations of ALP, GOT, CK, GPT and LDH and metabolic changes of albumin, urea, total protein, cholesterol, bilirubin, glucose and creatinine. Fluctuations in electrolyte levels of Mg, Fe, Na, K, Ca and P were monitored together with hematological changes in Hb, PCV, RBCs and WBCs.

On evaluation of the above results, The interactive water treatment with 1% alum and 1% polydadmac at 1:2 was considered toxic to Newzealand rabbits at the dose rates tried .Practical implications of the results were highlighted and suggestions for future work were put forward.

### TH 084
**Response of Newzealand rabbits to drinking water treatment with alum and polyDADMAC in terms of change in electroytes**

AB Medani[1], SMA El Badwi[2], AE Amin[2]
[1]Khartoum College of Medical Sciences, KHARTOUM, Sudan
[2]University of khartoum,faculty of veterinary sciences, KHARTOUM, Sudan

Response of Newzealand rabbits to drinking water treatment with alum and polyDADMAC in terms of change in electrolytes
Medani,A.B. 1, Elbedwi,S.MA 2 and Amin,A.E.2

Abstract
Neazealnd rabbits of both sexes were purchased ,clinically adapted,given doses of polydadmac and alum at dose rates similar to those given by Khartoum Water Plant at flood season for human consumption.Sera were analyzed for electrolyte prior to experiment and there after at a week interval.As for Neazealnd rabbits tested for polydadmac,Sodium levels investigations revealed significant (P< 0.05) increase in the group recieving the highest dose,where as the rest of the groups showed no significance (P>0.05) differences.For potassium, significant (P< 0.05 - 0.01) increases in different groups were observed.Calcium levels showed remarkable (P< 0.05) deviations from normal in the serum of most groups.Significant (P< 0.05 - 0.01) increases and decreases were highlighted when testing the undertest rabbits for their phosphorus levels, whereas the control rabbits showed normal values when tested for the above mentioned electrolytes the thing which can be attributed to the hjepatic damage induced by the chemical.Both test groups showed significantly low values (P< 0.05 - 0.01) in magnesium, iron, calcium, and phosphorus when compared to the control group in case of testing them fo alum. The control group animals showed normal electrolyte values.This can also be attributed to the direct effect of alum.Intestinal wall which was spotted with white (probably with alum causing focal enteritis) was greatly affected with the irritant alum and/or its metabolites. When the resin is precipitated by alum in its preparation, it is more apt to gripe; commonly the salt intensifies its action and the cream of tartar increases the hydragogue effect .This action was very clear on the congested mesenteric blood vessels and symptomatically, by diarrhea and salivation due to nausea.Similar picture was seen when using alum as atest material.Future suggestions were suggested and practical implications were forwarded.

### TH 085
**Evaluation of the toxicity of glyphosate and its different formulations using the cell line human HepG2.**

G Chaufan, I Coalova, MC Rios de Molina
Facultad de Ciencias Exactas y Naturales, BUENOS AIRES, Argentina

The herbicide N-phosphonomethyl glycine, commercially known as glyphosate, is one of the most widely used agrochemicals in the fields of Argentina and the world. The use of different glyphosate formulations for weed control in agriculture produces herbicide excess in the environment that may cause undesirable toxic effects in the biota. Although humans are not a direct target, they are in risk of glyphosate exposure. Because the molecular mechanism of gliphosate toxicity is poorly understood, this study will assess the possible adverse effects and the risk of human exposure to glyphosate. We studied the glyphosate toxicity in an in vitro model of human cells (hepatocytes cultures, HepG2). The human hepatoma cell line Hep G2 was cultured in minimal essential medium (MEM) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 units/ml penicillin, 100 mg/ml streptomycin and 2.5 mg/ml amphotericin B. Cells were cultured at 37 ºC in a humidified atmosphere of 5% CO2-95% air and the medium was renewed twice a week. For all experiments, confluent attached cells were removed from cell culture dishes with 0.25% sterile trypsin, diluted with MEM/10% FBS and replated into 96-well plates (0.2 ml; 2 x104 cells/well) for 24, 48 and 72h for the MTT assay and into 6 well plates (3ml; 3 x 105 cells/well) for 24h for the caspase 3/7 activity assay, and lipid peroxidations as thioborbituric acid reactive substance (TBARs) level. We measured the cytotoxicity (LC50) of Roundup® and of Atanor® glyphosate formulations with or not the addition of Impact® adjuvant, and the technical grade glyphosate in its acid form on cell line HepG2. All parameters were measured at sub-agricultural doses with all formulations.

The LC50 of different glyphosate presentations at 24, 48 and 72h was determinate: 41.2 (37.6 - 45.1), 35.2 (34.9 - 35.4), 34.7 (34.1 - 35.3) mg/L for Roundup; 93.9 (75.0 -117.4), 40.4 (31.2 - 52.2), 29.9 (17.8 - 50.4) mg/L for Atanor® with Impacto®; 445.7 (416.4 - 477.1), and 418.7 (405.1 - 432.8), 383.5 (372.8 - 394.4) mg/L for Atanor®. Not significant effect was observed at sub-agricultural doses with technical grade glyphosate in its acid form. The caspases 3/7 are significantly activated with doses of Roundup® (35 mg/L) up to 240% in 24h. Not significant effect was observed at this dose for TBARs levels.

We conclude that cytoxicity and apoptotic effects were more dependent on the formulations than on the glyphosate concentration.

### TH 086
**Dissolution study of silver nanoparticles in toxicology media**

M Tejamaya
University of Birmingham, BIRMINGHAM, United Kingdom

Currently, silver nanoparticles (AgNPs) are the most widely used nanomaterials, with particular applications as antimicrobial agents. Textiles, wound dressing, washing machines and cosmetics are some examples of consumer products containing AgNPs1,2. Due to their wide range application, exposure of AgNPs to the environment is likely3,4,5. Thus, risk assessment becomes more important.

Previous studies found that toxic effect of AgNPS was highly likely due to silver ions released from its NPs form6,7. As this study is part of larger study that will be looking at eco-toxicology of silver nanoparticles to daphnia magna, fish and algae, it is important to understand the solubility and dissolution kinetics of AgNPs in the toxicology media used for eco-toxicology study. Thus this piece of project will examine dissolution properties of silver nanoparticles with different physic-chemical properties in OECD toxicology media.

All the silver nanoparticles used in this study wese self-produced. Different techniques were implemented to generate particular size of NPs as well as capping agent. All of them were fully-characterised with several instrumentations such as UV-Vis spectrometer, DLS, Fl-FFF, TEM and AFM.

**A comparison of methods for measuring the metallothionein induction in metal-exposed Chironomus tepperi.**

L Engelstad[1], S Long[1], R Brown[1], V Pettigrove[1], AA Hoffmann[1], A Doronila[2]
[1]CAPIM, PARKVILLE, Australia
[2]The University of Melbourne, PARKVILLE, Australia

Biomarkers (changes in the biological functioning of an organism) have potential application in assessing the presence of pollutants in the environment including heavy metals. Metallothionein (MT) is a small, cysteine rich protein involved in detoxification and regulation of heavy metals in many species. It has previously been shown that exposure to metal contamination results in an increase in MT levels in a number of invertebrates. MT has therefore been suggested for use as a biomarker of metal contamination. This study compares three methods for the detection and quantification of MT in the non-biting midge *Chironomus tepperi*. The methods were Western transfer followed by immunoblotting using a specific antibody, a well established mercury saturation assay and the Brdicka differential pulse voltammetry (DPV) method. Tissue was collected from *C. tepperi* larvae following exposure to copper sulphate at sub-lethal concentrations in water, and controls exposed only to artificial water were run alongside exposed larvae. The immunoblotting method showed a clear difference in concentrations between two MT standards as well as in tissue from larvae exposed to different copper concentrations. As far as we are aware this is the first time a Western Blotting immunological method has successfully detected MT in chironomids. Results compared favourably with those from the well-established mercury saturation assay which uses mercury as a surrogate to MT. The Brdicka DPV method showed a clear difference between MT standards and was able to quantify MT in tissue at the higher contamination level, however polarographic peaks were indistinct. The immunoblotting technique may represent a relatively straightforward way of determining MT concentrations in aquatic invertebrates exposed to metals.

### TH 088

**Development of genitalia in the ivory shell (*Babylonia japonica*): observation of the specimens from wild populations and laboratory-reared juveniles**

T Horiguchi[1], Y Ohta[2], F Hamada[3], H Shiraishi[1]
[1]National Institute for Environmental Studies, TSUKUBA, IBARAKI, Japan
[2]Faculty of Agriculture, Tottori University, TOTTORI, TOTTORI, Japan
[3]Tottori Prefectural Sea Farming Association, TOHAKU-GUN, TOTTORI, Japan

We examined development of genitalia in the ivory shell (*Babylonia japonica*) with a histological method, using 2-year-old shells from wild populations and laboratory-reared juveniles for 0-1.6 year of age, in the chain of studies on analysis of induction mechanism of imposex caused by organotin compounds, such as tributyltin (TBT) and triphenyltin (TPhT) from antifouling paints, in gastropods. Parent ivory shells were collected in Miho Bay, Tottori, Japan by commercial fisheries and then reared in the tanks with flow-through systems and 60cm-glass aquaria with filtering systems, using natural seawater collected out at Sea of Japan and deep sea water collected at approximately 400 m in depth of Suruga Bay, Japan, respectively. Concentrations of TBT and TPhT in both of seawater were below the detection limit by gas chromatography with mass spectrometry (GC/MS). Egg capsules spawned by parent shells were rinsed by distilled water and then moved to other tanks/aquaria with flow-through systems. It took approximately 3 weeks until larvae hatched out. Veliger larvae were settled down at bottom of the tanks/aquaria within several more days. Settled juveniles were fed Antarctic krill (*Euphausia superba*) every day. Shells for approximately 6-month-old, 1-year-old, 1.2-year-old, 1.4-year-old and 1.6-year-old were removed for histological observation. After shell removal, soft tissues were fixed in Gendre's fluid (a 15:5:1 solution of saturated 2,4,6-trinitrophenol in 30% ethanol:35% formaldehyde:acetic acid) for 48h, and then embedded in paraffin. Serial sections were prepared using a microtome, stained with Hematoxylin-Eosin (HE) and observed with a light microscope. Two-year-old shells from wild populations in Miho Bay, Japan were also treated with the same method as described above. Differentiation of gonad (i.e., testis and/or ovary) was unclear before 2 years of age. Immatured vas deferens, however, was observed in juveniles for 1.2-year of age and older, although no penis was observed in those younger than 2 years old. Immatured oviduct was observed in 1-year-old juveniles in which vagina were not yet opened. Differentiation and development of genitalia preceded gonadal development in the ivory shell (*Babylonia japonica*), suggesting that regulatory mechanism of reproduction could be different between gastropods and vertebrates, in terms of differentiation and development of reproductive organs.

### TH 089

**Interactions between endogenous and exogenous antioxidants against Pb-induced oxidative stress in wild ungulates from a Pb polluted mining area**

J Rodríguez-Estival, M Martínez-Haro, R Mateo
Instituto de Investigación en Recursos Cinegéticos, CIUDAD REAL, Spain

Heavy metal mining and smelting commonly contaminates air, water and soil and this contamination is then transferred to biota through food chains. It has been widely suggested that certain physiologic disorders and diseases attributed to the exposure of lead (Pb) are related to the generation of oxidative stress. To protect from oxidative damage, organism rely on a complex antioxidant system composed of endogenously produced compounds such as glutathione (GSH), superoxide dismutase (SOD) and glutathione peroxidase (GPX); and dietary antioxidants such as vitamins A and E. The aim of this work was to study the interactions between both kinds of antioxidants and to evaluate the importance of dietary antioxidants to fight against Pb-induced oxidative stress in wild ungulates living in a mining area. Wild boar and red deer from the mining sites had higher bone and liver Pb levels than the controls. The results obtained in this work certify that important differences exist in the antioxidant cycling system between red deer and wild boar and their response to Pb pollution. Both red deer and wild boar exposed to Pb showed disturbed hepatic vitamin A and E homeostasis, which were closely related with the effects observed on endogenous antioxidants, therefore suggesting that dietary antioxidants are especially important for wildlife to fight against Pb-induced oxidative stress. Bone Pb in boar was essential to explain the main differences between control and mining area, therefore ratifying that long-term effects exposure on the antioxidant system are present in this species. We suggest that the management of these game species should consider a supplementary feeding with foods enriched with vitamins A and E when animals are suspected may be exposed to Pb pollution.

### TH 090

**Assessment of DNA adducts in Dreissena polymorpha exposed to benzo[a]pyrene**

A Châtel[1], V Faucet-Marquis[2], A Pfohl-Leszkowicz[2], F Vincent-Hubert[1], E Uher[1]
[1]Cemagref, ANTONY, France
[2]Université de Toulouse, INPT/ENSAT, Laboratoire de Génie Chimie, AUZEVILLE TOLOSANE, France

Genotoxicity analysis is widely used in biomonitoring programs for the evaluation of biological effects of pollutants on marine organisms whereas similar investigations are not clearly envisaged for freshwater animals. In the present study, the relevance of DNA adducts as biomarker of genotoxicity related to PAHs contamination of urban water has been investigated using the freshwater mussels Dreissena polymorpha This zebra mussel is a very suitable sentinel species for pollution monitoring in view of its abundance and its capacity of accumulation of metals and organic micro-pollutants. Mussels were collected in a reference site and then exposed in the laboratory to various concentrations of benzo[a]pyrene ranging from 1 µg/L to 100 µg/L for 4 days. Afterwards, mussels were kept in running water for 28 days of recovery period and DNA adducts levels were subsequently measured on two different organs, the digestive gland and the gills, using the 32P post-labelling technique. Benzo[a]pyrene nominal concentrations and bioaccumulation in mussel tissues were measured by GC-MS (Gaz chromatography-Mass spectrometry). Results will depicted more precisely i) the dose response of DNA adducts formation following benzo[a]pyrene exposure and their relationship with nominal concentration and mussel benzo[a]pyrene accumulation, ii) the tissue differences in DNA adducts formation and iii) the persistence of DNA adducts. Ultimately, data converge towards the fact that DNA adducts represent a very promising biomarker for water quality monitoring.

### TH 091

**Flow cytometry methodology for measuring chemical induced cellular dead cell apoptosis and necrosis of splenic leucocytes in European bullhead, Cottus sp.**

A Bado-Nilles[1], S Jolly[2], A Geffard[1], B Gagnaire[3], JM Porcher[2], S Betoulle[1], W Sanchez[2]
[1]University of Reims Champagne-Ardenne, REIMS, France
[2]Ineris, VERNEUIL-EN-HALATTE, France
[3]IRSN, SAINT-PAUL LEZ DURANCE, France

In environmental immunotoxicology, leucocyte apoptosis and necrosis parameters may constitute pertinent biomarkers of immunological disturbance due to their modulations by numerous xenobiotics. In an ecotoxicological concern, the aim of this study was therefore to develop immune-related biomarkers using flow cytometry methodology in the European bullhead, Cottus sp., a current freshwater fish. In this context, spleens of bullhead were interesting due to sampling facilities and to their immune function. After spleen tissue disruption, leucocytes of each organ were isolated using density gradient centrifugation and cells were adjusted to 106 cells.mL-1. For each leucocyte sample, five aliquots were carried out. With the first aliquot, autofluorescence of cells were detected. YO PRO®-1 (100 µM) and Propidium Iodide (PI, 1.5 mM) were added in two different aliquots in order to obtain cellular fluorescence parameters indicating the presence of apoptotic and necrotic leucocytes, respectively. Both YO-PRO®-1 and PI were added in a double markedly method. Spleen leucocyte cellular aliquots were also treated with YO-PRO®-1, PI and quinoline alkaloid camptothecin (100 µM) which induce apoptosis. After incubation, cellular analysis were carried out with a CyanTM ADP flow cytometer connected to hypercyt®intellicyt (Beckmann Coulter). Apoptotic and necrotic dead cells showed green and red fluorescence, respectively. The camptothecin treated cells presented similar necrotic values and a higher percentage of apoptotic cells than those observed in controls. In consideration of these developments, dead cell apoptosis and necrosis were tested during in vivo controlled-laboratory experiments where European bullheads naturally infected with Saprolegnia sp. and Ichthyophtirius sp. were exposed to 25 µg.mL-1 of Copper. This exposure induced a decrease of cellular apoptosis and necrosis in contaminated organisms compared to controls. In conclusion, this work enabled a technical methodology to evaluate fish immune-physiological markers on spleen leucocyte of the sedentary bullhead, Cottus sp. For the assessment of wild fish health, further studies will be undertaken in order to characterize the potential and to validate the interest of these biomarkers in immunotoxicology studies.

### TH 092

**Integrated biomarkers responses in fish from active biomonitoring and whole effluent toxicity assessment of a mining polluted fresh water system**

OT Olubambi, V Wepener
University of Johannesburg, JOHANNESBURG, South Africa

An integrated biomarker response study was conducted on two fish species in the Blesbokspruit wetland subjected to water polluted primarily with mining effluent. This is a hydrological important wetland in the Gauteng region of South Africa and its ecological integrity is being continuously threatened by large volumes of effluent discharge. Previous studies were only conducted on metal accumulation. Active biomonitoring (ABM) was conducted by deploying laboratory reared Tilapia, Oreochromis mossambicus (n=20) in cages at five sites during the high flow period of 2009. After 4 weeks exposure whole samples of fishes were collected. In addition whole effluent toxicity (WET) testing was carried out in the laboratory on water collected from the respective sites using the standard fish test organism, Poecilia reticulata. Biomarkers of exposure: metallothioneins (MT), ethoxyresorufin-o-deethylase (EROD) and acetylcholine esterase (AChE) and biomarkers of effect: catalase (CAT), cellular energy allocation (CEA) and superoxide dismutase (SOD) responses were determined in all fish samples from the ABM and WET studies. Hundred percent mortalities were recorded in the ABM studies at sites 2 and 4. However the 96 h WET assessments revealed little or no mortality at all sites. Similar patterns in biomarkers responses were observed in fishes exposed both during the ABM and WET studies. For example, induction of MT and catalase stimulation both indicative of metal exposure and oxidative stress was observed during both times. EROD induction and AChE activity inhibition, which indicates organic and organometallic exposure was also observed. The WET exposed fish at sites 2 and 4 showed more altered biomarker responses. Integrated biomarkers studies were able to successfully demonstrate biological effects from toxicants in the system and allowed better understanding on organisms' responses to a combination of stressors other than just measuring mortality. The use of active biomonitoring as a reliable means of assessing environmental health is further established.

### TH 093

**Ex vivo evolution of kidney leukocytes immune parameters in European bullhead (Cottus sp.)**

S Jolly[1], A Bado-Nilles[2], A Geffard[2], JM Porcher[1], S Betoulle[2], W Sanchez[1]
[1]Institut National de l'environnement industriel et des risques (INERIS), VERNEUIL EN HALATTE, France
[2]Université de Reims, REIMS, France

In all living organisms, immunity is essential for body protection against biological pathogens. This physiological system is particularly sensitive to chemical contamination. Immune biomarker measurements can be used in laboratory experiments to assess the impacts of xenobiotics on cellular and humoral functions in an immunotoxicological concern. Moreover, these immune indicators can be also applied under field context to characterize the health of wild fish. In environmental immunotoxicology, analysis of immune parameters in native fish populations may be particularly difficult as immune cellular or biochemical responses have to be studied in fresh tissues with living cells. The aim of the present study was to determine in laboratory, required conditions to analyze cellular immune responses from kidney tissue samples in European bullhead (Cottus sp.). For this purpose, eight bullheads were sacrificed and kidneys were immediately dissected out in order to study some immune markers. Each immune response was analyzed either immediately after tissue homogenization (T0) or 12 and 24 hours after tissue kidney treatment. Oxidative burst activity was measured by a chemiluminescence technique. Cellularity, cell mortality (apoptosis versus necrosis and leukocyte phagocytosis activity were performed by flow cytometry. Results obtained from analysis realized 12 or 24 hours after fish dissection were compared with those obtained when analysis were done immediately after kidney dissection and homogenization. In this context, no significant variation in kidney leukocyte composition was observed at 12 or 24 hours. Cellular mortality and phagocytosis activity were reduced 12 hours after kidney dissection whereas the oxidative burst activity decreased only 24 hours after tissue sampling. Simultaneously, leukocyte viability was increased 12 hours after kidney treatment. The sampling procedure and tissue treatment may be responsible for stressful conditions for isolated leukocytes which must be taken into account for the following cytometric procedure. Under field conditions, kidneys must be homogenized immediately after dissection but cellular analysis and immune marker measurements may be done only 12 hours after kidney sampling procedure. So, in the field context of environmental immunotoxicology, it is not necessary to analyze immune cellular responses directly in field and a time of 12 hours is useful to obtain low stressed-isolated leukocytes suspensions.

**TH 094**

**Litter degradation of transgenic corn, a potential pathway of Bt-toxin in streams**

R Böttger[1], S Lintow[2], J Schaller[2], M Feibicke[1], G Dudel[2]
[1]Federal Environment Agency, BERLIN, Germany
[2]Dresden University of Technology, Institute of General Ecology an Environmental, DRESDEN, Germany

Corn (Zea mays) has been genetically changed to produce the toxin Cry 1Ab against the lepidopteran European corn borer (Ostrinia nubilalis). Studies on the effect of Bt-corn on non-target organisms were mainly focused on terrestrial species. However, the exposure pathway of chaffed plant biomass into adherent ditches and creeks has so far hardly been taken into account. Data on half-live of the Cry 1Ab protein in decaying submerged corn material is up to now not available. Therefore a fate study by use of decaying plant material in microcosms was performed. The concentration of Bt-toxin in corn leaves was measured over a period of 23 days along with other components (lignin, cellulose, polyphenoles, C:N) of the leaves. Even after 23 days a relevant share of initial concentration of the toxin was detectable. The results will be discuss in the context of Bt-toxin fate and restricted decay under submerged aerobic conditions.

**TH 095**

**Health risk of heavy metals (lead, cadmium) in game species**

F Soler, E Gallego-Rodríguez, D Hernández-Moreno, M Pérez-López
Veterinary Faculty, CÁCERES, Spain

One of the most important aspects of environmental pollution for humans is the intake of toxic elements in the diet. There is an increased interest among consumers in meat from animals kept in natural conditions, as in game occurs, because its high nutritional values, special sensory properties and it is considered a free-chemical food. However, these species often show higher levels of contaminants which can constitute a health/toxicological threat. In the European Union, the Commission Regulation 1881/2006 sets maximum levels (MLs) for certain contaminants (including lead and cadmium) in food derived from domesticated and wild organisms, but no level has been set for wild game.

In this study, concentrations of Cd and Pb in the muscle of free-living wild boar (n = 310) and red deer (n=205) were analysed by stripping anodic voltamperometry after acid digestion. Samples were taken from hunting activities in several places of Extremadura (East of Spain).

There were no important differences between the sampling places and between the two species. Levels of metals (mg/kg) in muscle of red deer ranged as follows: Cd: <LD-0.389 (mean: 0.016), Pb: <LD-11.557 (mean: 0.546). Samples with a concentration <LD were 45.8% for cadmium and 13.2% for lead. In muscle of boar these levels were: Cd: <LD-0.293 (mean: 0.011), Pb: <LD-20.678 (mean: 0.780); and samples <LD were 53.9% for Cd and 19.7% for Pb.

Metal concentrations exceeded the permitted values for domestic animals (Cd 0.05; Pb 0.1 mg/kg) in 10.73% and 3.23% of samples for Cd, 49.3% and 49.7% for Pb in red deer and boar respectively. However, these LMs can not be applied directly to game muscle since its consumption is quite lower than that of meat from domestic animals.

Another way to stablish the public health risk of these meats is the comparison with the PTWI (Provisional Tolerable Week Intake) set by the WHO. Our results show that the intake of these game meats represents <0.5% of the PTWI for both metals and species. A extreme situation is when the game meat is the only meat consumed (as in some consumers like hunters). In this case consumption of red deer meat could be 4.08 and 38.86% of the PTWI for Cd and Pb, respectively, and boar meat could be 2.86 and 55.79 % of the PTWI for Cd and Pb, respectively. Lead concentration in game animal, particularly wild boar, represent a serious health risk for this group of consumers.

**Development of tissue-based mammalian toxicity reference values for use in Ecological Risk Assessment**

BR Deshields, TB Orr, M Pattanayek
ARCADIS, PETALUMA, United States of America

Wildlife exposure to environmental contaminants is typically expressed as average daily dietary dose, where the total dose may consist of fractional ingestion of contaminated prey items, soil/sediment, or drinking water. Less frequently, wildlife exposure to contaminants is quantified in target tissues where contaminants exert toxic effects. Measurement of target tissue contaminant residues allows for estimating exposure at the site of action and serves as one line of evidence for evaluating potential risks to ecological receptors; however, tissue-based toxicity reference values (TRVs) are not typically available in the scientific literature, as is the case for dietary-based TRVs. Mammalian TRVs for kidney and liver tissue were developed for a subset of metals. The TRV development procedure consisted of three primary steps: (1) mechanism of action review; (2) a literature search for appropriate and applicable studies; and (3) TRV selection. Standard toxicology databases were reviewed to identify chemicals of interest (COIs) that have mechanisms of action relevant to kidney and liver tissue. The following COIs exhibit toxic effects in kidney and/or liver tissue: cadmium, chromium, copper, lead, and zinc. A literature search was performed to identify studies that met the following two primary criteria: (1) measured toxic effects that have been shown to produce potential population-level effects such as reproductive or growth impairments and survival; and (2) quantified kidney and/or liver COI tissue residues. A total of 348 toxicity endpoints from 212 studies were reviewed. Those studies that reported kidney and/or liver tissue residues that could be clearly associated with no observed adverse effect level and lowest observed adverse effect level concentrations were included in TRV development. Tissue-based TRVs were developed using a weight-of-evidence approach similar to the procedure described in the U.S. Environmental Protection Agency's Guidance for Developing Ecological Soil Screening Levels.

**Effects of polycyclic aromatic hydrocarbons (PAHs) by lipid oxidation in avian embryos**

HO Westman[1], M Nordén[1], M Larsson[1], K Winkens[2], H Hollert[2], M Engwall[1]
[1]MTM Research Centre, ÖREBRO, Sweden
[2]RWTH Aachen University, AACHEN, Germany

In this study we present a new avian assay for the study of chemicals effects on lipid homeostasis. The input of PAHs into the atmospheric, aquatic and terrestrial system has been accelerating since the beginning of early industrialization. PAHs are well known to be potentially carcinogenic to humans and ecotoxicological effects of PAHs have been shown in a diverse suite of studies, including microorganisms, reptiles, birds and mammals. Relatively few studies address questions concerning the health impact of PAHs in avian species, but some laboratory studies show that PAHs are highly embryotoxic to birds when injected into eggs. We have designed a method to investigate the effects of PAHs on the β-oxidation of fatty acids in hepatic embryonic tissue from chicken (Gallus domesticus). Using this assay previous results suggest a small but significant increase in β-oxidation of fatty acids in chicken embryonic liver tissue after in ovo exposure to some PFCs. The focus for this study is exposure to 16 PAHs injected on day 4 into the air cell. This is then followed by in vitro incubation of the embryonic livers on day 10 with a tritiated fatty acid mixture (palmitate 16:0). The fatty acids undergo oxidation and repetitive cleavage of carbons before entering the tricarboxylic pathway and cycles of β-oxidation. As a result of this lipid oxidation tritiated water is produced. The radioactive water (3H2O) is collected and measured. Using our assay the effects of PAHs on the enzyme function regulating the hepatic fatty acid metabolism can be studied in vitro. This approach could be a very useful trying to find out possible mechanisms behind avian toxicity including disturbance of fatty acid oxidation and lipid homeostasis. Other compounds than PAHs will be tested. To the best of our knowledge, this is the first time such study has been performed.

**In vitro effects of pesticides and metals on biomarkers in Cerastoderma edule tissues (Bivalvia: Cardidae)**

J Nilin[1], GC Ferreira[2], S Loureiro[2], LV Costa-Lotufo[1], AMVM Soares[2]
[1]Universidade Federal do Ceara, FORTALEZA, Brazil
[2]CESAM,Department of Biology University of Aveiro, AVEIRO, Portugal

Several studies have been showed that metals and pesticides in water can affect the activity of enzymatic biomarkers in bivalves. However there is little information on the mechanisms and pathways involved in the toxicity of these contaminants that can often affect non-target organisms. In this perspective the objective of this study was to evaluate the activity of glutathione-S-tranferases (GST), carboxylestarase (CaE) and cholinesterase (ChE) of *Cerastoderma edule* tissues exposed in vitro to mercury, cadmium, dimethoate and carbofuran. Cockles (20-30mm) were collected in July/10 from a site commonly used as reference in toxicity studies at Ria of Aveiro, Portugal (Barra). Digestive gland extracts, used for GST and CaE analyzes, and adductor muscles extracts, used for ChE analyzes, were prepared from three animals exposed to several concentrations of each chemicals (50, 25, 12.5 and 6.25 mM) during 30 minutes at 25ºC. This study will help to understand the range of the in vitro effects of metals and pesticides on the biomarkers before the whole metabolic process by organisms.

**Ifluence of radiation on prolificity and viability of stable strains Drosophila melanogaste**

BM Khudaibergenova
Institute of Biotechnology, National Academy of Sciences, BISHKEK, Kyrgyzstan

The pollution of biosphere with radioactive substances, heavy metals, organic pollutants initiates mutational changes. It is known the stable mutations, potential changes arise in chromosomes under mutagenic factors. These allterations may be restored to initial position for chromosomes or transfered to new mutations that would depend on external conditions.

Any changes of genetical material's metabolism (DNA, enzymes of replicating complex, synthesis of DNA precursors) will lead to alteration of mutational frequency. The mutations of definitive genes may arise damages in structure or function of enzymes. Those enzymes would participate in the processes of repairation, replication and recombination of genetical material.

The new stage in investigation of mutagenesis and recombination is bound with mobile genetical elements that were revealed in different representatives of each taxonomy group (including human). The research of mobile genetical elements (MGE) in pro- and eukaryotes have revealed their participation in realization not only mutations, but different adaptive and regulatory processes. Mobile elements are integral part of genome making its own correlation in manifestation morphological, physiological, biochemical characteristics of organism. In ordinary surroundings mobile genetical elements keep silence in cellular mechanisms, they occupy their constant sites of localizations in genome without moving. However, MGEs would be activated under unsuitable conditions such as radiation, heat shock, chemical mutagens. In its turn, this process leads to induction such indexes as increasing level of the mutational chromosomal rearrangements, alteration of gene expression, cell's death. That activation becomes the reason of new phenomena and signs, non-typical for individual organism.

The frequency of spontaneous mutations is sufficiently low and makes up 10 -5 - 10-7 range. The frequency of MGE's transpositions which are the basic reason for spontaneous mutagenesis is the same. Under different conditions the rate of transpositions of MGE may increase in a few orders. The reasons of increasing transpositional levels may be conditioned by genetical mechanisms or by activity of unfavourable external factors, to which heat shock, radiation, toxins are related .

**A watershed analysis of anthropogenic disturbance and fish species sensitivity in South Carolina, USA**

AN Sayer[1], SJ Klaine[2], M Scott[3], CJ Marion[3]
[1]Clemson University, SENECA, United States of America
[2]Institute of Environmental Toxicology, PENDLETON, United States of America
[3]South Carolina Department of Natural Resources, CLEMSON, United States of America

In 2009, the population of the State of South Carolina, USA was over 4.5 million people and has increased at a rate of around 13.7% during the last decade. While the population density per sq. mile is relatively low compared to other US states, it seems certain the population will further increase in years to come. Increasing population density leads to urbanization, which usually results in an increase in impervious surfaces, such as roadways, parking lots, and building roofs. This changing land use can have dramatic effects on smaller streams and creeks which form the upper reaches of watersheds. In eastern North America, the development of once forested land causes habitat loss and interferes with natural processes and cycles especially in aquatic systems. During storm and rainfall events metals, polycyclic aromatic hydrocarbons (PAHs), and other contaminants are washed into lakes, rivers, and streams instead of being absorbed into the ground. These chemicals are being found in drinking water which is often prepared from surface water. Aquatic ecosystems are sinks for many contaminants. Despite the fact that waterways can be fragmented, watersheds encompass the entire drainage area of a locale. An investigation was conducted in 2009 to determine anthropogenic disturbances on watersheds throughout South Carolina, USA. Fish biomarker, fish species/diversity, water column metals, and land use data were used to determine endpoints of fish species sensitivity and resilience. The results from this investigation indicate the disappearance of fish species as well as reduced species diversity may be influenced by land development.

**TH 101**

**Influence of radiation on prolificity and viability of stable strains Drosophila melanogaster**

BM Khudaibergenova, ShJ Jorobekova
Institute of Biotechnology, National Academy of Sciences, BISHKEK, Kyrgyzstan

The pollution of biosphere with radioactive substances, heavy metals, organic pollutants initiates mutational changes. It is known the stable mutations, potential changes arise in chromosomes under mutagenic factors. These allterations may be restored to initial position for chromosomes or transfered to new mutations that would depend on external conditions.

The new stage in investigation of mutagenesis and recombination is bound with mobile genetical elements that were revealed in different representatives of each taxonomy group (including human). The research of mobile genetical elements (MGE) in pro- and eukaryotes have revealed their participation in realization not only mutations, but different adaptive and regulatory processes. Mobile elements are integral part of genome making its own correlation in manifestation morphological, physiological, biochemical characteristics of organism. MGEs would be activated under unsuitable conditions such as radiation, heat shock, chemical mutagens. In its turn, this process leads to induction such indexes as increasing level of the mutational chromosomal rearrangements, alteration of gene expression, cell's death. That activation becomes the reason of new phenomena and signs, non-typical for individual organism.

The frequency of spontaneous mutations is sufficiently low and makes up 10 -7 - 10-8 range. The frequency of MGE's transpositions which are the basic reason for spontaneous mutagenesis is the same. Under different conditions the rate of transpositions of MGE may increase in few orders. The reasons of increasing transpositional levels may be conditioned by genetical mechanisms or by activity of unfavourable external factors, to which heat shock, radiation, toxins are related.

In some cases correlation between behavior of retrotransposons and changes of quantitative and adaptive signs are observed. In other cases the selection on dicreasing adaptive characteristics have lead to changing sites of MGE. The selection on increasing adaptive level have lead to special insertions in the previous sites. Such behaviour of MGE provides genotypical adaptations to harmful factors.

**Haematological effects of 1% Alum to Newzealand rabbits**

AB Medani[1], SMA El Badwi[2], AE Amin[2]
[1]Khartoum College of Medical Sciences, KHARTOUM, Sudan
[2]University of khartoum,faculty of veterinary sciences, KHARTOUM, Sudan

Newzealand rabbits were purchased form Balsam pharmaceutical factory, weighed and divided into groups. Group 1 animals were the undosed controls. Test groups were given alum at dose rates of 1% for a period of 10 weeks after an adaptation period of two weeks during which the animals were under ideal experimental conditions. .

Clinical signs,postmortem and histopathological examinations were closely observed together with hematological changes in Hb, PCV, RBCs and WBCs.

On alum challenge, Newzealand showed inappetance, nervous signs and were finally recumbent. The mortality rate was 100 %. On atomic absorption only the lungs kept residual alum , while the livers washed- out the substance ,may be via bile . Notably oral dosing with alum caused congested liver with white spots, stiff-greenish lungs and inflammed empty intestines. The un-dosed group 1 goats showed a normal picture.

On histopathology, alum-dosed goats showed necrosis in the cortex and medulla of the kidney in one group member, emphysema in the lungs and necrosis in the hepatocytes and congestion in the liver . Practical implications of the results were highlighted and suggestions for future work were put forward.

**Copper exposure increases histamine levels in marbled crayfish (Procambarus sp.)**

B Soedarini[1], L Klaver[1], D Giesen[1], I Roessink[2], WFM Röling[1], B Widianarko[3], NM van Straalen[1], CAM van Gestel[1]
[1]VU University, AMSTERDAM, The Netherlands
[2]Alterra, WAGENINGEN, The Netherlands
[3]UNIKA Soegijapranata, SEMARANG, Indonesia

The kinetics of 0.05 mg Cu /L and 0.5 mg Cu /L in the form of $CuSO_4$ to marbled crayfish were studied. Marbled crayfish exposed to copper individually in aerated glass jars for 14 days and then transferred to copper free water for another 14 days. At different sampling times the animals of each treatment were dissected to collect their organs. The copper uptake and elimination in the crayfish organs (hepatopancreas, gills, muscle, ovaries and exoskeleton) were evaluated with a one compartment model ; and the levels of histamine (neuromodulator) present in the heptopancreas and muscle over the exposure time were determined. The results showed that the copper accumulated mostly in the hepatopancreas where the uptake rate (223 ± SE 114 L.kg-1.d-1) was much higher than the elimination rate (0.008 ± SE 0.032 L kg-1.d-1). In the other organs, the copper concentrations were strongly regulated due to their efficient excretion. The histamine concentrations found in the hepatopancreas significantly increased with the duration of exposure. Animals treated with copper 0.5 mg/l contained higher level histamine than animals treated with copper 0.05 mg/l; in hepatopancreas were 13.8 ± 5.93 W.B. µg/g and 5.39 ± 1.01 µg/g W.B. respectively while in muscle were 1.46 ± 0.31 µg/g W.B. and 1.36 ± 0.02 µg/g W.B. respectively. The conclusion is that excess copper in water will be accumulated in the hepatopancreas and that the organ contained higher copper concentration had higher histamine level.

## ET07 - Endocrine disrupting chemicals in the environment

**TH 107**

**Testing the effects of environmental levels of xenoestrogens as found in the Douro River estuary (Portugal) on the maturation kinetics of fish gonads - A stereological study using the zebrafish**

P Silva[1], MJ Rocha[2], C Cruzeiro[3], F Malhão[4], B Reis[4], R Urbatzka[3], RAF Monteiro[1], E Rocha[1]
[1]CIIMAR - CIMAR LA and ICBAS - U.Porto, Porto, Portugal, PORTO, Portugal
[2]CIIMAR - CIMAR LA and ISCS-N, PORTO, Portugal
[3]CIIMAR - CIMAR LA, PORTO, Portugal
[4]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal

A wide range of chemicals, both natural and man-made, do cause endocrine disruption. Particularly, some these compounds are contaminants that evoke biological responses mimicking those caused by female sex steroids. This event is occurring at many locations worldwide, and both field and experimental data point that negative consequences exist not only for individuals but also for populations. The mechanisms by which those compounds exert final effects are being disclosed, but doubts remain, including on impacts in the gametogenesis kinetics. Also, since in natural environments fish populations are exposed to many potential xenoestrogens, understanding impacts of mixtures continues to be of great interest. The main objective of this study was to understand if and how an environmental relevant mixture of xenoestrogens that we found in the Douro River, by chemical screening, can disrupt the normal gametogenesis in fish. Our hypothesis is that physiological disruption can end up disturbing the normal amounts of gametogenic compartments at breeding. For this purpose, adult zebrafish of both sexes were exposed during 21 days to an environmental mixture (MIX) of eleven xenoestrogens of diverse sources. A 100 ng/L ethynylestradiol positive control was added. Vitellogenin mRNA expression, evaluated by QT-RT-PCR, was greatly increased in both treatment groups, confirming the success of the experimental exposure setup and the estrogenicity of the mixture of xenoestrogens at concentrations observed in the Douro River estuary. A quantitative (stereological) analysis was made in the gonads, at light microscopy, targeting both the relative and the total volumes of the gametogenic stages. Point counting and the Cavalieri's principle were used. Preliminary data point that the estrogenic stimuli induced changes in structural compartments, and particularly in the positive control; with decreasing trends for the advanced maturation stages. There was a trend for a greater amount of interstitial connective tissue. This kind of effects was never structurally quantified in fish gonads. Despite the ultimate consequences of such disruptions are unknown, it could be logically argued that reduction / slow-down of the most mature cohorts and/or eventual interstitial fibrosis can adversely count when breeding is at stake. The findings add further explanatory bases to understand the negative impacts of xenoestrogens.

**Ethinylestradiol exposure of brown trout hepatocytes in primary culture can induce the emergence of smaller peroxisomes, mimicking new estrogenic effects uncovered in vivo**

I Pinheiro[1], F Malhão[1], MJ Rocha[2], RAF Monteiro[1], E Rocha[1]
[1]CIIMAR - CIMAR LA and ICBAS - U.Porto, PORTO, Portugal
[2]CIIMAR - CIMAR LA and ISCS-N, PORTO, Portugal

Pharmaceuticals are biologically active compounds often found as environmental pollutants of aquatic systems. Estrogens are one of these pollutants and are able to promote substantial morphofunctional changes in liver peroxisomes. Our group discovered a seasonal pattern of peroxisome modifications in the trout model. There is a negative correlation between ovary maturation and the size of hepatic peroxisomes. There was found in vitellogenic females under endogenous estradiol induction a decrease in the peroxisomal volume and in its enzymes activities. This pattern can be reproduced by experimental *in vivo* exposure to waterborne estrogens. We aim to better establish the details of peroxisome morphofunctional kinetics under estrogenic influences and so herein we tested an experimental model, based on trout primary hepatocyte cultures exposed to ethynylestradiol (EE2). This study has a biomedical interest, namely when concerning all the potentially hidden impacts existing from the use of birth controlling pills, estrogen therapy or drugs that can achieve the environment and evoke peroxisome changes in reference models. Juveniles of brown trout (*Salmo trutta*) were used. The hepatocytes were isolated by means of a perfusion technique using collagenase and were seeded in a density of 5x105 cell/ml in a 24-well plate coated with poli-L-lysin, with white L-15 medium. After 24 h in culture, cells were exposed to 1, 10 and 100 µM of EE2 and to 0.1% of ethanol (solvent control). After 48 h and 96 h of exposure, cell pellets were submitted to catalase cytochemistry and then processed for transmission electron microscopy. Manual stereology was used on microscopic photographs for estimating relative volumes, surfaces and numbers of peroxisomes. Their mean surface, volume and spherical equivalent diameter were secondarily derived.

The preliminary results show a decrease in mean surface, volume and spherical equivalent diameter of peroxisome with the increase of EE2 concentration, however without modifications in their number. Despite this trend, only for 100 µM the results were statistically significant. In brown trout, similarly to what was described *in vivo*, there is *in vitro* a regulation of hepatic peroxisomes by estrogenic stimuli. In this way the *in vitro* test proved to be a good model for getting mechanistic insights about effects of estrogenic compounds in hepatic peroxisomes of brown trout.

**Synergistic androgenic effects of an engine oil caused by the joint action of at least three chemically different compounds**

MTO Jonker, A Candido, CM Vrabie
Institute for Risk Assessment Sciences, UTRECHT, The Netherlands

In previous studies, we showed that a series of crude oils and refined petroleum products generally caused (anti-)estrogenic and/or anti-androgenic effects in recombinant yeast and mammalian in vitro assays. As such, oils may represent an important source of EDCs in the environment. Interestingly, one oil (a BP engine oil; EO) caused a clear dose-dependent synergistic effect when combined with testosterone (T) in an androgenic (AR) yeast assay. As there is only little knowledge on synergistic effects and compounds, in particular for the androgenic system, the objective of the present study was to investigate this oil in more detail. To this end, the EO was fractionated into the so-called SARA fractions: saturates (i.e. aliphatic compounds), aromatics, resins (i.e. more polar compounds), and asphalthenes (i.e. very high molecular weight compounds). When dosing the AR yeast assay with T combined with the separate SARA fractions, no synergistic effects were however observed anymore. When pooling the fractions again, the synergism returned. From subsequent exposures of the yeast to combinations of two or three SARA fractions it appeared that at least the resin and the aliphatic fraction were required for the synergistic response. These results indicate that the mixture effect (synergism) was caused by a mixture of at least three compounds, presumably having different chemical properties: testosterone, a resin compound, and an aliphatic compound. They add to the growing body of evidence on complex mixture effects of EDCs, indicating that an addition assumption may be a too simplistic approach.

**Chemical and biological monitoring of EDCs in Italian drinking waters: a case study**

L Canesi
University of Genoa, GENOA, Italy

EDCs are routinely detected in surface waters. Due to the large number of suspected ECDs and the potential hazard to human health, there is a growing interest in their presence in drinking water and their fate during drinking water treatment. Both conventional and more specific treatment processes may be partly ineffective in completely removing selected EDCs, removal efficiency also depending on the water quality.
A pilot study was carried out in Italy (2008-2010) to detect the presence of estrogens and estrogenic EDCs and the estrogenic activity in raw and drinking water samples from 6 Italian waterworks (ACSM - Como, Acquedotto Pugliese-Bari, Publiacqua-Firenze, Hera-Bologna, Mediterranea delle Acque-Genova, SMAT-Torino). The project (www.edinwater.com) involved the Italian Istituto Superiore Sanità (ISS) for chemical analyses, and the Universities of Pisa and Genoa for biological analyses. Samples of raw and treated waters from 5 different sampling campaigns were analysed for the presence of 6 representative estrogenic compounds (17beta-estradiol, 17alpha-ethynylestradiol, estrone, Bisphenol A, 4-octylphenol, Nonylphenol) and for their estrogenic activity by two in vitro assays, the YES (Yeast Estrogen Screen) and the E-screen assay (human MCF-7 cell proliferation).
Chemical data indicate that relatively low concentrations of the chosen analytes are present in raw water samples (<LOR - 1914 ng/l) and that treatment processes are generally effective in removing these compounds (<LOR - 621 ng/l). Chemical data were supported by biological data of estrogenic activity obtained with estrogenic assays (EEQ low ng/l). A fair correlation was observed between data obtained by the two different assays utilising yeast cells and human cell lines. The present study is the first example of chemical and biological monitoring of EDCs in drinking water in Italy. The results obtained represent and important basis for comparison with similar surveys in other European countries.

**TH 111**

**EDCs as Obesogens: effects of Bisphenol A (BPA) and Tetrabromobisphenol A (TBBPA) on lipid accumulation and PPAR expression in rat hepatoma cells**

L Canesi, A Voci, L Vergani, R Fabbri, G Gallo, E Grasselli
University of Genoa, GENOA, Italy

The development of obesity and related disorders ( fatty liver disease, type 2 diabetes, insulin resistance) in western countries has been associated with exposure to environmental chemicals. According to the 'Environmental Obesogen' hypothesis, obesogens are chemicals that can affect lipid homeostasis in various tissues by interfering with nuclear receptors (such as steroid, thyroid, retinoid receptors and Peroxisome Proliferator-Activated Receptors-PPARs) involved in regulation of lipid metabolism. Potential candidates are Bisphenol A, phthalates, brominated flame retardants, organotin compounds.
Bisphenol A (BPA), a potential estrogenic EDC, has been recently shown to promote adipogenesis. However, little is known on the direct effect of BPA on lipid homeostasis in the hepatocytes. In this study, the effects of BPA were investigated in the rat Fao hepatoma cell line. BPA induced lipid accumulation, as evaluated by Oil-Red-O staining and determination of triglycerides (TAGs). This effect was accompanied by down-regulation of all the three PPAR subtypes (PPARalpha, gamma and delta, that play key roles in lipid homeostasis. Moreover, down-regulation of the antioxidant genes catalase and superoxide dismutase-SOD was observed. The results support the hypothesis that BPA directly affects lipid homeostasis and redox balance in the hepatocytes. On the other hand, the flame retardant TBBPA (tetrabromo bisphenol A) did not affect the hepatocyte lipid content; however, TBBPA reduced TAG accumulation in fat enriched Fao cells and modulated the expression of different PPARs. The lipid-lowering effects were comparable with those observed with equimolar concentrations of thyroid hormones.
Our results demonstrate that different EDCs can directly interfere with lipid metabolism in the hepatocyte. The effects of obesogens on activities and expression of enzymes crucial in metabolic pathways (glycolysis, fatty acid oxidation, Lipid droplet formation) are under investigation.

**TH 112**

**Ligand-independent activation of the Aryl hydrocarbon receptor (AhR) by the imidazole fungicide Prochloraz**

TA Lammel[1], ML Fernandez Cruz[1], B Herradón[2], JM Navas[1]
[1]Instituto Nacional de Investigación y Technología Agraria y Alimentaria (INIA), MADRID, Spain
[2]Instituto de Química Orgánica General (CSIC), MADRID, Spain

Microcystin is a toxic substance released by cyanobacteria, among which stands out *Microcystis aeruginosa* (MA). In the natural environment, blooms of cyanobacteria (FC) where MA is present alone will rarely happen. Normally, we can find in cyanobacteria blooms different cyanotoxins and substances that together to microcystins may increase or decrease the effects of this toxin on the aquatic organisms. In this study we evaluate whether microcystin-LR (MC-LR), present in lyophilized FC and MA, is able interfere on detoxification enzymes (glutathione S-transferase-GST) and on antioxidant defenses (superoxide dismutase-SOD, catalase-CAT, glutathione peroxidase-GPx and reduced glutathione, GSH) and cause DNA damage. Juveniles of *Prochilodus lineatus* were exposed to solutions containing 1 mg.L$^{-1}$ of lyophilized FC or MA or only water (control) for 24 and 96 h. After exposure, aliquots of water were collected for quantification of MC-LR and the fish were anesthetized for blood sampling, and then killed to remove the gills and liver. Biochemical analyses were run in gills and liver samples and the comet assay (CA) was performed using red blood cells. The analysis of water containing FC and MA showed 0.9 µg.L-1 MC-LR. When compared to controls, fish exposed to FC for 24 h showed a significant increase on liver SOD, and after MA exposure there was an increase on SOD, CAT and GPx in the gills and GST, CAT and GSH in the liver. After 96 h exposure, the exposure to FC lead to an activation of SOD and GPx in gills and GSH in the liver, while after MA exposure, there was an inhibition of GSH in gills and CAT in liver. DNA damage was detected only after 96 h exposure to MA. In summary, these results show that after 96 h exposure to MA there was inhibition of antioxidant defenses leading to oxidative stress and DNA damage of erythrocytes. Thus, it appears that exposure to lyophilized MA was more toxic to the P. lineatus than the exposure to lyophilized FC, although the two materials have the same concentration of MC-LR. This variation is a sign that, in addition to MC-LR, there are other cyanotoxins and/or other substances in lyophilized FC that inhibited the effect of MC-LR on the fish species studied in this work.

**TH 113**

**Effects of Decabromodiphenyl ether (BDE-209) exposure on mRNA transcription of thyroid hormone pathway and spermatogenesis associated genes in Chinese rare minnow (Gobiocypris rarus)**

W Li, J Zha, L Zhu, Z Li, L Yang, Z Wang
Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, BEIJING, China

Polybrominated diphenyl ethers (PBDEs) are widely used as flame retardants, which are ubiquitous environmental contaminant found in both abiotic and biotic environmental samples. DecaBDE (BDE-209) is the principal component, which is currently used worldwide. In this study, the effect of BDE-209 on the mRNA levels of thyroid hormone related genes and spermatogenesis associated genes were determined from larvae and adult rare minnow (*Gobiocypris rarus*) exposed to concentrations 0.01, 0.1, 1, and 10 µg/L for 21 days. The results showed that the type II deiodinase (*dio2*) and sodium iodide symporter (*nis*) mRNA levels were significantly up-regulated in the larvae at 10 µg/L treatment. In adult, histopathological observations showed that liver of female fish were degenerated at 10 µg/L treatment, and inhibition of spermatogenesis were observed in testis in male fish. In addition, the *thyroid hormone receptor α* (*trα*), *dio2*, and *nis* mRNA levels in the liver of male and female fish were significantly up-regulated, whereas *dio2* and *nis* mRNA levels were significantly down-regulated in the brain. These results indicate that exposure to BDE-209 could result in tissue-specific alternations of TH-related genes expression in adults. Moreover, the mRNA levels of the testis-specific apoptosis genes, the *spermatogenesis-associated 4* (*spata4*) and *<span id='1291038086947S' style='display: none'> </span>spermatogenesis-associated 17 (spata17), were* down-regulated in 10 µg/L treatment in testis of male fish. Our results suggest that BDE-209 may pose threat to normal thyroid and reproductive function.

**Acute and short-term effects of 2-Chloro-4-Phenylphenol on mRNA expression of endocrine hormone receptor (TR, ER, and AR) in Chinese rare minnow (Gobiocypris rarus)**

L Zhu, J Zha, W Li, Z Wang
Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, BEIJING, China

In aquatic environment, phenols are a large group of organic contaminants because of their high solubility in water, strong reactivity, and poor biodegradation. They are toxic, persistent and bioaccumulative in animal and vegetable organisms and may pose serious threat to public health. 2-chloro-4-phenylphenol is one of PCBs metabolites, whereas quantitative data on the toxicity are not available. In this study, the acute toxicity tests of 2-chloro-4-phenylphenol to Chinese rare minnow (*Gobiocypris rarus*) were carried out by using Karber method. The results showed that the $LC_{50}$ value of 2-chloro-4-phenylphenol on fish in 96h was 1.29 mg/L. And histopathological observation showed that mass cell apoptosis were observed in liver of die fish. Moreover, to determine the endocrine disruption effects of 2-chloro-4-phenylphenol, adult fish was exposed to concentrations 0, 0.1, 1, 10, and 100 µg/L for 21 days. The results showed that no effects on growth, gonadosomatic index (GSI), and hepatosomatic index (HSI) were observed between treatment and control. However, histopathological observations showed that inhibition of spermatogenesis were observed in testis in male fish. In addition, the *thyroid hormone receptor α* (*TRα*), *estrogen receptor* (*ER*), and *androgen receptor* (*AR*) mRNA levels in the liver of male and female fish were significantly down-regulated. These results indicate that exposure to 2-chloro-4-phenylphenol had antiandrogenic activity in male, antiestrogenic activity in female, and negative effected on thyroid system in male and female. Therefore, 2-chloro-4-phenylphenol could be a potential endocrine disruptor.

**Study on multi-generational effects of perfluorooctanesulfonate (PFOS) in Japanese medaka (Orizias latipes).**

NT Tatarazako[1], TO Oka[1], KS Saito[1], MK Koshio[1], SO Oda[1], TI Iguchi[2]
[1]National Institute for Environmental Studies, TSUKUBA, Japan
[2]National Institute for Basic Biology, OKAZAKI, Japan

Multi-generational effects of perfluorooctanesulfonate (PFOS) on medaka (Orizias latipes) were investigated. The present study was carried out according to the Draft Guideline of Medaka Multi-generation Test (MMT) which was prepared by National Institute for Environmental Studies in Japan. All adult fish or eggs used in MMT were maintained in test medium at 26 ± 1°C and fed exclusively the brine shrimp. PFOS (CAS 1763-23-1) was obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). PFOS (10, 30, 100, 300, 1000 ppb) and controls were exposed during the exposure phase for 25 weeks in the flow-through system. For the first generation (F0), adult spawning fish were exposed various concentrations of PFOS for 4 weeks. Three pairs (female-male breeding pair) were placed in each test tank containing 5L test medium (duplicate). An adult pair and 10 sub-adult fish in the second and third generations (F1 and F2) were exposed PFOS in 2L test medium (6 replicates). Endpoints including survival rate, growth (body length and weight), time to hatch, hatching rate, fertility (reproduction), sexual development (secondary sex characters and gonad morphology), and hepatic vitellogenin concentrations were continuously measured during exposure phase. Chemical analysis of PFOS in the test medium was carried out once/every-week using high performance liquid chromatography (HPLC)-mass spectrometry (MS).
In the F0 generation, eggs were counted to investigate fecundity and fertility. PFOS had no effect on fecundity of F0 adult medaka, whereas statistically significant decrease in fertility was observed in 300 and 1000 ppb PFOS groups. Eggs were collected from breeding pairs to propagate the next generation. In the F1 generation, PFOS had no effect on time to hatch, hatchability and mortality of eggs. Adverse effects on fecundity and fertility were not observed in F1 sub-adults. In the F2 generation, PFOS influenced mortality of egg-sac fry depending on concentrations. NOEC (the no observed effect concentration) about all effects by this test showed 100 ppb.
We are planning to report the additional data such as the gonad histopathology.
(Funded by the Japanese Ministry of the Environment.)

**Occurrence of endocrine disruptors in Garda Lake and Mincio river (Italy): chemical analyses, in vitro assay and risk assessment**

S Bordonali, DB Baderna, SM Maggioni, SC Colnaghi, AC Colombo, GR Rotella, ML Lodi, EB Benfenati
Mario Negri Institute for Pharmacological Research, MILAN, Italy

An extensive characterization was conducted on the presence of endocrine disruptors in water and sediments from Garda Lake and its effluent Mincio river. Investigated compounds include selected natural and synthetic steroid hormones, alkylphenols, bisphenol A, triazine herbicides, polycyclic aromatic hydrocarbons, dioxins and polychlorinated biphenyls. The attention was also focused on the influent and effluent of a wastewater treatment plant which is located at the bottom of the lake and discharges treated water into the Mincio River.
Chemical analysis by liquid chromatography tandem mass spectrometry and gas chromatography mass spectrometry were integrated by biological assays to estimate the effects of the EDCs mix-

ture on MCF-7 cells. This in vitro model is an estrogen receptor (ER) positive cell line derived from a human breast adenocarcinoma. To determine the relative proliferative potency of organic extract from the waters, the E-SCREEN test was applied. This bioassay compares the cell yield between cultures of cells treated with estradiol, as positive controls, and cultures treated with different concentrations of extracts suspected of being estrogenic.
Our results showed low contamination of water and sediment by the monitored contaminants with levels below the quality standards defined for selected chemicals by the current Italian legislation. The effluent of the wastewater treatment plant contained estrone and estradiol in the range of 2-42 ng/L and nonylphenols, bisphenol A and tert-octylphenol in the range of 14-218 ng/L. The presence of estrone was also identified in the water from Mincio river.
Results from chemical analyses will also be analyzed applying the guidelines for human and ecological risk assessment in order to evaluate the adverse effects on human health and ecosystem induced by the levels of EDCs in the water.

**TH 117**

**Evaluation and identification of estrogenic activity with the Yeast Estrogen Screen and the HPLC DAD of some Tunisian WWTPs**

A Had Hassin[1], BI Bazin[1], MW Mnif[2], JG Junqua[1], BA Bartegi[2], GC Gonzalez[1]
[1]Ecoles des mines d'ales, ALES, France
[2]Biochimistry institute, MONASTIR, Tunisia
In the present study, the yeast estrogen screen (YES) has been used to assess the estrogenic activity in effluent and influent of some WWTPs and surface waters of a coastal region in Tunisia. In order to assess the estrogenic activity, a recombinant yeast-based assay has been used. Two sampling campaigns have been carried out in 2004 and 2010 to measure the estradiol equivalent concentrations of fourteen different stations in Tunisia. Dose-response relationships for selected substances and their relative estrogenic potencies expressed as estradiol equivalent factors (EEFs) were determined. EEFs together with previously obtained concentration data based on liquid chromatography tandem mass spectrometry measurements (HPLC-DAD) were used to calculate estradiol equivalent concentrations. Solid-phase extraction C18 SPE was carried out on approximately 1l water samples. From the final extract volume, aliquots were used for the measurement of estrogenic activity and a other one for chemical analysis, which was performed by liquid chromatography coupled to high performance liquid chromatography HPLC-DAD. From 14 samples, water samples and suspended matter showed an estrogenic response. Based on the activity of 17-_-Estradiol in the YES assay, we estimated the estrogenic activity. The response in the YES was expressed as measured estradiol equivalents (EEQs). Samples from Wastewater Treatment plants located near an industrial or tourist area showed high estrogenic activities. Data obtained on high performance liquid chromatography (HPLC-DAD), confirmed the presence of various estrogenic compounds (17 _ estradiol, ethynilestradiol, estrone and estriol). The main contributors to the overall estrogenic activity were synthetic and natural hormones. Finally, the results obtained by biological and chemical analysis were compared.

**Tournament of bioassays: Comparing different in vitro systems for detecting endocrine activity in environmental samples**

M Wagner[1], S Buchinger[2], A Magdeburg[1], D Stalter[1], G Reifferscheid[2]
[1]Goethe University Frankfurt am Main, FRANKFURT AM MAIN, Germany
[2]Federal Institute of Hydrology, KOBLENZ, Germany
Due to the ever-growing universe of synthetic chemicals, environmental pollution has reached a considerable level of complexity. This not only concerns the sources, fate, and groups but also the biological effects of man-made chemicals introduced in the ecosphere. With regard to the latter, the potential of chemicals to induce endocrine disrupting effects is of special concern because it might impair reproduction and development of diverse biota and, therefore, affect the integrity of wildlife populations.
Besides environmental chemistry, bioanalytical techniques (i.e. in vitro bioassays) add value to the investigation of the endocrine potential of complex environmental samples because they provide a direct measure of the relevant biological effect, e.g. estrogenic activity of sediment extracts or effluents of sewage treatment plants. The application of bioassays for environmental monitoring has two main advantages: First, bioassays integrate the joint effect of complex mixtures of chemicals and, therefore, realistically characterize mixture toxicity. Second, bioassays include the effects of so-far unidentified compounds that are missed in traditional chemical analysis. In that sense bioassays are a valuable tool to tackle the complexity and, thus, provide a more holistic picture of the universe of environmental chemicals.
To facilitate the use of bioassay data in regulatory practice, standardized assay systems and procedures are needed. In that context, we focus on estrogenic endpoints, for which not only a broad base of scientific data but also an array of in vitro bioassays exists. This includes reporter-gene assays based on yeast (e.g. Yeast Estrogen Screen) or mammalian cell lines (e.g. ER-CALUX) as well as proliferation assays (e.g. E-Screen). Within the scope of a project funded by the German Federal Environment Agency (FKZ 3710 26 323) we compile information on different in vitro methods that are commonly used for the quantification of estrogenic potentials. Here, we will compare several systems in terms of sensitivity, reproducibility, and applicability and discuss advantages and disadvantages with respect to different test matrices (waste water, surface water and drinking water).

Over the past 15 years, the "endocrine disruptor hypothesis"has been the subject of attention in the scientific community and the media. The hypothesis postulates that certain substances act like natural hormones, causing adverse effects by interfering with the endocrine systems of wildlife and humans. A component of the process is risk characterization, integrating all credible scientific information on hazard, dose-response, exposure and uncertainty to reach a scientifically defensible risk determination. To integrate available data into risk characterization, 'weight of evidence' (WOE) approaches are often used to examine and prioritize results. Hazard identification and risk characterization for endocrine active chemicals has been presented in various documents, including reports from ECETOC and the US EPA's two-tiered Endocrine Disruptor Screening Program. In the US program, chemicals selected for screening are subjected to a battery of 11 assays to determine their potential to interact with the endocrine system through androgen, estrogen, or thyroid pathways. Data integration is necessary, beginning with screening assays that identify potential interactions with the endocrine system, to testing for adverse effects in long-term reproductive and developmental toxicity assays, to mode of action analysis and risk characterization. We have formulated a framework for conducting WOE evaluations to help meet these objectives. For evaluating results of screening studies, null hypotheses are constructed for each of the three targeted hormonal modalities to test the premise that the chemical does not interact as an agonist or antagonist in estrogen, androgen, or thyroid pathways or with the aromatase or steroidogenic enzyme systems. Data for evaluating each hypothesis are weighted based on published recommendations for reliability and validity. Reliability is assessed on the basis of transparency and completeness of data reporting. Validity is assessed according to the degree to which three fundamental tenets are met, including that measurements are authentic and verifiable within an acceptably small degree of error, that accuracy is not compromised by extraneous uncontrolled factors and influences, and whereby results using the method are replicable by independent scientists. Each hypothesis is tested by comparing data from the screening battery versus the response produced by the appropriate prototype hormone and positive and negative controls.

**Endocrine disrupting potential of six major organophosphate flame retardants in H295R cells**

X Liu, kh Ji, ky Choi
Seoul national university, SEOUL, South-Korea
Flame retardants have been widely used in construction materials, furniture, plastics, electronic equipments, textiles, and other materials. Among the flame retardants globally used, organophosphate (OP) flame retardants are the third important group of flame retardants next to alumina trihydrate and brominated flame retardants. Compare with brominated flame retardants, OP flame retardants have received little attention with regards to potential health effects. Because of the ban of polybrominated diphenyl ethers (PBDEs), production and use of OP flame retardants has surpassed that of PBDEs in Europe. OP flame retardants have been detected in the house dust, surface water, fresh water biota, human urine and milk, at the levels similar to or greater than those of PBDEs.
In the present study, we evaluated the potential risk of OP flame retardants using H295R cell. The test compounds include tris-(2-chlorethyl) phosphate (TCEP), tricresylphosphate (TCP), tris-(2-butoxyethyl) phosphate (TBEP), TPP, tris-2-chloroisopropyl phosphate (TCPP), and TDCPP. The cytotoxicity of H295R cells by using MTT assay showed that TCP and TPP have highest cytotoxicity (1 mg/L), followed by TCEP, TBEP, TDCPP (10 mg/L), and TCPP did not show cytotoxicity even at 100 mg/L. In the H295R steroidogenesis assay, we found that all of these chemicals could increase 17β-estradiol (E2) concentrations. The E2 concentration significantly increased when exposed to 0.001 mg/L of TCP, 0.01 mg/L of TDCPP, 0.1 mg/L of TCEP and TBEP, 1 mg/l of TPP, and 100 mg/L of TCPP or greater. Concentration of testosterone also increased when exposed to concentration of 0.1 mg/l of TCP, TBEP, TDCPP, 1 mg/l of TCEP, and 10 mg/l of TCPP or greater. Mechanisms of endocrine disruption and the consequences should be further investigated.

**Assessment of in situ estrogenic effects in the Black chinned Tilapia (Sarotherodon melanotheron) using vitellogenin measurement by ELISA method**

A Ndiaye[1], O Palluel[2], JD Durand[1], F Brion[2], JM Porcher[2], J Panfili[1], W Sanchez[2]
[1]Institut de Recherche pour le Developpement (IRD), MONTPELLIER, France
[2]INERIS, DRC_ECOT, VERNEUIL-HALATTE, France
The aim of this study was to develop an enzyme linked immunosorbent assay (ELISA) to quantify vitellogenin in the Black chinned Tilapia (Sarotherodon melanotheron). Tilapia vitellogenin T-vtg) was first purified from plasma samples of estradiol-induced fish using a two-step chromatographic method. The T-vtg was characterized with an estimated molecular weight of 482 kDa under native conditions. Polyclonal antibodies against T-vtg were raised in rabbits and the specificity of the antibodies to recognized T-vtg was verified by Western blotting and indirect ELISA experiments on blood samples. By using these antibodies and purified T-vtg, a competitive ELISA was set-up and validated. This assay appears sensitive, with a detection limit of 1.81 ng/ml, and specific, as shown by the competition curves, obtained by serially diluting blood of females, that were parallel to the T-vtg standard curves. The ability of the T-vtg ELISA to quantify vtg induction was achieved by in situ experiment. For this purpose, adults males and females tilapia were collected in 8 West African sites and circulating vtg concentration was measured. The present study shows that the developed T-vtg ELISA is a useful tool to assess the effect of estrogenic contamination in wild Black chinned Tilapia.

**Effects of EDCs in a wild gudgeon population (Gobio gobio L.) in Luxembourg**

L L'Hoste[1], DA Dohet[1], GAC Gutleb[1], PO Palluel[2], PJM Porcher[2], SW Sanchez[2], HL Hoffmann[1], CHM Cauchie[1], P Doyen[3]
[1]CRP Gabriel Lippmann, BELVAUX, Luxembourg
[2]INERIS, Ecotoxicological Risk Assessment Unit, VERNEUIL-EN-HALATTE, France
[3]Centre de Recherche Public - Gabriel Lippmann, BELVAUX, Luxembourg
For many decades human activities have dispersed toxic chemical substances in the environment. Over the last years new xenobiotics such as endocrine disrupting chemicals (EDCs), antibiotics or nano-particles have appeared. In order to assess the health of river ecosystems in relation to this increasing pressure, twenty sites contaminated at different levels were sampled by electrofishing across the Luxembourg hydrographical network. The status of fish communities was characterized according to an index of biotic integrity (IBI). Furthermore, on six sites, population structure, reproductive parameters and biochemical assays were performed on gudgeon (*Gobio gobio*) as sentinel species. Stress factor responses were observed at different levels of biological organization: from molecule up to fish communities. At one site, male gudgeons exhibited high levels of plasmatic VTG. Histological examinations revealed high alterations of the gonads: feminization of the testes and high incidence of atresia in ovary. No significant difference in the level of plasmatic VTG was noticed between intersex and non-intersex fish. Conversely, the incidence of atresia seems to be linked with VTG synthesis in female gudgeons. Weight index of the liver also highlighted an exposure to EDCs. More surprisingly, no impairment of the gudgeon population was pointed out. This study provides interesting data concerning endocrine disruption and their higher-level effects of the biological organisation in a wild fish population inhabiting Luxembourg's rivers. Factors potentially leading to alterations of the reproductive tract and more generally to a reduced fertility seem to be diverse and varied, and not exclusively VTG-dependent. By using a multiparametric and multiscale approach, a better understanding

of response mechanisms to pollution in fish may be achieved and help improving the ecological status of river ecosystems.

### TH 124

**Assessing the endocrine disrupting potential of Bacillus thuringiensis israelensis based insecticides**

M Wollenweber, S Maletz, T Floehr, H Hollert
Institute for Environmental Research, AACHEN, Germany

Synthetic insecticides have always played an important role in ecotoxicological research. The excessive use of insecticides such as dichlorodiphenyltrichloroethane (DDT) has lead to crucial hazardous impacts on wildlife. Several indications also implicate that humans are affected. In response, a protein isolated from *Bacillus thuringiensis israelensis* (*Bti*) has been used as a specific biological control agent against mosquitoes since 1981. So far no adverse effects on the environment have been observed. Hence *Bti* has been increasingly used over the past decades.
However, recent studies implicate that *Bti* may act as an endocrine disruptor. To assess a potential threat to the environment, four different *Bti* formulations have been analyzed in the lyticase yeast estrogenic screen (LYES assay). The LYES assay is used to investigate estrogen receptor mediated endocrine activity. Three *Bti* formulations have shown estrogenic activity in the LYES assay with estradiol equivalent quotients (EEQ) ranging from 9.2 ng/l to 22.8 ng/l.
Furthermore, to assay the effect of *Bti* on the steroid genesis surface water samples are currently analyzed in the H295R Steroidogenesis assay (H295R assay). The samples have been collected before and after the application of *Bti* and were extracted using solid phase columns.

### TH 125

**Endocrine disruption effects of 3,3',4,4'-tetrachlorobiphenyl (PCB-77) on juvenile zebrafish**

DF Costa, MS Monteiro, I Domingues, AMVM Soares
Universidade de Aveiro, AVEIRO, Portugal

The main evidence suggesting that exposure to environmental chemicals can lead to disruption of endocrine function comes from changes seen in a number of wildlife species. Persistant organic pollutants (POP), such as the PCBs (polychlorinated biphenyls), are of major concern for human and ecosystem health due to their high degree of persistence and bioaccumulation in the food web. PCBs are a type of industrial chemical that might cause endocrine changes, in terms of estrogen-regulated processes, such as, vitellogenesis - vitellogenin (Vtg) production. Commercial PCBs exists as mixtures of several congeners, among them, the PCB congener 77 (3,3',4,4'-tetrachlorobiphenyl) is one of the most toxicologically important PCBs, representative of a class of PCBs, as a di-ortho substituted non-coplanar congener. Zebrafish (*Danio rerio*) has been used as model organism to study endocrine-disrupting compounds (EDCs) effects and their mechanisms of action and to make the functional link between environmental effects and human health level disturbances. With the aim to assess the effects and potential mechanisms of reproductive toxicity of PCB-77 to zebrafish during gonadal differentiation, juveniles (30 days post hatch) were exposed through water to PCB-77. The LC50 for 96h was determined and fish were then exposed to sub-lethal concentrations during 14 days, using a semi-static test design with test medium renewal each three days. A control solvent and a positive control (100 ng $L^{-1}$ 17β-estradiol) were also included in the test. Results will be discussed based on endocrine (gonad histology, Vtg induction) and adverse effects endpoints (survival and growth, sex ratio, gonadosomatic index (GSI) and hepatosomatic index (HSI)) recorded at the end of exposure.

### TH 126

**Concentrations and space-temporal trends of polybrominated diphenyl ethers (PBDEs) in Eurasian eagle owl (Bubo bubo) unhatched eggs from Southeastern Spain**

P Gómez-Ramírez[1], E Martínez-López[1], P Maria-Mojica[1], AJ Zweers[2], M León-Ortega[1], JM Pérez-García[3], AJ García-Fernández[1], NW van den Brink[2]
[1]University of Murcia, MURCIA, Spain
[2]Alterra, WAGENINGEN, The Netherlands
[3]University Miguel Hernández, ELCHE, Spain

Since the 1960´s PBDEs have been added to plastics, textiles, foams and electronic products to reduce fire risks, becoming ubiquitous in the environment. Because PBDEs are considered endocrine disruptors, it is essential to get more insight in temporal and spatial trends of their environmental levels. In Southeastern Spain, the Eurasian Eagle Owl could be considered a suitable sentinel species for monitoring local pollution of PBDEs. Our study area is relatively large and was divided in two sub-areas. In the Northern subarea, citrus and dry farming predominate, and rabbits, the Eagle Owl's main prey, is very abundant, while in the Southern some nests are located around 16 Km far from Cartagena, an important industrial city, there are some irrigation orchards and rabbits are less abundant. Hence the Eagle Owl's diet is completed with birds, rats and hedgehogs. Between 2004 and 2009, 58 unhatched eggs were collected from monitored nests. A subsample from each homogenized egg was mixed with anhydrous $Na_2SO_4$ and extracted with n-Hexane using Soxtherm. Extracts were cleaned up by GPC and congeners 28, 47, 99, 100, 153, 154 and 183 quantified with a GC-MS. General linear models applying a log-link function were used to analyse spatial and temporal trends in levels. The PBDE profile was characteristic of terrestrial birds and dominated by BDE 99, 47 and 100, which coincides with the Little Owl eggs from Belgium. Concentrations were very low (median ∑PBDEs 19.58 ng/g lipid weight) compared with most terrestrial birds, including owls. These levels are about 1000 times lower than the PBDEs LOEL (32 µg/g lw) in kestrels eggs. When analysing spatial and temporal trends, a significant interaction between space and time was found ($F_{\text{prob overall analysis}}$<0.001, t<sub>prob interaction term year*subarea</sub>=0.007, $t_{\text{prob year}}$=0.198, $t_{\text{prob subarea}}$=0.007). While concentrations in the Northern decreased, levels tended to increase in the Southern. This apparent increasing trend could be due to the release from PBDE containing products used in Cartagena. A shift in the Eurasian Eagle Owl diet could also explain the trend, as this has been previously reported as a cause for changes in the organochlorine loads in raptors. Supported by the Spanish Government (CGL2004-5959/BOS, CGL-2008-4318/BOS), Seneca Foundation (08758/PI/08) and WIMEK. Thanks to Autonomous Community of Murcia Region for sampling permission. Special thanks to E. Pérez and J.A. Lacalle for sampling efforts.

### TH 127

**Where to cut-off ? - Endocrine hazard profiles of EBI fungicides.**

T Frische, P Kotschik
Federal Environment Agency (UBA), DESSAU-ROSSLAU, Germany

The new EU pesticide regulation states: "An active substance, safener or synergist shall only be approved if, on the basis of the assessment of Community or internationally agreed test guidelines, it is not considered to have endocrine disrupting properties that may cause adverse effects on non-target organisms unless the exposure of non-target organisms to that active substance in a plant protection product under realistic proposed conditions of use is negligible." (EC 1107/2009, Annex II, 3.8.2). Thereby, a paradigm shift in the environmental risk assessment and decision making was introduced for substances with this specific mode of toxic action: The risk-based approach as required by the precedent directive 91/414/EEC is now changed for a hazard-based approach. I.e., the risk that may arise from the intended use of the plant protection product under consideration is not characterized quantitatively by a comparison of the expected exposure of non-target organisms with established (no) effect thresholds. Instead, only the proven presence or assumed absence of endocrine disrupting properties shall be decisive for a (non-) approval of the respective plant protection product. However, the debate on specific scientific criteria for such a "cut-off"decision making regarding endocrine disrupting properties in wildlife has only just started. As a contribution to this debate, a case study was conducted to characterize and compare the endocrine hazard profiles of a selection of ergosterol biosynthesis inhibiting (EBI) fungicides. Active Substances of this heterogeneous chemical group (triazoles, imidazoles, pyrimidines) share a similar pesticidal mode of action: inhibition of ergosterol synthesis in fungi. The target enzymes in fungi is partly analogous to enzymes involved in the production of steroid hormones in vertebrates as well as in other animal classes with sexual steroids, what is why EBI fungicides are known to harbor an intrinsic endocrine hazard potential. Based on available mechanistic evidence and observed adverse effects endocrine hazard profiles of the selected active substances were developed with special emphasis on vertebrates (mammals and fish). The resulting endocrine hazard profiles are compared, with the results being discussed regarding endocrine "cut-off"decision making.

### TH 128

**In vitro screening of estrogens in waters pointed out another possible source of EDCs pollution than waste water treatment plants**

B Jedlickova, K Hilscherova, L Blaha, M Stecek
Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic

Waste Water Treatment Plants (WWTPs) have been widely discussed as one of the main sources of compounds that are able to disrupt endocrine systems of organisms and numerous cases of feminized male fish downstream of WWTPs have been reported. In the Czech Republic (CZ) majority of WWTPs contain mechanical treatment and activated sludge systems, therefore this type of WWTP was investigated in our studies. Reporter gene assay was used to evaluate efficiencies of estrogen removal at 7 municipal WWTPs in CZ. The efficiencies ranged from 92 % to more than 98 % and levels of estrogenic potential of treated effluents varied from less than 0.5 ng/l EEq to 2.0 ng/l EEq. Considering proportional contribution of the effluents to the recipient rivers, levels of estrogens detected in these effluents would not be most probably fully sufficient to cause fish feminization observed at some locations. In another study Polar Organic Integrative Samplers were used to sample surface water at 7 relatively unpolluted areas of CR to (i) obtain approximate background levels of estrogenic potential and (ii) evaluate the impact of 7 WWTPs of smaller towns which are the only substantial source of anthropological pollution in these studied areas. Estimated background levels of estrogenic potential of surface water (samples upstream from the WWTPs) varied from below 0.1 to 0.3 ng/l EEq with most values around 0.2 ng/l EEq. The same rivers downstream of WWTPs contained approximately 2 times higher levels of estrogenic potential compared to upstream locations but in two out of seven cases, the estrogen potential was approximately 8 times higher and reached values around 2 ng/l EEq. At the locations with the highest EEq levels, the contributions of WWTP effluents to the overall flux of the rivers were 30 % and 10 % respectively. This means that if the effluents were the only source of estrogens, they would contain approximately 7 and 20 ng/l EEq. Relatively low levels of estrogenic potential found in the first study in WWTP effluents and considerably enhanced EEq levels detected in two out of seven rivers downstream of WWTPs (second study) brought up important question about other sources of estrogens e.g. discharging non-treated waters to the recipient waters due to insufficient capacity of WWTPs. These studies have been supported by the projects ENVISCREEN (Ministry of Education C.R. No. NPVII 2B08036) and CETOCOEN (CZ.1.05/2.1.00/01.0001) from the European Regional Development Fund.

### TH 129

**U-shaped responses of fish zona pellucida protein and vitellogenin gene expression after octylphenol waterborne exposure**

G Genovese[1], MC Maggese[2], M Guerreño[1], DE Towle[3], FL Lo Nostro[2]
[1]Universidad de Buenos Aires, CIUDAD AUTONOMA DE BUENOS AIRES, Argentina
[2]Consejo Nacional de Investigaciones Científicas y Tecnológicas (CONICET), CIUDAD AUTONOMA DE BUENOS AIRES, Argentina
[3]MDIBL, MAINE, United States of America

The endocrine disrupting chemicals have become ubiquitous in the environment and affect development and physiology by interfering with normal endocrine functions of human and wildlife. Octylphenol (OP) is a degradation product of alkylphenol ethoxylate surfactants (mainly used in industrial applications, agrochemicals, cleaners among others) which can mimic natural estrogens and cause reproductive impairments. Our previous results showed that in the cichlid fish Cichlasoma dimerus, zona pellucida proteins (ZP) that form the eggshell, and vitellogenin (VTG) the precursor of egg yolk, are both synthesized by the liver of mature females under estrogenic control but are normally not produced by males. The aim of the present study was to assess the effect of environmentally relevant concentrations of OP on ZP and VTG gene expression in C. dimerus males, which were exposed to 0.15, 1.5, 15, and 150 µg/L OP for 28 days. The expression of a putative housekeeping gene, Na+/K+-ATPase, was measured. Estrogenized female livers were used for the standard curve to normalize data. Exposure of male fish to OP caused down-regulation of Na+/K+-ATPase expression except for the lowest concentration of OP. However, exposition to 0.15 and 150 µg/L OP caused significant up-regulation of both forms of ZP (β, γ) and VTG while the other two concentrations of OP (1.5 and 15 µg/L) caused minor non-significant effects. These U-shaped dose-response curves or hormesis provide new evidences for the need of risk assessment of toxicants with a wider dose range. Conventional way of risk assessment of low dose might not be accurate by simple extrapolation based on the traditional theory of the threshold or linearity. It has been suggested that U-shaped responses appear as an over compensatory response to maintain homeostasis or take place by the combined contribution of different receptor subtypes with different affinity, accessibility or signaling cascade. Our preliminary data support the latter explanation.

**Endocrine disruptor in humans: a longitudinal study of exposure and effects**

R Cipelli[1], LW Harries[2], D Melzer[2], TS Galloway[1]
[1]University of Exeter, EXETER, United Kingdom
[2]Peninsula College of Medicine & Dentistry, EXETER, United Kingdom

Bisphenol A (BPA) is a base chemical compound widely used as a plastic monomer and plasti-

cizer. BPA is suspected to have estrogenic properties and endocrine-modulating ability. Due to the ubiquity of this compound, human exposure to BPA is virtually universal.
Associations have been reported between urinary BPA concentrations, heart disease and diabetes in adults. Given this evidences, further human studies on the effects of low levels chronic exposure are needed.
We present the first longitudinal study on the daily exposures to BPA in a population representative sample of European adults. Measures of daily intake rely on two different time-points (the baseline of the study and nine years after). Epidemiological analyses were performed to investigate BPA endocrine disrupting activity (circulating hormone and metabolite concentrations).
A Genome Wide Analysis study was carried out and targeted replications were performed to validate the results.
Study design: Analysis were performed on the baseline stage of the InCHIANTI follow-up study, an Italian population based cohort. Participants were 1453 adults aged more than 20. BPA excretion rates were measured by liquid chromatography mass spectrometry (LC-MS).
Results: Demographic differences in UER BPA and BPA daily intake estimation will be presented. Possible mechanism of actions of BPA resulting from the G.W.A. study will be shown.

### TH 131
**Estrogenic active substances in bottled mineral water?**
PY Kunz[1], D Tropiano[1], BJ Brüschweiler[2]
[1]Ecotox Centre, Swiss Centre for Applied Ecotoxicology, Eawag/EPFL, DÜBENDORF, Switzerland
[2]Federal Office of Public Health (FOPH), Nutritional and Toxicological Risks Sect, ZÜRICH, Switzerland
Two recent studies in Germany and Italy found estrogenic activities up to 75 ng 17β-estradiol-equivalents (EEQ)/L in bottled mineral waters which were packaged in PET- and glass bottles (Wagner & Oehlmann 2009; Pinto & Reali 2009). These results have caused public concern and raised the question about the safety of beverage containers, particularly PET-bottles. The purpose of this study was to investigate if the findings for German and Italian bottled mineral water also hold true for Switzerland. A screening study with 31 mineral waters (22 brands of 15 manufacturers) with high market-share in Switzerland was conducted. Fifteen mineral waters showed very low estrogenic activities (mean 4.84±1.59 pg EEQ/L; maximum value 8.0 pg EEQ/L) in the ER-CALUX® assay, just above the limit of quantification (LOQ) at 3.6 pg EEQ/L. No significant differences could be determined between waters from PET- and glass bottles as well as between carbonated and non-carbonated waters. The measured estrogenic activities are around 1'900- to 3'700-times lower than the EEQ measured in bottled mineral waters in the two studies from Germany and Italy. According to current knowledge the very low estrogenic activities in Swiss mineral water samples do not pose a health risk.

### TH 132
**Assessing estrogenic activities of sediment samples from Laguna Lake, Philippines and fractions obtained by Effect directed analysis in the LYES-Assay**
C Schönlau[1], T Schulze[2], W Brack[2], G Streck[2], T Floehr[1], AV Hallare[1], H Hollert[1]
[1]Institute for Environmental Research (Biology 5), RWTH Aachen University, AACHEN, Germany
[2]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
Due to the increasing use of several diverse chemicals by modern society and the large-scale production triggered through the ongoing industrialisation in all parts of the world, nearly every living space is affected by numerous known and unknown chemicals of anthropogenic origin. A large range of these chemicals have shown to act as endocrine disrupting compounds. The present study was conducted to further investigate the state of contamination level of sediment samples from Laguna Lake. It is the second largest freshwater lake in Southeast Asia and the largest lake in the Philippines, it is also part of the Living Lakes Network. In this study the LYES-Assay (Yeast estrogenic screen assay assisted by enzymatic digestion with Lyticase) was performed to screen for estrogenic active fractions in sediment samples from Laguna Lake. Based on preliminary results, the present study selected sediment samples of two different sites for fractionation and effect-directed analysis: Central Bay and East Bay. While the watershed around the Central Bay is urbanized and industrialized, that around East Bay is basically residential and agricultural area. The sediment samples have been extracted by using an accelerated solvent extraction method. The fractionation of Central Bay and East Bay extracts was conducted using an automated multistep fractionation method developed by Lübcke van Varel et. al. (2008). Each fraction was tested in seven different dilution steps. Furthermore five different Blanks, a Crude Extract and a Fraction Summation from both study sites were tested. In the sediment samples from East Bay four fractions showed a significant endocrine effectiveness at the one fold concentration (fraction 11, 15, 16, 18). The estrogenic activity ranged from 8.43 ± 4.37 ng/L at fraction 18 to 10.79 ± 5.28 ng/L at fraction 15. Fraction 16 also revealed a significant endocrine effectiveness at the ½ fold concentration of 12.59 ± 9.91 ng/L. Only one fraction indicated a significant endocrine potential from sediment samples of Central Bay. Indeed fraction 18 already showed the first significant endocrine effectiveness at the 1/8 fold concentration of 8.80 ± 2.29 ng/L up to 27.32 ± 18.39 ng/L at the one fold concentration. The data was statistically analysed by a Kruskal-Wallis One Way ANOVA on Ranks and a following post-hoc test according to Dunn. Overall the sediment samples did not reveal a high estrogenic impact as it can be observed in some European sites.

### TH 133
**How to deal with endocrine disruptors - a joint strategy for different chemical regulations**
F Stock, J Bachmann, T Frische, A Kehrer, G Maack
Federal Environment Agency (UBA), DESSAU, Germany
While being identified as of special concern in the environment since decades, in the regulatory context, endocrine disruptors were not treated differently to substances acting via other toxic modes of actions until recently. Now, taking into account the current revisions of the Pesticides and Biocides directives, endocrine disruptors are at least explicitly mentioned in all substance regulations (REACH, Pesticides and Biocides directives, Pharmaceuticals). However, the way how substances with endocrine disrupting properties are identified, the outcome of the identification and the regulatory consequences differ between the individual regulations.
While disturbance of the endocrine system is a toxic mode of action among others, it may result in adverse effects in the environment difficult to predict with our current set of laboratory tests. Although for some species (e.g. fish) tailored test systems and test strategies are available, similar approaches for other organism groups like invertebrates are still missing.
A common understanding on how to identify substances of special concern due to their endocrine disrupting properties for the environment among different regulations was developed by the German Federal Environment Agency (UBA). UBA proposes to differentiate between three groups a) substances for which endocrine disrupting properties are the basis of the pesticide or pharmaceutical mechanism of action in target organisms b) substances where endocrine disrupting properties are decisive for the overall side effects on non target organisms and c) substances where endocrine mechanisms of action are identified but are not relevant for the overall risk assessment. UBA proposes to focus special regulations on the second group. Some general thought on how to identify these types of substances e.g. for the identification as a substance of very high concern under REACH or as a "cut-off - candidate"for pesticides will be presented.

### TH 134
**A transcriptomic approach for the fish embryo test with zebrafish and medaka to identify endocrine disruption**
V Schiller[1], R Kriehuber[2], X Zhang[3], M Hecker[3], A Wichmann[1], M Fenske[1]
[1]Fraunhofer Institute for Molecular Biology and Applied Ecology, AACHEN, Germany
[2]Forschungszentrum Jülich GmbH, JUELICH, Germany
[3]Toxicology Centre, University of Saskatchewan, SASKATOON, Canada
The endocrine system is susceptible to disruption by various chemicals occurring in the environment. The current testing approach in regulatory ecotoxicology for endocrine disrupting chemicals (EDCs) relies on long-term reproductive, animal intensive studies. These labour intensive tests entail high costs and are ethically disputable. The need for alternative test strategies for EDCs is urgent, and zebrafish and medaka embryos have good potential as alternative test approaches for EDCs. Relevant endocrine pathways are already developed in the embryos, and endocrine related genes have shown to respond similarly than in reproducing fish. Both species have their particular advantages in this context. The rapid development of zebrafish is beneficial for screening applications, whereas the longer embryogenesis of medaka may alleviate the prediction of chronic effects. To compare medaka and zebrafish, we used embryos of both species to study adverse effects of endocrine active compounds like genistein, linuron and methylparaben. 48h zebrafish were analysed by microarrays and 7-day old medaka by qPCR, to gain insights into the specific transcriptional modes of action. Sets of responsive genes specific to each chemical were found of which several indicate effects on endocrine pathways. In both species, genistein and methylparaben enhanced mainly the expression of estrogenic genes; linuron on the other hand, repressed androgen-dependent enzyme genes. Simultaneously, we found a considerable intersection of steroidogenic genes regulated by all tested substances. Some of these genes show good promise for ED marker gene candidates and are now being validated for a potential screening application. The goal is to establish qPCR arrays for EDC-specific suites of genes suitable to screen specifically for EDCs in fish embryo and larvae of zebrafish and medaka. Such a transcriptomic fish embryo assay approach could become a valuable component of an alternative EDC testing strategy.

### TH 135
**Validation and interpretation of the amphibian metamorphosis assay**
J Burke, G Last, P Bowen, G Pap
Covance Laboratories, HARROGATE, United Kingdom
In response to these new data requirements our laboratory has developed and internally validated test systems for the conduct of the amphibian metamorphosis assay OECD 231 and OPPTS 890.1100. The amphibian metamorphosis assay (AMA) was conducted with stage 51 xenopus laevis tadpoles using a chemical known to interfere with the normal function of the hypothalamus-pituitary-thyroid (HPT) axis. The amphibian metamorphosis assay is considered to provide a well-studied, thyroid-dependent process which responds to substances active along the HPT axis, and it is the only proposed assay that assesses thyroid activity in a species undergoing morphological development. Four days after fertilisation the best spawn is selected based on hatching success and tadpoles (Stage 45/46) were transferred to glass tanks at a density of 10 tadpoles per litre and develop to stage 51 within 12 days (approx. 17 days after fertilisation). The test was conducted with a control group and three test concentrations containing four replicates per treatment in a randomised block design.
The results of daily observations of sub-lethal effects, malformations, abnormal behaviour and mortality. Body weight, hind limb length, snout to vent length and developmental stage after 7 and 21 days exposure are reported. At test termination (21 days) five animals (stage-matched) from each replicate were sampled for histological assessment of the thyroid gland e.g. thyroid gland hypertrophy/atrophy, follicular cell hypertrophy, follicular cell hyperplasia , follicular lumen area etc.

### TH 136
**The short term fish reproduction assay**
J Burke, G Last, P Bowen, G Pap
Covance Laboratories, HARROGATE, United Kingdom
The fish short-term reproduction assay was conducted with fathead minnows using a chemical known to induce endocrine disrupting effects. A control and three test groups were prepared each including four replicate tanks containing two males and two females. The test was designed to detect changes in spawning, morphology, gonadal size/architechture and specific biochemical endpoints that reflect disturbances in the hypothalamic-pituitary-gonadal (HPG axis), including oestrogen agonists/antagonists and vitellogenin induction in males. Collectively, the endpoints observed are intended to allow inferences to be made with regard to possible endocrine disturbances involving the estrogen hormonal pathway and, thus, provide guidance for further testing. The test was conducted under continuous flow conditions in 18.0 L glass tanks with a test media volume of 10 L and a 2.7L/hr flow rate. The concentration range was selected using the maximum tolerated concentration (MTC). Environmental conditions were 16h:8h light:dark photoperiod @ 540 to 1080 Lux, temperature was maintained at 25 ± 1°C, pH 6.5 to 9.0, Dissolved oxygen >60% ASV. Test media concentrations were determined on a weekly basis.

### TH 137
**Contraceptive choices and the resultant estrogenic load on the environment**
U Khan, J Nicelll
McGill University, MONTREAL, Canada
More than a decade of evidence suggests that the estrogenic content of wastewaters being released to the environment feminizes fish and that such feminizing effects could potentially comprise the reproductive capacity of the effected fish. Environmentally-relevant estrogens can be broadly categorized in two classes; namely, those that are endogenously produced and those that are exogenously consumed. Of the two, the excretion and therefore the subsequent environmental presence of endogenous estrogens can be considered to be omnipresent since they are a fixed characteristic of our biology. When considering exogenously consumed estrogens used for human contraception, the most important by far in terms of amounts consumed and environmental relevance is the female birth control pill, containing the synthetic estrogen ethynylestradiol as its active ingredient. The pill was first approved 50-years ago as a form of contraception and is

currently used by approximately 11 million women in the USA for this purpose. Since the use of ethynylestradiol, and hence the estrogenic content released as a consequence, is a contraceptive choice made by members of society, a logical question arises: When evaluated from an environmental perspective, should the use of ethynylestradiol be mitigated or even eliminated? And if so, do greener alternatives exist to this contraceptive? How does one go about making such an evaluation? Further, the mere suggestion that society's contraceptive choices be altered to mitigate environmental impact should be analyzed in broader context. Are contraceptive choices that are greener also clinically and personally preferred? Would such a switch to more greener contraceptive choices also be financially feasible? This study will present a first attempt at answering these questions.

**TH 138**

**Morphological changes in Girardia tigrina induced by atrazine**

AR Ribeiro, GA Umbuzeiro
State University of Campinas - Faculty of Technology, LIMEIRA - SÃO PAULO, Brazil

Atrazine is applied to control weeds in different plantations and is among the most used herbicides in the world. This herbicide is also an endocrine disruptor and has been found in several water bodies worldwide therefore exposure of animals from different trophic levels is expected. Laboratory tests can help in the hazard evaluation of those substances to non target organisms. Among them, planarians, such as *Girardia tigrina*, are interesting because of they are metazoan, present sexual and asexual reproduction, are able to regenerate and are easy to be cultivated and maintained under laboratory conditions. The objective of this work was to evaluate the effects of pure and commercial atrazine in *G. tigrina*. Atrazine p.a. and a commercial product containing 50% of atrazine were used. Atrazine p.a. was tested from 10 to the maximum water solubility (33 mg/L). The commercial product was tested from 10 to 100 mg/L (doses expressed in atrazine). Acute toxicity tests were performed with young specimens using two vessels per dose. Seven healthy *G. tigrina* with maximum age 10 days were exposed to 50 ml of each test solutions in 100-ml vessels. Morphological alterations and mortality were observed under a stereomicroscope after 24, 48, 72 and 96 hours of exposure. Both atrazine p.a. and the commercial product presented similar results. The 96-h $LC_{50}$ was only calculated for the commercial product (34 mg/L expressed in atrazine). It was not possible to calculate the $LC_{50}$ for atrazine p.a. because of limited solubility. But both LOAEL (Lowest Observed Adverse Effect Level) were similar: 20 mg/L to p.a. atrazine and 25 mg/L to commercial herbicide. Morphological alterations were observed in the survivors of the tests performed with commercial and atrazine p.a. Some animals showed retractable pharynx permanently exposed, changes in the shape of the pharyngeal region and loss of the posterior part of the body. The affected regions are the ones responsible for feeding and reproduction. Therefore, the exposure of atrazine at subletal concentrations can cause adverse effects in those animals. More studies are necessary for understand how atrazine causes these alterations in *G. tigrina*.

[5]Dow Chemical Corporation, MIDLAND, MI, United States of America
[6]American Chemistry Council, WASHINGTON, DC, United States of America

Bisphenol A (CAS RN 80-05-7) may enter the environment via permitted effluent discharges. In surface water, bisphenol A will rapidly biodegrade and some will become entrained in suspended particles and deposit onto sediment. Currently, the assessment of potential risks to benthos in sediments containing measurable concentrations of bisphenol A is based on aquatic toxicity chronic values and equilibrium partitioning to provide estimates of sediment toxicity. A recently completed risk assessment for bisphenol A in the European Union used this approach to assess risks to sediment dwelling organisms. To support the hazard assessment of bisphenol A in sediment, chronic toxicity tests have been performed using three sediment dwelling species representing different feeding and living conditions: an endobenthic freshwater annelid (the oligochaete, Lumbriculus variegatus), an epibenthic insect (the midge Chironomus riparius), and an estuarine crustacean (the amphipod Leptocheirus plumulosus). The no observed effect concentrations (NOEC) reported for the three species ranged from 22 to 54 mg/kg-dw. Predicted no effect concentrations (PNEC) were calculated using current European Chemicals Agency guidance by dividing the lowest chronic NOEC for sediment organisms of 22 mg/L by an assessment factor of 10 for freshwater and 50 for marine sediments. The freshwater and marine PNEC are 2.2 mg/kg-dw and 0.44 mg/kg-dw, respectively. PNEC were then compared to freshwater and marine surface sediment concentration data from monitoring programs reported from Europe and North America. Risk characterization ratios were calculated using median and upper 90th or 95th percentile concentrations of bisphenol A in European and North American sediments. The risk characterization results will be used to update and refine sediment risk assessments in these regions.

## ET11 - Mechanistic modelling for risk assessment: sub-lethal responses and population-level effects

**TH 147**

**Bayesian calibration and evaluation of agent-based models: a case study of a skylark population model for pesticide risk assessment.**

TM Kulakowski[1], KA Matuszewska[1], RM Sibly[1], MA Beaumont[2]
[1]University of Reading, READING, United Kingdom
[2]University of Bristol, BRISTOL, United Kingdom

European regulations concerning pesticide risk assessment focus on protecting populations rather than individuals [2]. As field experiments at a population scale are necessarily very expensive and may pose risks to wildlife populations, population models for higher tier risk assessment have recently become more widely used. Especially agent-based models seem to solve best the problem of extrapolation from the individual scale of laboratory data to the population scale necessary for risk assessment. They incorporate knowledge about individual behaviour and pesticide effects and population characteristics emerge from simulations. To use those models in practice, however, their credibility has to be ensured. For that a proper calibration and validation need to be provided.

We are currently developing a skylark (Alauda arvensis) agent-based model and at the same time a set of calibration and validation tools. We have chosen skylarks as they are often used as focal species in risk assessment due to their arable habitat and diet. The validation and calibration methods we are applying are based on the Bayesian paradigm and on the work of Mark Beaumont on Approximate Bayesian Computation [1]. We present those procedures we are performing for the skylark model together with the separate data sets we have acquired for the purpose. We hope they are a step in the direction of getting risk assessment models more widely accepted and used by risk assessors and managers.

**Dynamic energy budget theory meets individual-based modelling: a generic and accessible implementation for population risk assessment**

T Martin[1], E Zimmer[2], V Grimm[1], T Jager[2]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]Department of Theoretical Biology, Vrije Universiteit, AMSTERDAM, The Netherlands

Dynamic energy budget (DEB) theory provides a quantitative framework for modelling the acquisition and use of resources for organisms over the entire life cycle. It thereby generates a quantitative explanation for the time patterns of life history traits such as growth and reproduction. DEB theory has been widely used in the field of ecotoxicology. The process-based approach used in the DEB analysis of toxicity experiments differs from standard ectoxicological analysis (LC50, ECx, ect.) in that it links the effect to internal concentration of the chemical and takes into account the biological characteristic of the test individual used. This is of great advantage in a population context because it allows one to extrapolate the effect of the chemical to among different size classes and to differing environmental conditions and exposure scenarios. So far, however, DEB theory has only occasionally been used in the population context. We therefore implemented an individual-based population model (IBM) that is based on DEB theory. Our program is designed as a tool for risk assessment of a wide range of species and substances. It allows for a relatively simple extrapolation from the individual effects determined from the analysis of standard OECD tests to population level. As an example, we present our initial results using this approach with *Daphnia magna*. We discuss the potential of DEB theory and our implementation of this theory in an IBM to serve as a standard tool for ecological risk assessment of chemicals.

**TH 149**

**Effects of uranium in Daphnia magna exposed over three successive generations: extrapolation of DEBtox analyses to the population level**

PA Biron[1], E Billoir[1], S Massarin[2], F Alonzo[2], S Charles[1]
[1]University of Lyon, VILLEURBANNE CEDEX, France
[2]Laboratoire of environmental Modelling, DEI/SECRE/LME, IRSN, CADARACHE, France

As part of the ecological risk assessment associated with radionuclides in freshwater ecosystems, toxicity of waterborne uranium was recently investigated in the microcrustacean Daphnia magna, exposed over three successive generations. Toxic effects on daphnid life history and physiology, increasing over generations, were demonstrated at the individual level under controlled laboratory conditions. Nevertheless, response to toxicant at higher levels of biological organisation, in terms of demographic toxicology, is now recognized as more relevant in a broader ecological context than toxicology at the individual level.

Extrapolating effects to the population level requires considering key ecological factors, like life cycle characteristics. Concomitantly the complexity of relationships between individuals and populations makes necessary the use of modelling approaches, especially when ecotoxicological outcomes are expected to be predictive and not only descriptive. Uranium effects at the individual level were previously described with a DEBtox modelling approach based on the dynamic energy budget (DEB) theory, which describes how organisms acquire energy from food and allocate it towards survival, growth, maturity and reproduction. Here, we extrapolated effects from the individual to the population level through multigenerational Leslie matrix models.

DEBtox models were fitted to experimental data for each of the successive generations with Bayesian inference, a statistical method combining prior information (expert knowledge or literature) and data to provide parameter estimates as posterior probability distributions reflecting uncertainty. Matrix model inputs were calculated from the individual level models with parameter sets sampled from those distributions. This approach allowed us to echo DEBtox parameter uncertainty to the population level and to predict the population dynamics over the three generations as a function of the uranium exposure concentration. The population extinction probability is suggested as a mathematically convenient and ecologically relevant toxicological outcome for risk assessment.

**TH 150**

**Modelling harpacticoid copepod populations; matrix and individual based modelling**

E Lundström[1], M Breitholtz[1], M Brinkmann[2], TG Preuss[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]RWTH Aachen University, AACHEN, Germany

To increase the ecological relevance in the risk assessment process several authors have suggested that there should be an increased focus on the population level. The use of population models is a way of achieving this; and toxicity tests including development and reproduction provide data suitable for this kind of modeling. Copepods are important test species since they are a significant food-source to fish, and therefore provide an important ecosystem service. A life cycle test for copepods is also suggested for standardization (e.g. Amphiascus tenuiremis). The aim of this study was to compare the output of simple matrix- and individual based models, which were both calibrated using the same data sets that were generated in life cycle tests with harpacticoid copepods.

Two data sets with harpacticoid copepods were modeled: Nitocra spinipes which had been exposed to different sewage effluents and Amphiascus tenuiremis which had been exposed to Lindane (unpublished data from validation of OECD test method at Stockholm University).

An individual based model (IBM) that was developed for harpacticoid copepods was compared to a more traditional Lefkovitch matrix model. The matrix model included survival, developmental proportions, and fecundities. The IBM included survival, developmental proportions and rates, sex ratios, latencies (time from mating to first brood), time for embryo development, brood size and brood success. Both models used the same data sets for each of the test species.

The main effect that sewage effluent had on the copepods was reduced proportions of animals developing to the next stage. Lindane however, mainly affected the rates at which development took place; e.g. development was shifted. Changes in proportions are easily captured in matrix models, but changes in rates are not. In the IBM, rates are inherently modeled.

Simple individual based models do not require more data than simple matrix models. Individual based models are more powerful tools compared to matrix models since they inherently incorporate rates, not only proportions.

### TH 151

**Population models in Gammarus (Crustacean) and Potamopyrgus (Gastropod): depicting the seasonal variability in demographic sensitivities to toxic stress by sensitivity analysis**

R Coulaud[1], J Garric[1], S Charles[2], A Chaumeau[1], O Geffard[1], H Quéau[1]
[1]Cemagref, LYON, France
[2]Université de Lyon, LYON, France

Today there exists a large consensus that ecological models with populations rather than individuals as targets to protect have a high potential to be implemented into ecotoxicological risk assessment [1]. Indeed, they revealed particularly useful to solve the challenging issue of extrapolating toxic effects measured at the individual level towards possible contamination impacts on populations. Nevertheless, with the perspective to project or predict population answer, the environmental relevance of these models has to be improved, accounting for variability in population vulnerability and making them transferable with native species. In this way, the extrapolation process could be also used within a diagnostic framework.
Our work was focused on two phylogenetically and ecologically contrasted species (the Crustacean Amphipod Gammarus fossarum and the Mollusk Gastropod Potamopyrgus antipodarum), widely present in European rivers and for which ecotoxicological (sub)individual biomarkers are available. We first developed environmentally realistic size-structured population models including both in situ caging and laboratory data, and relating individual-level demographic parameters (survival, growth, reproductive activity, fecundity, size at maturity) to the dynamics of reference native populations all along a year.
Second, this methodology was coupled with in situ biotests or laboratory bioassays, in order to allow a population-level assessment of water quality or chemical compound toxicity. We showed thus the relevance to take into account the phenology of population dynamics (seasonal variability), by illustrating how it strongly controls the demographic sensitivity to toxic alteration of individual fitness traits in native species. More precisely, the poster will exemplify how sensitivity analyses of population endpoints were able to improve the comprehensive evaluation of possible contamination impacts on ecologically relevant biological levels.

### TH 152

**Decomposition analysis of LTREs may help to design short-term ecotoxicological tests: population modelling approach**

NT Hamda, DM Jevtic, R Laskowski
Institute of Environmental Sciences, Jagiellonian University, KRAKOW, Poland

A Life Table Response Experiment (LTRE) lasting 42 days was performed to investigate toxic effects of cadmium (Cd) and imidacloprid on reproduction and survivorship of aphids (*Acyrthosiphon pisum* Harris). Daily life table data obtained from the experiment described by Laskowski (2001) were used to construct and develop an age classified matrix model to estimate population growth rate ($\lambda$) at each treatment level. Decomposition analysis was performed to examine the relative contribution of changes in each life-history trait on $\Delta\lambda$, that is the difference between the control and a treatment.
Results of the decomposition analysis indicate that the contribution of differences in survival to $\Delta\lambda$ was most important at the 1st and 2nd weeks, while the contribution of differences in fertility to $\Delta\lambda$ was the greatest at the 3rd and 4th weeks. The two toxicants exhibited different actions though. Cadmium affected $\Delta\lambda$ mostly by impairing fertility at the age of three weeks and survivorship from 2nd to 3rd week. On the other hand, imidacloprid affected mostly the survivorship at the 1st and 2nd weeks of the age.
This LTRE analysis clearly indicates the shortcomings of traditional ecotoxicological assays, which usually concentrate on the traits that are most sensitive to toxicants. As shown by this study, the population-level interpretation of individual-level effects requires information on both the effects of a toxicant on vital rates and the demographic sensitivity of life stages. LTREs with decomposition analysis, as shown in this study, can be used as an important analytical tool to fill this gap by combining effects of toxicants with demographic sensitivity of the organism.

### TH 153

**Correlated random walk as mode of short distance dispersal for Asellus aquaticus - an experimental approach for model parameterization**

J Augusiak[1], NJ Diepens[1], JM Baveco[2], PJ van den Brink[1]
[1]Wageningen University, WAGENINGEN, The Netherlands
[2]Alterra, Wageningen University, WAGENINGEN, The Netherlands

Current EU legislation on ecological risk assessment (ERA) of pesticides mainly focuses on individual-level laboratory toxicity tests whereas envisaged protection goals mainly aim at populations of non-target species. Within the context of pesticide ERA, ecological models are rarely recommended in official documents but are sometimes applied by researchers to estimate risks to populations, communities and ecosystems. Some of the reasons for the hesitation to use ecological models in official ERA studies are a lack of case studies showing real model application and validation data that make models more trustworthy to describe real, natural systems.
An individual-based model, MASTEP (Metapopulation model for Assessing Spatial and Temporal Effects of Pesticides), has been developed at Alterra (Wageningen, The Netherlands) and was used to estimate the combined allogenic and autogenic recovery of Asellus aquaticus after exposure to an insecticide. In the case of A. aquaticus, and other species also (e.g. Gammarus pulex), recovery by immigration of individuals from uncontaminated sites is an important factor for re-establishing population densities after pesticide exposure. However, not much information on movement patterns of aquatic macroinvertebrates is available. In the submodel on dispersal in MASTEP, correlated random walk (CRW), as a relatively standard way to model animal movement, is applied for short distance dispersal of A. aquaticus individuals. The parameters for this submodel have been estimated from previous observational studies. However, such studies did not sufficiently account for habitat quality or density effects on locomotion of asellids.
Therefore, we performed video tracking experiments to derive information on movement behaviour of individual A. aquaticus, specifically to obtain relevant parameters for the CRW, such as preferred turning angle range, resting times, and movement velocity. The experiments tested for different population densities and habitat qualities (e.g. presence of food or shelter) as different locomotion activities were assumed under varying conditions. The next step will be to use this information to parameterize and adjust the dispersal submodel in MASTEP to enable for more realistic estimations of population dispersal in different environments.

### TH 154

**The importance of maternal environment in determining offspring size in Daphnia magna population models**

F Gabsi, TG Preuss
Institute for Environmental Research- RWTH Aachen University, AACHEN, Germany

This study is in the context of a Marie-curie training Network (CREAM Project) aiming to develop population models for risk assessment of chemicals. Population-level ecotoxicology has recently gained much interest and its relevance for risk assessment is now well documented. The impact of toxicants on populations depends on exposure, toxicity and also on the life-cycle of the species as well as abiotic and biotic interactions. Individual-based models were proven to provide an excellent methodology for population modeling, allowing to account for such interactions and to consider the individual variability within the population. Amongst the species used in modeling, *Daphnia magna* is an ideal organism that has been adopted in many studies due to its well-studied biology.
In 2009, Preuss *et al.* developed an individual-based model (IDamP) predicting the population dynamics of *Daphnia magna* under different feeding conditions. In this work, we use the IDamP model to describe the effects of sub-lethal exposure to toxicants on *Daphnia magna* populations. One adopted chemical is known to shift the reproductive strategy of the species by producing larger broods but smaller and less fit offspring. Offspring size is a key life history trait in *Daphnia* as it is intimately associated with important individual traits on the population level such as growth rate, maturation and reproductive allocation. It is subjected to variation with different maternal conditions like size, density and food level. Thus, it is crucial to consider these conditions when modeling *Daphnia* populations, and this has not been included in IDamP or other *Daphnia* population models yet.
In this poster, we provide a mathematical description of the offspring size relation to maternal environment. This relation was achieved by means of multiple regression analysis of data under toxicant-free conditions.
Preliminary analysis revealed a linear relation between offspring size and mother size; an exponential decay function related offspring size to density, and finally maternal food level negatively affected offspring size. In this context, laboratory experiments were conducted to determine the equation that best fits the data.
Toxicity is integrated using a relation derived from toxicity data of the chemical. Therefore, the population dynamics and size structure of *Daphnia* will be simulated in the IDamP model under control conditions and in the presence of a toxicant with a defined mechanism of action.

### TH 155

**Modelling toxic effects on Chaoborus populations under field conditions - an individual-based simulation study**

T Strauss[1], E Bruns[2], G Görlitz[2], TG Preuss[3]
[1]Research Institute gaiac, AACHEN, Germany
[2]Bayer CropScience, MONHEIM, Germany
[3]RWTH Aachen University, AACHEN, Germany

For the application of mechanistic population models in ecological risk assessment, a sufficiently high ecological complexity and an accurate description and prediction of the effects is recommended. This study presents a modelling approach for the extrapolation of toxic effects from individuals in the laboratory to populations in the field.
As a model organism for emerging insects, we used the multivoltine aquatic phantom midge Chaoborus crystallinus, which is a common pelagic invertebrate predator in ponds and is known as a frequently very sensitive organism to pesticide exposure.
We used an existing mechanistic individual-based population model for Chaoborus crystallinus, which was formerly validated with experimental data from aquatic outdoor mesocosms. In this model the individual chaoborids are explicitly modelled and population dynamics emerge directly from their individual life-cycles.
In order to predict ecotoxicological effects on the population dynamics of the chaoborids precisely under field conditions, the Chaoborus population model was coupled with a toxicokinetic-toxicodynamic (TKTD) model following the General Unified Theory for Survival (GUTS). The TKTD model was parameterised by data derived from toxicological experiments with individual Chaoborus larvae exposed to triphenyltin (TPT) in the laboratory.
The results of the advanced coupled model were validated using data from aquatic outdoor mesocosms treated with TPT that caused pronounced adverse effects on chaoborids, daphnids, copepods and rotifers. Due to the fact, that TPT is toxic to Chaoborus as well as to its zooplanktonic prey, a combination of direct toxic effects on Chaoborus and indirect effects caused by reduced food availability was taken into account in this modelling approach.
The poster will show results of simulated control populations, acute effects and recovery time.

### TH 156

**Ecological risk assessment of pesticides on wood mouse populations using individual-based models**

C Liu[1], RM Sibly[2], P Edwards[3], R Murfitt[3], P Thorbek[3]
[1]Syngenta Ltd/Reading Univ., BRACKNELL, United Kingdom
[2]Reading University, READING, United Kingdom
[3]Syngtenta Ltd, BRACKNELL, United Kingdom

The wood mouse (*Apodemus sylvaticus*) is the most common and widespread wild rodent species on agricultural land in much of Europe. It is commonly used as a focal species in higher tier risk assessment of pesticides. The aim of the project is to construct an ecological model in support of population level risk assessment of pesticides for the wood mouse. An individual-based model (IBM) is being developed to simulate and predict the population dynamics so as to assess the risk of pesticides with different potential toxic effects, e.g. - acute effect on survival, sub-lethal effects on reproduction and somatic growth.
Here both a control model and an experimental model are presented, the former showing the population dynamics without pesticide application and the latter showing some preliminary runs with a hypothetical pesticide. Both models included life history traits (e.g. breeding pattern, dispersal, *etc*) and behaviour (e.g. foraging and territoriality) of the wood mouse; whilst the experimental model also tested the effects of the pesticide application patterns (i.e. where, when and how much) as well as interactions with other agricultural practices (e.g. ploughing, tillage and harvesting).

### TH 157

**SAM-X (R) - R implementation of an algae population model for potential application in the risk assessment of pesticides**

S Weber[1], J Ranke[1], TG Preuss[2], HT Ratte[2], M Dorgerloh[3], D Schaefer[3], E Bruns[3], G Goerlitz[3]
[1]Harlan Laboratories Ltd., ITINGEN, Switzerland
[2]RWTH Aachen University, AACHEN, Germany
[3]Bayer CropScience AG, MONHEIM AM RHEIN, Germany

The environmental risk assessment of pesticides for aquatic organisms in the European Union is a

comparison of effect data from laboratory studies and model-predicted environmental concentrations (PEC, using the FOCUS models).
The FOCUS exposure patterns often show peaks of different height and duration on a variable time-scale. The effects of such pulsed exposure patterns at population level (*e.g.* algae populations), including the ability and time to recover of affected populations, are important issues.
Population models are promising higher-tier risk tools to assess the effects of time-variable pesticide exposure on representative aquatic organisms (*e.g.* green algae). A recently developed and verified simulation model describes the growth of algae species depending on variable environmental conditions (nutrients, light, and temperature) and the effects of chemical substances on these algal populations. The model consists of four compartments described by differential equations and uses standardised parameter sets of the physiological species properties.
In the context of the regulatory acceptance of population models for pesticide risk assessments, transparency and reproducibility of simulated processes are highly desirable. This presentation reports an implementation of the SAM-X algae model in the open source software environment R. Advantages over alternative implementations using commercial software (*e.g.* Matlab©) include 1) the free availability of the underlying R software for all major operating systems, 2) the possibility to inspect the code of R.
The model was used to describe experimental laboratory data from algae population capacity and competition tests. The simulation results were compared with results from an alternative implementation of the model.

**TH 158**

**A case study of aquatic population modelling for pesticide regulatory risk assessment using the MASTEP model: chlorpyrifos**

GS Weyman[1], SM Norman[2], P Manson[3], P van den Brink[4], I Roessink[4], N Galic[4], H Baveco[4]
[1]Makhteshim Agan, THATCHAM, United Kingdom
[2]Dow AgroSciences, ABINGDON, United Kingdom
[3]Cheminova, HARROGATE, United Kingdom
[4]Alterra / Wageningen University, WAGENINGEN, The Netherlands

Chlorpyrifos is an organophosphate insecticide which is highly toxic to aquatic invertebrates and has a Regulatory Acceptable Concentration (RAC) of 0.1 μg/L, based on EU review of a number of outdoor mesocosm studies in north and south Europe. Application rates of chlorpyrifos of up to 1000 g/ha in apple orchards and 2400 g/ha in citrus are registered. The combination of the low RAC coupled to a high exposure potential from spray drift onto edge-of-field water bodies makes the aquatic risk assessment challenging. However, the mesocosm studies on which the RAC is based are short-term static systems, whereas recovery may be possible in moving water, larger water bodies, or over longer timescales; and the exposure calculations are simplistic. It is not possible to test all possible eventualities and processes in reality. However, modelling offers the opportunity to theoretically test options. When based on realistic parameters, the model offers some degree of realism in its predictions. The individual-based population model MASTEP (Metapopulation model for Assessing Spatial and Temporal Effects of Pesticides) has been used to evaluate the recovery potential of four aquatic invertebrates known to be sensitive to chlorpyrifos, with differing life histories, using real toxicity data, in various water bodies, with input from various crops, and with various risk mitigation measures. Model runs deliberately included scenarios that cause prediction of strong effects, to indicate its sensitivity. Then various mitigation measures were tried to determine their influence on recovery. The methods and results to date will be presented and discussed. Toxicokinetic/toxicodynamic considerations are also planned. This case study on chlorpyrifos is designed to explore whether population modelling can provide valuable information to risk assessors and, in particular, to risk managers to support decisions on realistic risk mitigation possibilities.

**TH 159**

**Spatially-explicit risk-assessment: what's the appropriate spatial scale for observing recovery?**

JM Baveco, N Galic, P van den Brink
Wageningen UR, WAGENINGEN, The Netherlands

When applying spatially-explicit individual-based population models for pesticide risk assessment in a realistic situation as defined in FOCUS scenarios, several spatial scales become relevant: the typical scale of the species set by its movement attributes, of the exposure pattern and of the structure of the habitat. Taking population recovery as an endpoint in risk assessment, we have to choose the most appropriate spatial scale of observation. Do we have to estimate time to recovery for the total population in the system or just for the population living in the (most) exposed part? How far should the total system extend, and which part of it may we consider as 'the landscape context' that may potentially act as a source of migrants for the exposed part?
We investigate these questions using simple individual-based models (MASTEP) for four aquatic species with different life-history and mobility, roughly representing Asellus, Gammarus, Chironomus and a mayfly species. We assume a constant environment (no seasonality driven by e.g., temperature), linear aquatic habitat (ditch) and for all species equal sensitivity to a hypothetical pesticide defined by a single dose-effect relationship for acute mortality.
The landscape context is set by the length of the ditch: 200 to 1000m. A fixed part (100m) is directly exposed (spray-drift); the remaining part has exposure exponentially declining with distance. Only peak-values of exposure are considered. We calculate recovery times for the 100m part as well as for the whole system population and compare these to the ones expected for a well-mixed population recovering in absence of density-dependent limitation. Expected recovery time is determined by population growth rate λ, which we obtain by solving a discrete version of the Euler-Lotka equation.
Simulated total population recovery times that are longer than expected, indicate that the total system cannot be treated as well-mixed: the species operates at a smaller spatial scale and heterogeneity in exposure at this smaller scale does matter. Simulated recovery times at the 100m scale that are shorter than expected, indicate that the 100m part is too small to be considered in isolation: the species operates at a larger spatial scale and exposure outside the 100m zone has an impact on recovery in the 100m zone. Comparing outcome for different total system size we are able to identify for each species the most appropriate spatial scale for recovery.

**TH 160**

**Development of ecological risk assessment methods for space- and time-varying herbicide exposure**

TI Hayashi, Y Imaizumi, N Tatarazako, N Suzuki
National Institute for Environmental Studies, TSUKUBA, Japan

Ecological risk assessment methods to analyze risk from herbicides under space- and time-varying exposure were developed. First, we analyzed spatial variations of risk from herbicides by creating ecological risk maps in Japan. The hazard ratio of maximum environmnetal concentration predicted by G-CIEMS (Geo-Referenced Multimedia Environmental Fate Model System) simulations to ecotoxicity data (EC50) was used as a risk index at a site level. The number of the sites in which the harzard ratio exceeed one was used as a risk index at the national level. Second, we analyzed ecological risk under time-varying herbicide exposure by combining time series variations in environmnetal concentration predicted by G-CIEMS simulations and dynamic energy budget toxicity models. The predicted total loss in the biomass of algae population over an exposure period was used as a risk index. We analyzed the risk from pretilachlor, butachlor and symetrin. Our analysis suggested that pretilachlor was the predominant risk factor among these herbicides.

**TH 161**

**An IBM to explore the effect of local variability in soil contamination levels on population dynamics of Folsomia candida**

M Meli[1], JB Schmidt[1], A Palmqvist[1], VE Forbes[1], V Grimm[2]
[1]Roskilde university, ROSKILDE, Denmark
[2]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

The abundance and diversity of Collembola have been widely used to assess the environmental impact of pollutants on soils, and a standard test guideline has been developed for the parthenogenetic springtail *Folsomia candida* for this purpose. However, the guideline assumes homogenous contamination of the soil matrix, while recent evidence from different biological systems, modelling approaches, and perturbation types indicates that local variability in habitat conditions has an impact on population dynamics.
An individual-based model will be presented that simulates the avoidance behaviour of *F. candida* and the effect of heterogeneously contaminated soil on population dynamics. It has been implemented using the NetLogo software platform. In the model, springtails are characterized by their position, age, time that passed since reaching adulthood and the number of days they spend on contaminated patches of soil. Spatial units of soil are characterized by their concentration of toxicant and the collembolan's avoidance probability. Individuals are assumed to sense and avoid contaminated patches with a certain probability, which depends on contamination level. Movement is random if the patch ahead of the animal is not contaminated. Model rules and parameter are based on data from the literature and are evaluated against experimental data sets.
Average age-mortality curve of individuals in simulated populations was in good accordance with laboratory observations. Specific laboratory experiments to test the avoidance behaviour of *F. candida* have also been designed, and the results utilised to calibrate model parameters related to the toxicant effects. Preliminary simulation results show a clear influence of the level of heterogeneity on population dynamics of *F. candida*. Implications of these effects for standard tests based on *F. candida* and for risk assessment of chemicals in general will be discussed.

**TH 162**

**Modelling population response to toxicants considering multi-species interaction**

M Kattwinkel, M Liess
Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

Chemical risk assessment is getting more and more complex as ecological realism is increasingly included. However, not each and every field situation can be tested in the risk assessment. Therefore, ecological models offer the opportunity of virtual experiments to investigate a wide range of field-relevant situations. Additionally, modelling approaches can be used to investigate the combined effect of different processes identified in the laboratory.
Biological interactions are an essential part of ecological systems. Thus, also individuals that are confronted with chemical stressors are affected in nearly every situation by predators, synergists and / or competitors of the own and other species. Such biological interactions are, however, rarely taken into account in chemical risk assessment.
In this study we therefore present a generic, individual-based model (IBM) of two competing species. We investigate how lethal and sub-lethal effects of toxicants measured on the individual level are translated to population level response. The model incorporates variables that are measured as endpoints in standard individual tests (acute and chronic mortality, reproduction).
To conclude, competition strongly influences the effect of toxic stressors on the population level. Additionally, the effect mode of a toxicant on the individual is an important factor determining the response. Hence, biological interactions as well as the life cycle parameters that are influenced by the specific toxicant should be taken into account to improve the realism and therefore accuracy of toxicant risk assessment.

**TH 163**

**Why a population model of the cyclopoid copepod Mesocyclops leuckarti for the ecological risk assessment of chemicals is absolutely necessary**

DP Kulkarni[1], TG Preuss[1], U Hommen[2], A Gergs[1]
[1]RWTH Aachen University, AACHEN, Germany
[2]Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME-AE, 57392 SCHMALLENBERG, Germany

Copepods are important species in aquatic systems, quick to colonize and arguably the most dominant zooplankton. However copepods are mostly under-represented and not studied well with respect to ecotoxicology despite them being organisms of interest in this matter owing to their sexual life cycle, different developmental stages and prominent switch in food strategies during development. Thus they are well suited to study the traits essential for characterization of both lethal and sub-lethal effects of toxicants. A fair amount of work has been done on harpacticoid copepods (bottom dwelling) in this area, mostly marine. Yet, cyclopoid copepods are certainly more abundant and relevant for freshwater ecosystems and there is a great need to study them in the light of chemical risk assessment.
Out of the three freshwater free-living copepod orders namely Calanoida, Cyclopoida and Harpacticoida, the cyclopoid copepods are mostly planktonic. A detailed literature review on the distribution of freshwater cyclopoid copepods revealed their prominence in almost every freshwater habitat. Cyclopoid copepods are relatively easy to handle and maintain in the laboratory. They are also sensitive to environmental changes and can be good indicator organisms for ecotoxicological studies. Summer species of cyclopoid copepods exhibit the phenomenon of diapause in winter and dominate freshwater habitats in summer. These species show a relatively short life cycle compared to the winter species. Therefore they are the preferred organisms for full life cycle studies.
We will present the importance of copepods for environmental risk assessment and the culmination of the search for a relevant species of cyclopoid copepods for chemical risk assessment. The search was carried out by intense literature review and discussion with experts in the field of copepod ecology. The species finally selected for the study is *Mesocyclops leuckarti* which is widespread in occurrence. This species shows takes approximately 21 days to grow from naupliar stage to adult stage. The adults on average live for 20 days and the whole life cycle is completed in approximately 40 days. Based on life-cycle and population tests we aim to develop a mechanistic

population model of this species applicable in the risk assessment of chemicals.
The study is a part of the **EU Project CREAM (Mechanistic Effect Models for Ecological Risk Assessment of Chemicals)**.

### TH 164

**Screening for realistic worst-case species of freshwater fish for pesticide risk assessment in edge-of-field water bodies in the EU**

L Ibrahim[1], TG Preuss[2], U Hommen[3]
[1]Fraunhofer IME c/o Institute for Environmental Research-RWTH Aachen University, AACHEN, Germany
[2]Institute for Environmental Research, RWTH Aachen University, AACHEN, Germany
[3]Fraunhofer IME, SCHMALLENBERG, Germany

Fish are considered under all EU directives and regulations that are related to the environmental risks of chemicals. The assessment of potential effects of chemicals on fish is usually based on ecotoxicological tests on the level of the organism (e.g. effects on survival, growth, reproduction). However, because the environmental protection goals are, in most cases, related to the sustainability of populations, there are two types of extrapolation which might improve risk assessment for fish: from sub-lethal effects on individuals to the population and from test species to ecologically relevant species. There are several ecological models developed for fish available in the open literature. However, so far, none is used within the regulatory framework for plant protection products to refine the standard risk assessment for fish. Therefore, we intend to develop a population model of a realistic worst case fish species which is applicable to the EU. A comprehensive dataset on the EU freshwater fish species is filtered by habitat (excluding riverine, lacustrine, and brackish species), and by range (excluding endemic species and species of small range relative to the 3 zones of mutual recognition according to the new EU pesticide regulation). Then, the species are ranked for population sustainability under stress based on their life history traits. To achieve this, a toxic effect is considered as a disturbance in the life-history of a species, and thus vulnerability is assigned to a species based on the dependence of its population growth rate on changes in its life-history parameters. This dependence is determined via elasticity analysis using age- or stage-based matrix models. Based on the results of the elasticity analysis, as well as the availability of information on life cycle traits, density dependence, and population dynamics in the field, we intend to select one species for the analysis of potential pesticide effects in more detail by means of an individual based model.
In this poster we present the screening approach and the resulting list of the worst-case species.

### TH 165

**Modelling data from field trials of rodenticides in anticoagulant-resistance areas: are resistance-breakers better for the environment?**

LJ Daniells[1], P Thorbek[2], M Greener[2], AP Buckle[1], CV Prescott[1]
[1]University of Reading, READING, United Kingdom
[2]Syngenta, BRACKNELL, United Kingdom

Anticoagulant rodenticides (ARs) are used globally to control pest rodent infestations. Resistance to ARs first appeared against warfarin and diphacinone in Scotland in 1958. In the wake of this more potent ARs were produced but resistance has since developed to some of these. Surveying carcasses of predatory and scavenging animals in the UK has shown that ARs may affect a range of non-target species, including some of high conservation value. The risk to wildlife depends on several factors, including AR concentrations in individual rats, total AR residue in rat populations, and probably also rat population densities, as predators are known to be attracted to high concentrations of prey. In this paper we show that resistance also plays a part because AR-resistant rats are not controlled by some AR baits and this can lead to rat infestations carrying substantial residues of ARs that are available in the environment. Field trials of three ARs (brodifacoum, bromadiolone and difenacoum) were conducted on farms in the Münsterland region in North-west Germany where resistance to bromadiolone and difenacoum in Norway rats (Rattus norvegicus) is conferred by the tyrosine139cysteine mutation. Rat population censuses were carried out pre- and post-baiting and bait applications were conducted according to product labels. Pulsed-baiting was used for brodifacoum and surplus baiting for bromadiolone and difenacoum (all baits contained 50ppm of active substance). Here we present a model that utilises the data obtained from these trials to predict the amount of AR in different environmental compartments through the course of the trials. Baiting with brodifacoum resulted in the lowest levels of AR entering the rat population during the treatments, because it was used in smaller quantities and was effective against the resistant rats. Residues were also short-lived because the rat infestations were quickly reduced. Bromadiolone and difenacoum resulted in markedly higher and potentially long-lived burdens of AR in the rat populations because they were used in greater amounts and were less effective. The use of compounds that are not 'resistance-breakers' results in greater uptake of AR into the rat population and long-lived AR residues available to wildlife. Thus, resistance influences the total amount of AR available to non-targets and should be considered when dealing with rat infestations, as resistance-breakers may present a lower risk to wildlife.

### TH 166

**Use of the Comprehensive Aquatic Systems Model for Atrazine (CASMATZ) to estimate potential changes in primary producer community structure based on intensive stream monitoring chemographs.**

P Hendley[1], SM Bartell[2], RA Brain[1], AJ Hosmer[1], S Wall[1]
[1]Syngenta Crop Protection Inc., GREENSBORO, United States of America
[2]E2 Consulting Engineers, Inc., MARYVILLE, TN 37801, United States of America

In 2003, the US EPA required an intensive stream water exposure monitoring program to determine the potential impact of atrazine on the aquatic primary producer community structure. The Comprehensive Aquatic Systems Model (CASM) was parameterized to use atrazine laboratory toxicity data and region-specific characteristics to translate daily atrazine exposure concentrations generated from the stream monitoring program into estimated potential effects on individual model populations of aquatic primary producers and consumers in a generalized 2nd-3rd order Midwestern U.S. stream. CASM_Atrazine (CASMatz) is a bioenergetics-based approach that describes daily production dynamics for a user-specified aquatic food web. It considers the combined implications of varying exposure concentrations/durations, changing environmental conditions, differential population sensitivity to atrazine, and grazing/predator-prey relations in estimating any potential direct and indirect risks posed by site-specific measured atrazine chemographs The generic stream producer community consists of populations of phytoplankton, periphyton, and macrophytes while populations of zooplankton, benthic invertebrates, decomposers, and fish constitute the consumers. In reference simulations, individual population biomass (carbon) values vary as nonlinear functions of daily values of light, temperature, nutrients (N, P, Si), current velocity, water depth, and complex grazing and predator-prey interactions. CASMatz estimates of magnitudes and temporal patterns of population biomass in the absence of other stressors are similar to those reported for 2nd/3rd-order streams. CASMatz provides the flexibility to use alternative methods to estimate exposure-response based on an extensive database of atrazine laboratory toxicity studies and the resulting modelled changes in producer population biomass for varying atrazine exposure scenarios compare favorably with effect and recovery results measured in 33 atrazine microcosm/mesocosm experiments. This generic stream version of CASMatzdemonstrates that potential population-level responses to time-varying herbicide chemographs can be characterized for risk assessment using bioenergetics-based models. Importantly, CASMatz provides ecological complexity commensurate with more realistic modeling of potential changes in aquatic primary producer community structure and consumer communities.

### TH 167

**Estimating costs of chemical impacts on populations: a case study on peregrine falcon exposed to PBDEs**

AM Schipper, AJ Hendriks, MAJ Huijbregts
Radboud University Nijmegen, Institute for Water and Wetland Research, NIJMEGEN, The Netherlands

Besides contributing to human welfare, the production and application of chemical substances may generate significant side effects in terms of adverse ecological impacts. To quantify the trade-offs between these benefits and risks, monetary evaluation methodologies can be used.
To estimate ecological costs caused by chemical pollution, the following steps are involved: 1) quantifying changes in ecosystem attributes resulting from a chemical impact, and 2) translating these changes into monetary values. So far, very few studies in ecological risk assessment have integrated these two parts. Here, we present an approach to assess the costs associated with chemical impacts on animal populations. We used a model in which population dynamics are related to environmental contaminant concentrations by adjusting survival and reproduction rates in accordance with substance and species-specific concentration-response curves. The model was extended by including introduction of captive-bred individuals to compensate for declines in the population caused by contaminant impacts. In the second step, we calculated the costs associated with the introduction of these captive-bred individuals. We applied the model in a case study aimed to assess the costs associated with the impacts of PBDEs on peregrine falcons (Falco peregrinus) in California. Our approach illustrates that incorporating actual replacement costs in an impact assessment model enables the calculation of actual monetary estimates, circumventing the limitations associated with more subjective valuation methods like 'willingness-to-pay' surveys.
In our presentation we will outline our modelling approach, present the main results of our case study, and discuss benefits and limitations.

### TH 168

**Analyzing in vitro-in vivo genotoxicity gap: mechanistic models for in vivo liver genotoxicity and in vivo MNT**

OG Mekenyan[1], P Petkov[1], SK Kotov[1], S Stoeva[1], S Dimitrov[1], M Honma[2], H Makoto[2], R Benigni[3]
[1]University Prof. Assen Zlatarov, BOURGAS, Bulgaria
[2]National Institute of Health Sciences, TOKYO, Japan
[3]Laboratory of Comparative Toxicology and Ecotoxicology, ROME, Italy

*In vivo* tests measure the toxic effects of chemicals in the whole organism, where the "logic"of the metabolism is different, since it is "organized"towards detoxification. The investigation of *in vitro-in vivo* gap with respect to genotoxicity at different levels of biological organisms is the main goal of the current work. This allowed better understanding the nature of *in vivo* detoxification effects in terms of *in vivo* bioavailability. The latter is assumed to be the primary difference between *in vitro* and *in vivo* effects whereas the reactivity factor acts in same way in *in vitro* and *in vivo* interactions. In difference with the *in vitro* generated metabolites, which are freely available to interact with macromolecules, the metabolites in *in vivo* detoxification pathways are "trapped"being engaged in enzyme complexation (channeling effects) and subsequently unable to interact with DNA and proteins. A classification scheme interrelating the different levels of genotoxic effects has been created on the basis of a large amount of quality assured documented data. The relationships established in the scheme allowed development of models for *in vivo* liver genotoxicity and *in vivo* MNT which are the other aims in this work. These mechanistic models are of practical importance given that genotoxicity test bateries commonly comprise two *in vitro* (AMES, CA, MLA, SCE) and one *in vivo* tests (UDS, Comet, MNT). The two *in vivo* models are implemented in the TIMES platform (http://oasis-lmc.org) and could be used for predictive purposes. The scheme is a good basis for in-depth investigation of the *in vitro-in vivo* gap with respect to genotoxicity and building reliable mechanistic models for these effects.

## HM02 - Impact and remediation of wastewater

### TH 172

**Determination of SSRIs in sewage sludge by hollow fiber liquid phase microextraction**

E Sagristà[1], EL Larsson[2], JMC Cortés[3], VS Salvadó[1], MH Hidalgo[1], JÅJ Jönsson[2]
[1]University of Girona, GIRONA, Spain
[2]Lund University, LUND, Sweden
[3]University of Castilla la Mancha, ALBACETE, Spain

Pharmaceuticals are emergent contaminants in the aquatic environment, wastewater treatment plants and municipal sewage treatment plants (STPs). Selective serotonin reuptake inhibitors (SSRIs) are new antidepressants used for psychiatric illnesses. These compounds are becoming the most-prescribed drugs due to their selectivity. SSRIs include citalopram, paroxetine, sertraline and fluoxetine which is metabolized to norfluoxetine. Few studies dedicated to the determination of SSRIs in sewage sludge have been reported. The complexity of the matrices and the trace amounts of pharmaceuticals make the application of extraction techniques for the enrichment and cleanup necessary steps.
The most common technique applied to the extraction of organic contaminants from sewage sludge is pressurized liquid extraction (PLE) combined with solid phase extraction (SPE). However, this technique needs a considerable manipulation and the co-extraction of some interferences is not avoided. Liquid phase microextraction (LPME) is an alternative technique for the selective extraction, clean-up and enrichment of organic pollutants. The most important advantages are that LPME minimizes organic solvent and reagent consumption, gives an efficient clean-up and selectivity, short time of analysis and low cost.
Three phase hollow fiber liquid phase microextraction (HF-LPME) has been applied for the determination of concentration of SSRIs in sewage sludge. Enrichment factors between 250 and 900 have been obtained in water samples. Slurry samples spiked with different contents of sludge were analyzed and an increase of enrichment factor was observed. By relating this increase of the concentration in acceptor phase to the spike levels, initial concentrations of SSRIs in sludge can

be calculated. Concentrations found in sludge samples from Källby WWTP (Lund, Sweden) were 530 ng $g^{-1}$ for citalopram, 37 ng $g^{-1}$ for paroxetine, 210 ng $g^{-1}$ for fluoxetine, 472 ng $g^{-1}$ for norfluoxetine and 251 ng $g^{-1}$ for sertraline.

### TH 173

**Analysis of perfluorinated compounds in sludge by pressurized solvent extraction followed by liquid chromatography-mass spectrometry**

M Llorca[1], M Farré[1], Y Picó[2], D Barceló[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]Nutrition and Bromatology Laboratory, University of Valencia, VALENCIA, Spain

Perfluorinated compounds (PFCs) are widely used in everyday life and one of the main recipients of these compounds were waste water treatment plants (WWTPs). Due the structure and physicochemical properties of PFCs, these compounds could be redistributed from influent water to sludge or other WWTP treatments. The present work was focused to develop a useful extraction procedure for 18 PFCs from sludge samples based on pressurized solvent extraction (PSE) followed by anionic solid phase extraction (SPE) clean-up, analytes separation by liquid chromatography and analysis in an hybrid quadrupole-linear ion trap mass spectrometer (LC-MS/MS) working in a triple quadrupole mode.

During optimization process of PSE extraction, 3 different solvent mixtures including: water:methanol (90:10), water:methanol (50:50) and methanol (100 %) were tested. In parallel, 3 different temperatures were studied (70, 100 and 130ºC). The final method was established at 70ºC, 100 bar, 2 cycles and methanol as solvent extraction. The method was validated using a blank sewage sludge fortified at different concentration levels. The method limits of detection were ranging from 15 to 79 ng/Kg, with exception of perfluorobutanoic acid (PFBA), perfluorohexanoic acid (PFHxA) and perfluorobutanesulfonate (PFBS) which were higher (831μg/Kg, 161μg/Kg and 219μg/Kg, respectively). The limits of quantification were from 50 to 264 ng/Kg for most PFCs. These values were comparable to the decision limit (CCα) and the detection capability (CCβ), which were 17-1134ng/Kg and 18-1347ng/Kg, respectively. The percentage of recovery, for the different fortification levels, was from 79 to 111% in the most cases. Finally, the repeatability of the method was in the range 4% (perfluorooctanesulfonate (PFOS) and perfluorooctanoic acid (PFOA)) to 25% (RSD%).

In order to evaluate the applicability of the method, 5 sludge samples from WWTP were analyzed. The results showed that the 18 PFCs were present in all samples. However, the concentrations for most of them were below the limits of quantification. The compound present at higher concentrations was PFOS, which was in concentrations from 53.0 to 121.1μg/Kg. The other PFCs were at concentrations between 0.3 and 30.3μg/Kg.

**Solid phase extraction combined with large volume injection-gas chromatogrophy-mass spectrometry for the determination of a wide variety of priority and emerging pollutants in wastewater samples**

O Zuloaga[1], A Iparragirre[1], E Bizkarguenaga[1], O Ros[1], A Vallejo[1], P Navarro[2], M Olivares[1], LA Fernández[1], A Usobiaga[1]
[1]University of the Basque Country, BILBAO, Spain
[2]CNRS-UPPA, PAU, France

In the complex process of harmonizing laws, directives and actions within the European Union countries, the European Water Framework Directive (WFD, 2000/60) is probably the most important international legislation introduced for many years in the water management and protection field [1]. According to the WFD, the good state of the aquatic bodies is obtained when the concentration of the priority substances in water, sediments and biota are below the established Environmental Quality Standards (EQSs), which have only been fixed for water. However, the WFD does not specify the analytical methods that have to be used, so there is an urgent need to develop monitoring tools and analytical methodology able to provide improved chemical and biological data at a lower cost in order to respond to the challenges of the various tasks involved in each type of monitoring [2].

In the present work a multi-class method is proposed for determination of a variety of organic pollutants including polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), polybrominated diphenyl ethers (PBDEs), pesticides, hormones, alkylphenols (APs), phthalate esters (PEs), bisphenol A (BPA) using solid phase extraction (SPE) combined with large volume injection-gas chromatography-mass spectrometry (LVI-GC-MS) in wastewater samples. Variables affecting the extraction such as the nature of the sorbent, the sample pH, the ionic strength, the methanol addition, the sample volume and the elution solvent were studied. In the case of the LVI, injection solvent, injection speed, cryofocusing temperature were considered. During LVI, the feasibility of the direct derivatisation of hormones, BPA and APs during the injection using N,O-Bis(trimethylsilyl)triufloroacetamide with 1% of trimethylchlorosilane (BSTFA+1 %TMCS). The matrix effect in both the extraction and analysis steps was also studied. Samples from three different WWTPs from the Basque Country (Spain) were analysed.

**Multi-trace analysis of pharmaceuticals in wastewater samples by GC and GC-MS techniques - optimization of derivatization step**

J Kumirska, N Migowska, M Caban, M Czerwicka, A Bialk-Bielinska, P Stepnowski
University of Gdansk, GDANSK, Poland

In recent years, there has been a continuously growing interest in the occurrence, fate, and possible effects of human and/or veterinary drug residues in the environment. During analysis of pharmaceuticals in wastewater samples there are often interfering elements. Due to mentioned above and low concentrations of studied analytes the extensive knowledge must be gathered by the means of elaboration of sensitive and selective analytical methods. GC-based analyses, although often require derivatization of polar pharmaceuticals, they still offer the highest chromatographic resolution. Moreover, the most recent trend in analytical methods for these analytes is the development of multi-component methods among several classes of drugs, too.

The main aim of our investigation is to elaborate the multi-trace analysis of drugs derived from four different classes of pharmaceuticals including non-steroidal anti-inflammatory drugs, hormones, β-blockers and β-adrenomimetics in wastewater. Special emphasis was laid on optimization of derivatization step in these analyses. Several derivatization agents (e.g. N-methyl-N-trifluoroacetamide (MSTFA), N-trimethylsilylimidazole (TMSI), the mixture of N,O-bis(trimethylsilyl)trifluoroacetamide with trimethylchlorosilane (BSTFA+TMCS)) were used to prepare the appropriate derivatives. Parameters such as the volume of derivatization reagents, time of the reaction, temperature of the reaction were tested. Additionally, different GC conditions were applied in term to obtain the highest chromatographic resolution and the lowest limits of detection. The results of this investigation will be shown and discussed.

**Matrix effect during the determination of endocrine disruptor compounds in wastewater samples during membrane assisted solvent extraction**

O Zuloaga[1], A Iparragirre[1], M Olivares[1], P Navarro[2], A Prieto[3], A Usobiaga[1], N Etxebarria[1], LA Fernández[1]
[1]University of the Basque Country, BILBAO, Spain
[2]CNRS-UPPA, PAU, France
[3]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany

EDCs, defined as "exogenous substances that alter function(s) of the endocrine system and consequently cause adverse health effects in an intact organism, or its progeny, or (sub)-populations"[1], can have synthetic and biological origin and include hormones, insecticides, phytoestrogens or industrial chemicals. Such EDCs are often detected in waste water treatment plants (WWTPs) effluents and their receiving environments since not all micropollutants are completely removed in such plants [2,3]. In fact, effluents from several WWTPs have been reported to be estrogenic to fish [4].

The determination of EDCs such as alkylphenols (APs), hormones and sterols requires of a preconcentration step in order to analyse target analytes at low ng/L level. During the last decade the use of sample preparation techniques that minimise solvent consumption have been proposed as alternatives to classical techniques. Membrane-assisted solvent extraction (MASE) guarantees low solvent consumption since the acceptor phase is protected by a non-porous membranes. Many variables are studied during MASE development and matrix effect should always be included when complex samples such as the influents and effluents of wastewater treatment plants are studied. In the present work matrix effect during the determination of a variety of EDCs in wastewater was studied both during the extraction and the detection steps. For the detection both liquid chromatography-tandem mass spectrometry (LC-MS/MS) and large volume injection-gas chromatography-mass spectrometry were considered.

**The fate of pharmaceuticals during biological nutrient removal sewage treatment**

T Popple[1], J Williams[1], R Oliver[2], E May[1], G Mills[1]
[1]University of Portsmouth, PORTSMOUTH, United Kingdom
[2]Brixham Environmental Laboratory, BRIXHAM, United Kingdom

Biological nutrient removal is becoming a widespread sewage treatment technology in the UK and Europe. The reduction in nutrients such as nitrogen and phosphorus from water bodies are key strategies outlined in the Water Framework Directive (2000/60/EEC). Sewage treatment plant (STP) effluents are identified as the principal contributors of these nutrients, which if left untreated can lead to eutrophication. Therefore in many sensitive areas STPs are designed to include a step to remove such problematic nutrients. With conventional activated sludge plants decreasing in numbers the aim of this research is to understand the potential underlying benefits of biological nutrient removal (BNR) for removing pharmaceuticals from wastewater.

During BNR the sewage passes through areas of differing redox potential, increasing the opportunity for alternative degradation pathways. Laboratory batch tests have been designed to reproduce the redox conditions necessary for BNR. These tests will assess the biodegradation outcome of five radiolabelled pharmaceuticals; salicylic acid, caffeine, diclofenac, carbamazepine and propranolol.

Nitrifying (aerobic) redox conditions are relatively simple to achieve by adding ammonium to the activated sludge biomass and aerating. Denitrifying (anoxic) conditions are attained by adding a source of nitrate with no aeration and anaerobic conditions by purging the vessel headspace with nitrogen. The reference compound $^{14}C$ PEG 400 was dosed at a concentration of 0.1 mg/l into aerobic and anoxic vessels, under each condition the compound was mineralised by over 75%. The reference compound demonstrated the viability of the activated sludge. In the next phase $^{14}C$ propranolol was dosed at 0.01 mg/l under the same conditions. Mineralisation was 50% for aerobic conditions and 27% for anoxic conditions. These results demonstrate the potential for anoxic conditions to mineralise $^{14}C$ propranolol suggesting when redox conditions are linked together in a flow through system representative of full scale plants total mineralisation could be higher than during aerobic only treatment. Further work will focus on removal during a flow through system.

### TH 178

**Biodegradation of pharmaceuticals by active heterotrophic biomass in activated sludge and its link to sludge age**

M Majewsky[1], T Gallé[1], M Bayerle[1], K Fischer[2]
[1]CRP Henri Tudor, ESCH-SUR-ALZETTE, Luxembourg
[2]University of Trier, TRIER, Germany

Microbial biomass is a key factor for the biological elimination of polar pharmaceutical active compounds (PhACs) during activated sludge treatment. It is usually addressed by lumped param-

eters such as volatile or total suspended solids (Xss) that do not consider differences in microbial activity or consortia. This can lead to biased estimations in fate prediction or in the determination of biodegradation rates. In this context, only little attention has been paid to identify responsible PhAC-degrading microorganisms as well as to the question of weather they can be actually characterized (cost-effectively) as a sum parameter or estimated from other parameters such as the sludge retention time (SRT). The latter has been suggested as a predictor parameter for slow growing bacteria resulting in increased pharmaceutical removal efficiency which is, however, controversially discussed in the literature.
Investigating this, the presented study focused on the active heterotrophic biomass Xbh that governs COD removal suggesting a potential determining factor for biological PhAC removal as well. Activated sludges from two wastewater treatment plants that clearly differed in size, operation, SRT and active biomass were investigated. The biodegradation rates of the five polar PhACs caffeine, paracetamol, sulfamethoxazole, diclofenac and carbamazepine were determined using a combination of biodegradation batch experiments and respirometry tests. The latter allowed the simultaneous estimation of the active heterotrophic biomass Xbh.
Fractions of Xbh / Xss varied significantly between the sludges showing that Xss contains little information if any concerning heterotrophic activity. Notedly higher removal rates of the selected compounds were observed in sludge with low SRT and a high Xbh fraction.
The variability of biodegradation rates could be largely explained by using the Xbh in pseudo first-order reactions. It suggests that Xbh greatly governs the removal of the selected pharmaceuticals which is consistent with the fact that high Xbh fractions are linked to low SRTs. The selected substances are all (heterocyclic) aromatic carbohydrates and are assumed to follow similar breakdown pathways as other aromatic carbohydrates present in wastewater and therefore being subject to non-specific enzyme cleavage. Naturally, due to the broad variety of xenobiotic compounds in domestic wastewaters, testing for other substances with different molecular structures is required.

**TH 179**

**Heavy metals mass balance and efficiency of removal in three wastewater treatments plants**

A Usobiaga, M Pazos, JA Carrero, N Goienaga, S Fernandez, G Arana, LA Fernandez, O Zuloaga
Euskal Herriko Unibertsitatea (UPV/EHU), BILBAO, Spain

The presence of heavy metals in wastewater is one of the main causes of pollution in water and soil [1]. There has been a growing concern over the effects of heavy metal due to their biomagnifications [2] and, in this way, metal production has decreased due to legislation, as in the case of Hg.
The behavior of heavy metals in wastewater treatment plants has been extensively studied in recent years [3]. The removal of these metals in the water line of the plants generates accumulation in sewage sludge. The destination of sewage sludge is one of the problems of the wastewater treatment plants as they have high concentrations of metals. The agricultural use of the sludge according to the spanish regulation RD 1310/1990 is one of the alternatives to minimize the impact on the environment [4].
This work analyzes the behavior, mass balance and efficiency of removal of 12 metals (Al, Ni, Cd, Zn, Hg, Fe, Cu, Mn, Sn, Cr, As and Pb) in three wastewater treatment plants in Bizkaia (Basque Country, Spain). These plants are located in the towns of Bakio, Gernika and Galindo and they present different characteristics due to the size of population they serve and to economical activity.
The analysis of the obtained results concluded that the behavior of these three plants is quite similar in spite of their different characteristics. The efficiency of removal for the majority of the metals is around 85 %, except for Cd, Mn and Hg. The analysis of the sludge concluded that they are useful for agricultural use according to RD 1310/1990.

**Degradation of PPCPs in activated sludge-comparison between degradation kinetics obtained from sludges from four different WWTPs under normalized conditions**

A Gieraltowska[1], J Vollertsen[1], JL Nielsen[1], X Chen[1], K Bester[2]
[1]Department of Biotechnology, Chemistry and Environmental Engineering, Aalborg Un, AALBORG, Denmark
[2]National Environmental Research Institute, Aarhus University, ROSKILDE, Denmark

The presence of pharmaceuticals and personal care products (PPCPs) in wastewater treatment plant effluents have been an emerging issue in environmental science, thus more knowledge on removal kinetics and mechanisms is needed.
In this study we focused on comparing the biodegradation kinetics of PPCPs in different activated sludge samples collected from four different wastewater treatment plants (WWTPs) under normalized conditions. Naproxen, Ketoprofen, Fenoprofen, Carbamazepine and Triclosan were analysed in the experiments. The 1st order degradation rates (normalized to sludge biomass) differed significantly (e.g. for Triclosan from 0.0025 to 0.0082, for Fenoprofen from 0.007 to 0.081) with huge consequences on potential removal efficiencies due to biodegradation in different activated sludges under aerobic conditions. Furthermore, the possible treatment plant-dependent factors influencing PPCPs removal, such as sludge concentration, sludge retention time, hydraulic retention time, temperature, pH and oxygen concentration were investigated.

**TH 181**

**Can laboratory activated sludge simulations be used to predict the fate of propranolol in sewage treatment plants?**

R Oliver, C Roberts
Brixham Environmental Laboratory, BRIXHAM, DEVON, United Kingdom

Propranolol is a non-selective beta blocker mainly used in the treatment of hypertension. It was the first successful beta blocker developed in the late 1950s and therefore it has been widely used for many years. It is excreted mainly as metabolites, but published data for sewage effluents and sewage treatment plant (STP) removal rates show that propranolol is discharged into the environment. This makes propranolol a good compound for comparing laboratory derived data with sewage treatment plant (STP) monitoring data.
The activated sludge (AS) simulation used 14C propranolol and was conducted following a modified OECD 303A approach. The study was dosed at 0.01 mg L-1 for the first 40 days, thereafter this was increased to 0.1 mg L-1. In the first 120 days liquid scintillation counting showed that there was up to 37% removal of propranolol from the effluent. By the end of the study (250 days), HPLC analysis of the effluent showed that radioactivity was not the parent compound indicating primary degradation of propranolol. The AS simulation mass balance data provided further information about the fate of propranolol. This showed that most of the radioactivity was in the effluent, and not adsorped to the sludge solids, <1% was trapped as 14CO2, indicating limited mineralisation in the first 120 days.
The laboratory simulation data is very similar to field STP data for the first 120 days. Data published in the last four years shows that propranolol is removed by up to 35% in modern STPs. However, the latter stages of the simulation show higher removal than field data. Future laboratory studies should include both LSC and HPLC analysis at each sampling point to remove any ambiguity when interpreting the data. AS simulations that run for long periods (>120 days) would benefit from microbial analysis to determine if there are any shifts in population dynamics. This would allow adaption and/or acclimation of the microbial communities to be evaluated. AS simulations would benefit by including tertiary treatments such as sand filtration, ozonation or/and activated carbon as these have been shown to be good at removing pharmaceuticals and are used frequently in STPs.

**TH 182**

**State of art of lanthanum-modified clays: concerns and evidence**

M Luini, E Papa, S Kovarich
University of Insubria, VARESE, Italy

Eutrophication is a common process of many lakes, rivers wetlands and estuaries caused by an abnormal proliferation of algae. The main cause of this large proliferation is the high concentration of nutrients, particularly phosphorus and nitrogen compounds, derived from natural and anthropogenic sources (such as urban and industrial discharges, use of fertilizers and detergents). The most important effects of eutrophication are: development of toxic species of phytoplankton, increased water turbidity and odor, decrease in the amount of oxygen dissolved and decline of biodiversity.
In recent years a variety of restoration techniques have been employed. The novel lanthanum-modified clays (generally bentonite) water treatment technology seems to be effective in remediation of eutrophic water system.
The active ingredient in these products is lanthanum ($La^{3+}$) that can bind phosphate from the water column and stabilize sediment in order to prevent possible resuspension phenomena.
The main concerns derived from the use of these products are linked to the possible environmental effects, especially for lanthanum ions released from bentonite to aquatic organisms after the application into the environment.
A fair number of studies and technical reports are available about toxicity, eco-toxicity and bioavailability of modified-clays and of lanthanum.
Most of these studies reported no significant evidences about lanthanum-modified clays toxicity to aquatic organisms and humans at suggested applied dose rate. It's also evident that the results of the toxicological tests are influenced by the conditions test (in particular by the physical-chemicals properties of the medium) and by tested species.
Available reports also suggest that the amount of $La^{3+}$ released from bentonite following the application in water system, is very low. Once released it would be almost immediately captured by the humic acids present into the natural waters, becoming not bioavailable to the organisms.
The informations currently available therefore suggest that the use of lanthanum-modified clays could be an effective and generally safe solution against eutrophication.

**TH 183**

**Concentration profiles and environmental load of emerging pollutants from Swedish sewage treatment plants**

MU Olofsson, P Haglund
Umeå University, UMEÅ, Sweden

In the society today, an ever-increasing number of chemicals are used. Some of these chemicals are eventually released into the waste streams handled by municipal sewage treatment plants (STPs). The purpose of this study was to perform an extensive screening of persistent organic pollutants (POPs), pharmaceuticals and personal care products (PPCPs) and other organic contaminants (including many emerging pollutants) both in effluent water and sludge from Swedish STPs. The STPs use conventional methods for treatment of the sewage, including mechanical, chemical and biological processes. Solids that are removed from the water is then anaerobically digested or aerobically stabilized and dewatered. The sampling campaign occurred in September and October 2010 when the weather conditions were approximately average of the time of year (average temperature: 9.4 ± 2 °C). Composite (n = 7) effluent samples were flow proportionally sampled in dark 2.5 L bottles (totally 17.5 L) and stored in a dark cold-store prior to chemical analysis. Sludge samples (1000 g wet weight) were collected as grab samples in dark bottles and stored in a freezer at -18 °C until chemical analysis.
In order to be able to estimate the environmental load, mass flows of the pollutants at each STP were calculated from their measured concentrations and estimates of water and solid mass flows at the time of sampling. The environmental load of the pollutants, as well as concentration profiles, did not differ very much between the STPs. The distribution between the water and solid fractions for the pollutants can, at least partly, be explained by their chemical and physical properties. The treatment process and load of the STPs (number of inhabitants, catchment area, geographic location, industry etc.) have also been taken into consideration during data evaluation. Lipophilic POPs are, as expected, separated to sludge while semi-persistent water soluble pollutants, in general, seem to pass through STPs relatively unaffected of the treatment process. PPCPs are highly presented in the sludge and also recovered in large proportions (about 40% in average) compared to the annual national consumption (based on Swedish national statistics). In conclusion, the overall pattern of the pollutants within the investigated STPs, as well as the environmental load, is rather similar.

**TH 184**

**Effects of the wastewater treatment plants on remediation of a closed gulf**

EN Sazakli, VP Ntzola, MN Leotsinidis
University of Patras, PATRAS, Greece

The level of pollution in Patraikos Gulf, Greece, was evaluated at two time intervals, in 1992 and eighteen years later, in 2010. Metals and Polycyclic Aromatic Compounds (PAHs) were determined in sediments, marine organisms and seawater. Sediment Quality Guidelines (SQGs) and Contamination Factors were applied to assess the contamination status. The main difference between the two time periods is that in 1990s no wastewater treatment plants existed to treat the municipal wastes produced by about 250000 residents living in the city of Patras and contiguous areas, while the adjacent industrial area was equipped with a secondary treatment plant discharging its effluents into a river (Pirros). The river's mouth is located at the center of the south coast of the Gulf. In the early 2000s two wastewater treatment plants were constructed and served the whole population while two submarine outfall pipelines started to discharge the treated industrial and municipal effluents with a dilution factor of about 1: 200.
Results. Metals that originate from the geological structure of the basin did not show any difference during the two time spans. On the contrary, metals reflecting anthropogenic activities, i.e. Cu, Zn, Cd, Pb and partially Ni, as the factor analysis revealed, were found at significant lower concentrations at the second sampling compared with the first one. As for PAHs, their mean values were close to the detection limit at both time periods. The indigenous marine organism Pinna squamoza was chosen as a living indicator during the first monitoring due to its specific characteristics. Significant decreases were observed in their metals' content during the second sampling reflecting the improvement of the situation. Seawater samples showed no significant variations in the metals' concentrations. Contrary, phosphorus has been significantly reduced.
Conclusions. The construction and operation of wastewater treatment plants, in compliance with the relative European directive, especially in coastal areas that were receiving wastewater effluents seems to improve the pollution status and contribute to the ecosystem reclamation. This fact proves that even closed gulfs that have been polluted, can be remediated so as to preserve the beneficial use of the sea and its product.

**TH 185**
**Heavy metals in intertidal rocky shore species: effect of sewage discharges**
PL Cabral-Oliveira, MA Pardal
CEF - Centre for Functional Ecology, COIMBRA, Portugal
The discharges of sewage effluent treatment plants have a major impact on coastal communities. Not only by the organic and nutrient enrichments but also due to heavy metals contamination. We can estimate the pollution caused by heavy metals on aquatic systems by analyzing water, sediments and marine organisms.
This study examines the influence of sewage pollution on the concentration of trace metals (Cu, Zn, Pb, Ni, Co, Cr, Fe, Mn) on intertidal rocky shore communities, quantifying those metals on water, sediment and the most abundant species.
The study was conducted on the Peniche peninsula, on the western Portuguese coast. We chose three shores: one received the effluent of a sewage treatment plant (impacted area) and the others were used as references.
The specimens were collected randomly by hand on the intertidal shores, and then placed in polythene bags and frozen at -20ºC. Metals concentrations were determined by atomic absorption spectrophotometry (GFAAS) after acid digestion.

**TH 186**
**First evidences of polycyclic synthetic musk compounds in surface water systems in Italy: galaxolide, tonalide and celestolide concentrations in the Molgora river (Lombardia Region, Northern Italy)**
S Villa, AL Assi, BP Bonfanti, FA Finizio
University Milano Bicocca, MILANO, Italy
Polycyclic synthetic musk (PCMs) compounds, are used as fragrances in a wide array of personal care products. In view of their yearly global use, such substances are classified as High Volume Product Chemicals in Europe. For instance in 2000, at EU level, it has been estimated a global usage of 1427 and 343 tons of galoxolide and tonalide respectively. The removal of PCMs during municipal sewage treatments process has been estimated at approximately 40-60%. In view of their broad form of use and biological stability it is not surprising to find these compounds as contaminant of aquatic environments. As matter of fact, in the last few years there is an increasing number of publications indicating the presence of PCMs in surface water systems and in the aquatic biota, with concentrations ranging from ng/L to μg/L and μg/kg to mg/kg lipid weight respectively. Surprisingly, literature data, reporting the presence of PCMs in the Italian aquatic systems, are very scarce and jeopardized even if the very large use of personal care products. To partially contribute to fill the gap of knowledge in our country a monitoring survey of galaxolide, tonalide, traseolide and celestolide started in 2010. The survey was conducted along the Molgora river located in a very densely populated area of Lombardia Region, Northern Italy. Water, river water and sediment samples were carried out seasonally in 7 monitoring stations. The first one located in a natural protected area was used as background level of pollution. The other monitoring stations were located up and downstream of the three sewage treatments plants (STPs) present along the river. The results obtained indicated in all cases an increase of PCMs concentrations immediately after the 3 STPs with the highest contamination in the last sampling station. Concentrations found are in agreement with literature data with galaxolyde > tonalide >> celestolide. Finally, no significant differences were found in samples collected seasonally in the same location indicating a continuous input of PCPs during the year.

**TH 187**
**Contribution and risk of antibiotics from hospitals in urban areas: the case of Lausanne, Switzerland.**
S Coutu[1], Y Bonnefin[1], L Blanc[1], N Chèvre[2], CS Mc Ardell[3], L Rossi[1]
[1]EPFL, LAUSANNE, Switzerland
[2]Unil, LAUSANNE, Switzerland
[3]EAWAG, DÜBENDORF, Switzerland
Antibiotics are substances commonly consumed by the population under medical prescriptions. These compounds may reach the environment through human excretion as they are partially eliminated in WWTPs. The occurrence of antibiotics in the aquatic environment is therefore of particular concern as they can present a risk for both ecosystems and human health. Furthermore, they have the potential to foster bacterial resistance.
One source of antibiotics in the environment can be linked with hospitals activities. In this study, antibiotics were measured in the effluent of the main building (650 beds) of the biggest hospital of Lausanne city (CHUV, 1200 beds), Switzerland. In parallel, the entry and the outlet of the WWTP of the city as well as the receiving waters (lake Geneva) were also investigated, collecting samples of wastewater or lake water. Nine antibiotics (azithromycin, ciprofloxacin, clarithromycin, clindamycin, metronidazole, norfloxacin, ofloxacin, trimethoprim, sulfamethoxazole) were analyzed with SPE extraction followed by LC-MS/MS analysis. Results showed high concentrations in the range 2.3 - 32'000 ηg/L at the outlet of the hospital that may represent a risk of bacterial resistance induction. The mass of antibiotics measured at the outlet of this hospital, expressed in nanograms per bed, was extrapolated to all clinics and medical centers of the city (representing 3540 beds in total) and used to compute the total production of antibiotics from hospitals for the all city. The total antibiotic mass at the entry of the WWTP of all hospitals and medical centers represent a small fraction of the total measured amount of antibiotics (< 5%) except for ciprofloxacin (15,1%) and sulfamethoxazole (23.6%). Similar results were obtained in a study at the hospital site in Baden. For some antibiotics (azithromycin, metronidazole, norfloxacin), concentrations at the entry of the WWTP were higher in comparison with hospital concentrations. This demonstrated an important consumption of antibiotics by the population outside of medical centers. After treatment in the WWTP, concentrations of antibiotics were reduced but were still bigger than PNEC values for clarithromicyn and sulfamethoxazole. Finally, after dilution in Geneva Lake, the measured concentrations are below effects values. However, the risk of multiresistant bacterial discharged from hospitals is another issue that needs consideration.

**TH 188**
**BOD5 and COD of leachate and piezometric water from semi controlled, non sanitary landfill in Novi Sad, Serbia**
M Djogo, A Dvornic, MV Miloradov, G Vujic, J Radonic, MT Sekulic
Faculty of Technical Sciences, NOVI SAD, Serbia
The absence of landfill liner systems means that disposal of solid waste often leads to water pollution. In such cases, water percolating through the waste and dissolving various materials is considered the most serious environmental impact of landfill and causes surface and groundwater pollution. Landfill leachate is one of the most complex problems of municipal solid waste landfills. Leachate is generated as a result of the percolation of water through landfill body and the squeezing of the waste due to its weight, and it is contaminated with dissolved and suspended organic and inorganic compounds with different characteristics. Since all natural waterways contain nutrients and bacteria, their enzymes will initiate biochemical reactions of almost any waste compounds that are introduced into such waterways. Any oxidizable material present in a leachate will be oxidized both by biochemical (enzymatic) or chemical processes. The result is that the oxygen content of the water will be decreased. Both the $BOD_5$ and COD tests are a measure of the relative oxygen-depletion effect of a waste contaminant. In August and September of 2008. research campaign was conducted to determine composition and quantity of waste that is disposed at landfill in Novi Sad. The landfill in Novi Sad is semi controlled non sanitary, municipal waste landfill without impermeable bottom liner to prevent impact contamination of soil and groundwater with leachate. The biggest part of waste from households and commercial sector is biodegradable organic waste that is decomposed by microbiological and chemical mechanisms in landfill body. The leachate samples and samples from piezometers were collected from collecting channel and 6 piezometers in municipal solid waste landfill in Novi Sad in January and May of 2010. From obtained results of $BOD_5$ and COD it can be concluded that the leachate from landfill in Novi Sad is contaminating soil and groundwater in continuus. The most contaminated piezometer is the one that is located downstream from landfill body and suffers most of the contamination. The groundwater level in this part of landfill is very high so there is justified concern for spreading of contamination. Because leachate is very toxic (high content of heavy metals, organic matter and pathogenic microorganisms) it is necessary for landfill to be sanitary in order to prevent further soil, groundwater and contamination of surrounding environment.

**Elimination of micropollutants using engineered constructed wetlands - a laboratory scale study**
L Rossi, AB Brovelli, PQ Queloz, DH Ho, DAB Barry
EPFL, LAUSANNE, Switzerland
In Switzerland, a new standard for wastewater treatment plants (WWTP) - 80% reduction of micropollutants from raw sewage - is under consideration. Five substances have been proposed as target compounds: Diclofenac, Carbamazepine, Mecoprop, Sulfamethoxazole and Benzotriazole. Although very efficient and reliable, advanced treatment technologies for traditional WWTPs - such as ozonation - are expensive and difficult to implement on relatively small WWTPs, of which there are many in Switzerland. To tackle this problem, we propose to develop a promising technology for supplemental treatment of wastewater: engineered subsurface flow constructed wetlands (ECWs).
Classical constructed wetlands (CW) are passive systems, using natural processes to transform and remove contaminants from wastewater. In this work, we have developed and proposed a different design paradigm, i.e., to combine in a single ECW both natural processes (as in CWs) and ad hoc engineered treatments. The resulting system - an ECW - will combine the strengths of both natural and engineered processes, that is, it will be efficient and reliable, with low maintenance and running costs. However, there is still a lack of detailed knowledge of the factors influencing micropollutant degradation and, ipso facto, in the ability to optimize the conditions for contaminant effective elimination.
A laboratory scale study was performed to develop a combination of treatments able to achieve the target elimination rate for micropollutants. Based on a literature review, two processes - direct photolysis and adsorption by light expanded clay aggregates (LECA) - were expected to remove more than 80% of all target compounds. Batch experiments were conducted to test the removal efficiency of each process alone. Direct photolysis removed 60 to > 95% of four compounds while adsorption by LECA showed only moderate elimination. A laboratory-scale ECW combining the two removal treatments with biodegradation was subsequently performed to evaluate whether the combined processes could enhance the degradation rate. It was found that removal of just three target compounds was enhanced. A conceptual model was developed and will be used as starting point for modeling micropollutant removal in ECW's in future studies. Based on the measurements and insights gained from the model, possible reasons for the relative poor performance observed will be discussed, and possible improvements presented.

**TH 190**
**Removal of selected endocrine disrupting chemical during on-site wastewater treatment using a constructed wetland**
M Mills[1], B Boulanger[2], N Engel[3], C Nietch[1]
[1]US EPA Office of Research and Development, CINCINNATI, United States of America
[2]Texas A&M University, COLLEGE STATION, United States of America
[3]University of Cincinnati, CINCINNATI, United States of America
Significant research has shown that domestic and industrial wastewater can be a source of endocrine disrupting chemicals (EDCs) to the environment. Much of this research has focused on municipal and industrial centralized wastewater treatment plants. These plants have been shown to be a significant source of both natural and synthetic hormones and alkylphenolic compounds to

receiving systems. However, in the US, about 25-30% of wastewater is treated using decentralized wastewater treatment technologies. These technologies (septic systems, constructed wetlands, etc) have not been adequately characterized for their capacity to manage these emerging contaminants. The focus of this study is to characterize both the seasonal loading of these compounds to a constructed wetland receiving domestic wastewater and to characterize the removal capacity of the wetland treatment unit.
The research was conducted over two years at a subsurface constructed wetland designed to treat domestic wastewater. The loading to the system is primarily from a retreat center in southwestern Ohio that receives a low flow (8-12 people) of domestic waste the majority of the time with periodic high flows (greater than 50-100 people).. The influent and effluent flows were characterized for hormones (7 natural and 1 synthetic), alkylphenol ethoxylates (including the octylphenol ethoxylates and nonylphenol ethoxylates and their respective metabolites), nutrient (species of N and P), TOC, and pathogens over a two year period to evaluate season loadings and treatment capacity of the wetland. Results have shown, to date, that the EDC are treated to varying degrees dependent on loading and seasonal condition of the wetland. Evaluations of loading rates, removal rates, and season relationships will be presented.

**Hot flushes and hormones - can microwave technology reduce endocrine disrupting activity?**

H Slater, D Mavinic, K Hall
University of British Columbia, VANCOUVER, Canada

Wastewater effluents and storm-water runoff are now thought to be among the major sources of endocrine disrupting chemicals discharged to the aquatic environment. Many studies have reported endocrine disrupting effects on fish located near wastewater outfalls and some EDCs once applied to soils can be taken up by plants. Environmentally relevant concentrations of a few selected EDCs have been reported but the concentration of many implicated EDC compounds in municipal sludge remains largely unknown.. Therefore, municipal wastewater sludge disposal in landfills and land application of biosolids may pose a risk to aquatic life in receiving waters through runoff and leaching processes.
Microwave processes have been widely used for diverse applications throughout the food industry. More recently, microwave technology has been applied and investigated for sludge drying, pasteurization, solids reduction and phosphate recovery. Uniform heating and precise temperature control are the key primary advantages of the microwave process. Non-ionizing electromagnetic radiation from the production of microwaves are thought to produce both athermal and thermal effects in sludge at a molecular level and this, in turn, could offer potentially valuable wastewater treatment options.
In this poster, we describe the application of microwave processes with pre- and post-digested sludge from a municipal sewage treatment plant utilizing conventional sludge digestion (mesophillic anaerobic) to investigate and demonstrate the viability of this innovative wastewater treatment technology to reduce whole estrogenic activity in municipal sewage sludge. Using GC/MS chemical analyses and bioluminescent yeast estrogenic screening assays, a mass balance approach was adopted to assess whole estrogenic activity in the municipal wastewater treatment plant sludge.

**TH 192**

**Electrocatalytic degradation of anions used in ionic liquids**

EM Siedlecka[1], S Steudte[2], A Fabianska[1], S Stolte[2], P Stepnowski[1], J Thöming[2]
[1]University of Gdansk, GDANSK, Poland
[2]University of Bremen, BREMEN, Germany

Ionic liquids (ILs) have been area of great interest owing to unique properties and unlimited resources for designed properties by variation of cation or/and anion. Among the several applications foreseeable for ILs in the chemical industry such as solvents in organic synthesis, as homogenous and biphasis transfer catalysts, and in electrochemistry, as extraction media. However, from the environmental point of view despite the excellence of their technical performance the release of these chemicals could be a problem for the environment. When effective regeneration or recovery at a reasonable cost is not possible, utilized ionic liquids should be destroyed using suitable advanced oxidation processes (AOPs). They are designed to generate hydroxyl radicals (-OH) as a primary, non-selective oxidizing agent. A few advanced oxidation technologies have been proposed as a consequence of some ILs being refractory to biological treatment. Among them, a particularly attractive treatment option for non-biodegradable ILs is electrochemical oxidation using so called "non-active"electrodes (BDD, $PbO_2$). The electrochemically oxidation of imidazolium cations showed the influence of their side chain structure on efficiency treatment and pathway of degradation process.
The main goal of the presented investigations is to shield more light on the electrochemical degradation processes of anions typically used in ILs. Degradation of 1-butyl-3-methylimidazolium salts with different anions ($Cl^-$, $Br^-$, $PF_6^-$, $BF_4^-$ $CF_3SO_3^-$, $C(CN)_3^-$) was carried out on "non-active"BDD and "active"$IrO_2$ electrode in $Na_2SO_4$ water solution. The obtained results are discussed and intercompared.

**Towards understanding of ionic liquid (IL) fate in the degradation processes: investigations of ILs interactions with O2-• radicals**

EM Siedlecka, J Czupryniak, A Fabianska, T Ossowski, P Stepnowski
University of Gdansk, GDANSK, Poland

In recent years ionic liquids have gained a broad of interest, because of their great potential to be used in industrial possesses based on different tuneable properties. Concerning the chance of wide applications of ionic liquids in the industry there appears a real risk of finding them soon in industrial wastewater and finally in the environment. Therefore, there is a need to look at their properties from the point of view of their ageing in industrial processes and through wastewater treatment, before they reach the surface- and groundwaters.
Electrochemistry plays an important role in many areas of science and technology. On the one side, some of IL could be very good electrolyties e.g. in batteries. From the other side the electrochemically methods successfully used for degradation of toxic and not readily biodegradable organic pollutants, could be applied for degradation of ILs in wastewater. Depending on conditions of electrooxidation process, active entities such as $^{\cdot}OH$, $O_2^{\cdot-}$, $S_2O_8^{2-}$, $ClO^-$ etc, could be generated on electrode surface. The identification of these entities, determine their reactivity towards the organic pollutants. Additionally they present information about degradation pathway and are very important for estimation of efficiency of the degradation method. From the other side it has been shown that these oxidizing entities may be present in all oxygen-metabolizing organisms and its toxicity has been recognized.
The investigation concern the interaction of superoxide ion with ionic liquids contains an imidazolium headgroup in cation. Some of the alkyl side chains were substituted by functional groups such as hydroxyl or phenyl residues. They were studied by the cyclic voltammetry technique. The generated intermediates were identified and the degradation pathway of IL by $O_2^{\cdot-}$ radicals is presented.

**The degradation of ionic liquid on the electrodes with different electrocatalytic properties**

EM Siedlecka[1], S Stolte[2], A Fabianska[1], AK Nienstedt[2], M Golebiowski[1], P Stepnowski[1], J Thöming[2]
[1]University of Gdansk, GDANSK, Poland
[2]University of Bremen, BREMEN, Germany

Industrial effluents containing toxic and recalcitrant organic compounds lead to serve environmental problem. Traditional treatment methods, including biological, physical and chemical treatment are ineffective, and thus a number of alternatives have been researched. Electrocatalytic oxidation is one of the alternatives for efficiency degradation of these compounds. It is suitable for a low-volume application, versatility, energy efficiency, amenability to automatization and environmental compatibility method. Electrode material is one of the most important factors influent on the efficiency of degradation process and cost effectiveness. Ionic liquids (ILs) (alternative solvents, extrahents, electrolytes, etc.) characterized by wide applicability which is mainly based on their beneficial physico-chemical properties and their tuning possibilities. Thus ILs become more popular and they may pose a real risk of being present in technological wastewater, aquatic environment and soil. The impact of ILs on aquatic ecosystem is highly important since some ILs have a high solubility in water. Therefore there is a need to look at possibilities of their degradation in effluent, before they enter environmental systems.
The presented investigations are focused on the electrochemical oxidation of 1-butyl-3-methylimidazolium chloride on anodes with different electrocatalytic properties such as: BDD, $PbO_2$, $IrO_2$ and Pt/Ir. Cyclic voltammetry experiments were carried out to get a better understanding of IL electrooxidation process. The investigations were also focused on the identification of main oxidants species and intermediates generated by electochemical process.

**Elimination of micropollutants in wastewater treatment plants : ozonation or activated carbon? Conclusions of a pilot project over one year.**

J Margot[1], A Magnet[2], D Thonney[2], C Chèvre[3], F de Alencastro[4], C Kienle[5], C Abegglen[6], AD Barry[4], L Rossi[4]
[1]Ecole Polythechnique Fédérale de Lausanne (EPFL), LAUSANNE, Switzerland
[2]Wastewater treatment plant, LAUSANNE, Switzerland
[3]University of Lausanne, LAUSANNE, Switzerland
[4]Ecole Polytechnique Fédérale de Lausanne (EPFL), LAUSANNE, Switzerland
[5]Swiss Centre for Applied Ecotoxicology, Eawag/EPFL, DÜBENDORF, Switzerland
[6]Swiss Federal Institute of Aquatic Science and Technology (Eawag), DÜBENDORF, Switzerland

Many organic micropollutants present in wastewater, such as pharmaceuticals and pesticides, are poorly removed in conventional wastewater treatment plants (WWTP). To reduce the release of these substances into the aquatic environment, advanced treatments are necessary and will be soon mandatory in Switzerland. Two advanced treatments were tested in pilot systems over more than one year at the municipal WWTP of Lausanne, Switzerland. The first pilot involves the ozonation of the effluent to oxidize organic substances. It is followed by a sand filtration (SF) to remove the readily biodegradable reaction products. The second pilot consists of a powdered activated carbon (PAC) addition into the effluent to sorb micropollutants. It is followed either by a membrane filtration (ultrafiltration) or a sand filtration to separate the PAC from the treated water. A selection of 58 potentially problematic substances (pharmaceuticals, pesticides, endocrine disruptors) were regularly measured at different stages of treatment by ultra performance liquid chromatography coupled to a tandem mass spectrometer, and a large battery of ecotoxicological tests (16 in vitro and 9 in vivo assays with different organisms) were performed to evaluate the toxicity of the effluents. The results showed that most compounds were removed over 80% with an average ozone dose of about 5.5 $mgO_3$/l or a PAC dose between 10 and 20 mg/l. Only some single compounds, such as X-ray contrast media, were only partially eliminated in both cases. A clear reduction in toxicity was also observed after the two treatments in most of the cases. These two processes (ozonation and PAC addition) are therefore effective to reduce the release of micropollutants into surface waters. Ozonation-SF and PAC-SF proved to be feasible in terms of implementation and operation at large-scale in WWTP, for relatively similar investment and operation costs (about 0.1 to 0.15 € per $m^3$ treated based on local costs). Each technique has its advantages and disadvantages. Therefore the method selection should be made case by case for each WWTP depending on the local constraints (e.g. space, security, energy costs, existing treatment processes, sludge disposal process, need for disinfection, etc.), the quality and the quantity of incoming water and the desired output water quality.

**Performance of coupling an heterogeneous photocatalysis (TiO2/UV) with activated sludge reactor for removing the color of an industrial wastewater.**

RN Padovan, EB Azevedo, UM Nascimento
Institute of Chemistry of Sao Carlos (USP), SÃO CARLOS, Brazil

Generally, wastewaters can be easily treated by biological reactors with a good efficiency regarding organic matter removal. However, the process can be impaired in the presence of compounds that are toxic or have low biodegradability. Advanced Oxidation Processes (AOPs) may be a choice to oxidize these compounds and minimize their toxicity and/or increase biodegradability. AOPs are based in the "in situ"generation of strong oxidants that reacts with the organic matter. The most important oxidant agent generated by AOPs is the hydroxyl radical (-OH), as they have a high oxidation potential. The aim of this work is to study, in laboratory scale, the decolorization achieved by the combination of a heterogeneous photocatalysis ($TiO_2$/UV) with activated sludge reactor, in the treatment of a wood's industry wastewater, optimizing catalyst concentration, temperature, and pH. The Hydraulic Retention Time (HRT) of the activated sludge reactor was 3 hours, with an interruption in the aeration of 30 minutes (same time used in the industry). Photocatalysis was carried out in a jacketed reactor with the irradiation of a medium pressure mercury lamp (250 W), away 20 cm from the wastewater surface (effective volume of 100 mL), magnetic stirred at 450 rpm. The biological reactor removed almost all COD of the effluent (85-90%), although color was not removed. When photocatalysis was used as a pre-treatment with 60 minutes of irradiation, there was a color removal of 60% and the ecotoxicity to lettuce seeds did not change, with the variables optimized pH 5.7, 25°C, and 0.42 g L-1 TiO2. However, color removal increased to 90% with an irradiation time of 5 hours and 30 minutes. The photocatalytic decolorization kinetics followed a first order model, with a R2= 0,992 and a of (2.60 ± 0.24) ′ 10-2 u.a. min-1. Photocatalysis is a good choice for removing the color of this effluent.

**Degradation of selected sulfonamides in the wastewater using heterogeneous Fenton system**

A Fabianska, P Stepnowski, EM Siedlecka
University of Gdansk, GDANSK, Poland

Sulfonamides are synthetic antibiotics frequently used in veterinary medicine. After use they are being excreted in large portion directly to the sewage either in the native form as well as biotransformation products. Traditional sewage treatment systems are incompatible to eliminate many residual pharmaceuticals. A very significant rate of these chemicals entering environment constitutes of sulfonamides, which environmental concentrations are noticeable and moreover most of them are quite resistant to physical and biological degradation. Therefore, the elimination process of these chemicals from wastewater is a very important step preventing their emission into the environment. Advanced oxidation processes (AOP) present highly effective alternatives to traditional water treatment processes while degrading toxic and biorefactory organic pollutants such sulfonamides. These methods are based on the generation of highly reactive agents such as hydroxyl radicals (-OH), which are a very strong and non-selective oxidants able to mineralize some of organic compounds to CO2 and H2O. Among the various types of AOPs, Fenton process presents cheap and quite useful option, where radicals are produced by catalytic decomposition of hydrogen peroxide in reaction with ferrous ion. The main drawback of this system are ferrous sludge. This problem can be solved by using heterogeneous catalyst.
The present study focused on degradation of five sulfonamides: sulfathiazole, sulfadiazine, sulfamerazine, sulfamethazine and sulfadimethazine by heterogeneous Fenton system with Fe(II)/Al2O3 as catalyst. The influence of initial pH, amount of catalyst and initial concentration of sulfonamides were studied. Biodegradability and efficiency of degradation sulfonamides in wastewater is also presented.

**Degradation of brominated flame retardants by the white-rot fungus Trametes versicolor**

E Baron[1], CE Rodríguez-Rodríguez[2], M Gorga[1], M Vilaplana[3], M Sarrà[3], G Caminal[2], T Vicent[3], E Eljarrat[1], D Barceló[1]
[1]IDAEA-CSIC, BARCELONA, Spain
[2]CSIC-UAB, BARCELONA, Spain
[3]UAB, BELLATERRA, Spain

Due to the environmental accumulation of polybrominated diphenyl ethers (PBDEs), the search of strategies for their elimination is of great interest. In the present work, *Trametes versicolor*, a white-rot fungus capable of degrading a wide spectrum of toxic contaminants, was tested for PBDE removal. Characterization of sludge from the El Prat de Llobregat WWTP (Barcelona, Spain) showed the presence of several PBDE congeners, although deca-BDE-209 was the most abundant. In vitro experiments with T. versicolor in liquid medium revealed elimination from 50% to 75% for deca-BDE-209. Similar experiments demonstrated removals of 85% and 67% (minimum degradation of 38% and 28%) for the penta-BDE and octa-BDE commercial mixtures. The fungus was then applied to sterile sludge obtained from two stages of the WWTP: the outlet of the anaerobic digestor and the thermally dehydrated sludge. For the former sludge, a slurry reactor with fungal pellets reduced the concentration of some congeners from 24% to 53%, while a solid-phase treatment of the dry sludge produced a remarkable degradation of 86% in the deca-BDE-209. The results suggest the potential of *T. versicolor* as a bioremediation agent for PBDEs removal.

**Uranium accumulation in aquatic plants: possibilities for phytofiltration**

PJC Favas[1], JMS Pratas[2], MNV Prasad[3]
[1]University of Trás-os-Montes e Alto Douro, VILA REAL, Portugal
[2]University of Coimbra, COIMBRA, Portugal
[3]University of Hyderabad, HYDERABAD, India

The work presented here is a part the on going study on the uraniferous geochemical province of Central Portugal in which, the use of aquatic plants as indicators of uranium contamination is being probed using aquatic plants emphasizing their potential use in the emerging phytotechnologies. Several of the uraniferous deposits were exploited either by underground or surface mining methods. Many of the places were left in different stages of degradation. The samples were collected in running and in standing waters (lentic and lotic) in the places were it was possible to observe aquatic species. In these sites, samples of the waters and of the vegetable species were taken. The plants collected represented the free floating and the rooted emergent plants. In the ponds, only free floating plants were found growing. The methodology adopted for the determination of the U content in the water and plants was fluorometry.
Even though we have observed very low concentration of U in the fresh waters of the studied sites we found a set of vegetable species with the ability to accumulate U in concentrations which are orders of magnitude higher than the surrounding environment. We have observed that Apium nodiflorum, Callitriche stagnalis, Lemna minor and Fontinalis antipyretica accumulated significant amounts of uranium, whereas Oenanthe crocata excluded U. These results indicate substantial scope for proper radiophytoremediation and phytosociological investigation exploiting the native flora. These species show great potential for phytoremediation because they are endemic and easy to grow in their native conditions. A. nodiflorum and C. stagnalis have high bioproductivity and yield good biomass.

**TH 200**

**Evaluation of the genotoxicity of textile effluents from the Region of Fez-Boulmane (Morocco) by the use of Saccharomyces cerevisiae mutation assay and plant micronucleus assay**

S Frassinetti[1], H Talouizte[2], M Merzouki[2], L Caltavuturo[1], C Geri[1], L Giorgetti[1]
[1]CNR, PISA, Italy
[2]Laboratory of Biotechnology, Faculty of Sciences Dhar El Mahraz, ATLAS-FEZ, Morocco

In order to investigate the genotoxicity effects of crude effluents from textile industries of Fez-Boulmane, Morocco, mutagenicity and phytotoxicity tests were carried out analysing different biological systems. Moreover the efficiency of a prototype of Sequencing Batch Reactor (SBR) working by activated sludges and obtained in Fez in a laboratory scale, was estimated by comparing the eco-toxicity results observed before and after wastewater purification in SBR system.
Evaluation of the genotoxic potential was firstly investigated by means of mutagenicity tests on D7 strain of Saccharomyces cerevisiae in different growth phases. This strain, obtained from Zimmermann, allows the contemporary evaluation of three different genetic effects: mitotic crossing over (CO), genetic conversion (GC) and point reverse mutation (PM).
In addition phytotoxicity tests were performed on Allium cepa L. and Vicia faba L., considered plant model systems for eco-toxicological studies. The same tests were also applied on Lactuca sativa L. as an example of vegetable largely cultivated in riverside areas of Fez and normally irrigated with untreated river water. The considered parameters were the mitotic index (MI), the study of cytogenetic anomalies during anaphases and telophases and the analysis of micronuclei presence.
The results obtained testing untreated wastewater demonstrated major mutagenic and phytotoxic effects in Saccharomyces and in the three analysed plant systems while after purification in SBR no more eco-toxicological consequences were observed.
The reuse of wastewater can be an obvious response to water shortage especially in African regions. But recycled wastewater can pose a danger to public health, environment, and agriculture if wastewater is not reused carefully. The data presented in this paper show the possibility of a good solution to tackle the problem of recycling wastewaters coming from textile industry pollution in Fez city, Morocco.

**Toxicity of biologicaly treated municipal and industrial effluents**

M Balode, M Pfeifere, I Putna, S Purvina, J Balodis, R Poikane, S Strake
Latvian Institute of Aquatic Ecology, RIGA, Latvia

The environmental situation in the Baltic Sea has drastically changed over recent decades. Human activities both on the sea and throughout its catchment area are placing rapidly increasing pressure on marine ecosystems. Inputs of hazardous substances also affect the biodiversity of the Baltic Sea and the potential for its sustainable use.
Effluents from industrial or municipal sources may contain hundreds to thousands of chemicals, but only a few of them can be responsible for aquatic toxicity. The prediction of waste water toxicity usually does not take into account any possible interactions between the compounds in the wastewater sample. Moreover, some highly toxic chemicals may go undetected in a complex waste water mixture.
The aim of this study was to identify the most important sources of 11 hazardous substances of special concern and to evaluate potential toxicity of biologically treated sewage from Latvian municipal and industrial waste water treatment plants (WWTP) based on the Whole Effluent Assessment (WEA) approach.
Test results show that biologically treated municipal waste water is none or slightly toxic year-around, while toxicity of industrial waste water has a seasonal character showing higher toxicity in autumn and winter.
Study revealed that biological treatment is not sufficient for acquisition of good quality status of industrial waste waters. Results demonstrate the importance of using the 'whole-effluent' toxicity approach for a reliable assessment of wastewater quality.
This study was performed in the frame of INTERREG project COHIBA "Control of hazardous substances in the Baltic Sea region".

**TH 202**

**Emerging pollutants in WWTPs effluents: ecotoxicological tests to assess the effects on specific organisms, representative of the aquatic environment**

G Carbonell, MM Babín, MV Pablos, F Martini, L San-Segundo, M Torrijos, MP Garcia-Hortigüela, JM Navas, ML Fernandez, A Valdehita, C Fernandez
INIA, MADRID, Spain

A significant entry route of priority and emerging pollutants into the aquatic environment is the discharge from wastewater treatment plants (WWTPs). The increasing presence of these substances is of concern because there is a lack of information on their fate in aquatic systems.
The purpose of this study was to characterize the effects on specific organisms representative of the aquatic environment (i.e. algae, invertebrates, amphibians and fish cell lines) exposed to WWTPs effluents in order to assess their environmental risk. In addition, chemical characterization, including priority (7 metals) and emerging contaminants (22 pharmaceuticals, 12 fragrances, 5 preservatives and 5 endocrine disrupters) have been conducted.
Four WWTPs located along the Henares-Jarama-Tajo River Basin (central Spain) were considered; samples were taken monthly for a year. General quality parameters, metals and emerging pollutants were analyzed. Acute toxicity tests (Daphnia magna, Chlorella vulgaris, Xenopus laevis), subacute test (D. magna feeding), in vitro citotoxicity and subletal effects (RTG-2 fish cell line); a new test with embryos of X. laevis, considering different molecular biomarkers and a yeast test (S. cerevisiae), stably transfected with the rainbow trout estrogen receptor and the ß-galactosidase coding sequence (LacZ) as reporter gene, were used to estimate potential adverse effects.
This study was funded by the Spanish projects CONSOLIDER-INGENIO (TRAGUA) CSD2006-00044 and RTA2010-00004-C02

**TH 203**

**Ecotoxicological evaluation of mixed domestic-industrial wastewater treatment plant effluent using Daphnia magna**

F Koçbas[1], R Oral[2], G Pagano[3]
[1]Celal Bayar University, MANISA, Turkey
[2]Ege University, Faculty of Fisheries, IZMIR, Turkey
[3]Federico II Naples University, Department of Biological Sciences, NAPLES, Italy

Organized industrial zone wastewater treatment plant receive mixed domestic and industrial influents and discharge into Gediz River with a capacity of 6,500 m3 / day in Manisa, Turkey. Samples from both influent and biological and chemical treated effluent wastewaters of treatmant plant were processed using bio-physico-chemical and toxicity tests. Toxicity of wastewaters were evaluated in an acute toxicity study using Daphnia magna as an aquatic experimental animal model. Both undiluted untreated (UWW) and treated wastewater (TWW) were severely toxic to D. magna and led to death of all exposed organisms. The 96-h ED50 value for UWW was 2.8 % and TWW was 20.4 %. The toxicity classification of effluent based on toxic unit (TU) showed that UWW was found high acutely toxic (35.7 TU) and TWW was acutely toxic (4.9 TU). Chemical analyses of UWW showed high concentrations of COD (1036.8 mg/l); TSS (58.1 mg/l); oil and grease (34.6 mg/l); total phosporus (5 mg/l), yet low concentrations of heavy metals according to effluent discharge standard regulations in Turkey. Chemical analyses of TWW showed that all parameters were lower than effluent discharge standards. In the Turkish Wastewater Control Regulations only toxicity dilution factor with fish is part of the toxicity monitoring program of permissible wastewater discharge. There is no toxicity limitation in this regulations. In conclusion, the results confirmed that toxicity testing should be applied to effluent standard regulation. The results also clearly showed that D. magna assay was an excellent method for evaluation of aquatic toxicity of mixed domestic-industrial wastewater treatment plant effluents.

**TH 204**

**Identification of potential toxicity caused by O3 and ClO2 treatment of pharmaceuticals in wastewater**

SM Furuhagen[1], M Hörsing[2], A Ledin[3], HR Anderssen[2], E Gorokhova[1], M Breitholtz[1]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Technical University of Denmark, KONGENS LYNGBY, Denmark
[3]Lund University, LUND, Sweden

Chemical oxidation treatment is an effective innovative technology in wastewater treatment plants for removal of micro-pollutants in the effluent. In particular, ozonation (O3) and chlorine dioxide (ClO2) treatments are commonly used to degrade organic pollutants. By oxidation, the micro-pollutants are generally transformed to compounds that are easier to degrade biologically. There is, however, a risk that the transformation products will have structures similar to the parent compound and still be biologically active. It has been shown, for example, that transformation products generated from Carbamazepine by chemical oxidation were more harmful to aquatic organisms compared to the parent compound. The aim of our study is to evaluate the potential risk of oxidation treatment, using O3 and ClO2, due to formation of toxic transformation products. The ecotoxicological effects caused by the two oxidation treatments were evaluated for milli-Q water spiked with an API-mixture (containing 114 pharmaceuticals), wastewater (WW) and WW spiked with the API-mixture. Tests were conducted to evaluate the toxicity of the API-mixture itself and the spiked waters had an API concentration corresponding to the EC50/LC50 values obtained from these tests. The three test systems were subjected to different doses of the oxidants and used to evaluate acute toxicity for the cladoceran Daphnia magna (48h, OECD 202) and the alga Pseudokirchneriella subcapitata (72h, OECD 201). The survival end-points were complemented by oxidative stress biomarkers to understand effect mechanisms in different test systems and species. All tests were complemented with chemical analysis to confirm to what degree the pharmaceuticals have been mineralized and degraded by oxidation.
Early results with APIs in milli-Q water treated with ClO2 indicate an increased mortality rate of daphnids in higher concentrations oxidant while the growth rate of P.subcapitata was unaffected by the oxidation treatment.

## NM02 - Fate and effects of nanoparticles

**TH 208**

**C. elegans as an indicator of environmental and human health risk due to fine dust from wood firing**

B Hegemann[1], A Ahlf[1], DR Dietrich[2]
[1]Institute of Environmental Technique and Energy Economics, HAMBURG, Germany
[2]Human and Environmental Toxicology, KONSTANZ, Germany

Along with the growing importance of wood as a renewable low-cost fuel for residential heating a risk for human and environmental health is emerging due to high particle emission from wood combustion. This project aimed to adjust biological test systems for a practicable risk assessment of fine dusts from residential heating. Test systems are supposed to account for the effect mechanism of various particles. As relevant properties of the particles we anticipate size, shape and chemical adsorbents. At first trials are conducted in suspension with characterised model particles and a sample of fine dust from wood briquette firing.
The nematode C.elegans is an appropriate test organism for environmental as well as human medical science. In the nematodetest on reproduction (ISO 10872) different effects of particles were observed accounting for their size. Particles <1µm can be internalised while particles >1µm only affect the cuticle. The shape of particles suggested an even stronger effect. The nematodetest is to be amended for gene expression analysis considering subacute response potentially inducing chronic diseases in humans. Preliminary results indicate different expression patterns of gst-4 and sod-3 according to different particle size. Biomarkers have been selected according to expected reactions towards fine particles from wood combustion. Besides gst-4 and sod-3 for oxidative stress, tir-1 and nlp-29 for immune response, vit-6 for endocrine disruption and cyp-35C1 for xenobiotic detoxification were selected. A further assimilation of the test is planned for use of filter samples and a more direct exposure at the interface between atmosphere and liquids using a chamber (Cultex) designed for this purpose.

**TH 209**

**Photo-induced toxicity of aged C60 in a marine invertebrate model**

N al Subiai[1], E Kadar[2], J Readman[2], A Moody[1], A Jha[1]
[1]University of Plymouth, PLYMOUTH, United Kingdom
[2]Plymouth Marine Laboratory, PLYMOUTH, United Kingdom

While there is growing concern over the potential detrimental impact of engineered nanoparticles (ENPs) on the human and environmental health, little is known about their fate and behaviour. We have assessed the effect of photo-oxidative aging of $C_{60}$ on its toxicity to the common mussel (Mytilus edulis). The DNA damage in the somatic cells (haemocytes) was assessed after 3 days of *in vivo* exposure to 1.0 mg $l^{-1}$ fresh $C_{60}$ ($FC_{60}$) and aged $C_{60}$ ($AC_{60}$) using the Comet assay. Whilst both forms of $C_{60}$ fullerenes caused significant increase in the level of the single strand breaks in the haemocytes, the aged form seems to be more genotoxic. In addition, significant bioaccumulation in all organs (i.e. adductor muscle, digestive gland and gills) was associated with clear signs of histopathological alterations. More subtle effects of $AC_{60}$ and $FC_{60}$ were explored using 2h pre-exposure of sperm followed by *in vitro* fertilisation and embryo development impairments were assessed. Aged $C_{60}$ caused significant mortality among spermatozoa with subsequent decline of fertilization success. Severe developmental abnormalities were also observed in 48-hr embryos developed from $AC_{60}$-exposed sperm. Spermiotoxicity is associated to DNA damage caused by production of intracellular ROS during exposure to $C_{60}$ ($AC_{60}$ and $FC_{60}$).
This study underlines the putative photo-oxidative amplification of the ecotoxicological impact of a widely used ENP.

**TH 210**

**Degradability of aged aquatic suspensions of C60 nanoparticles**

B Hartmann, I Buendía, A Baun
Technical University of Denmark, KONGENS LYNGBY, Denmark

While studies of the potential human and environmental effects of C60 and its derivatives are emerging in the scientific literature, the environmental fate of C60 is still largely unknown. In this study, aged aqueous suspensions of C60 (nC60) were investigated in the respirometric OECD test for ready biodegradability. Two suspensions of nC60 were prepared by stirring and aged under indirect exposure to sunlight for 36 months, which resulted in relatively stable suspensions with a dark-brown colour. The suspended nC60 could not be extracted into toluene and indicating that the particles were no longer present as underivatised nC60 but had undergone a transformation. TEM images and particle tracking analysis showed that the suspension consisted of particle aggregates with a size of 156 nm (SD=54nm) and 139nm (Sd=49), respectively, but also contained smaller aggregates. Samples of the nC60 suspensions (approx. 20 mg/l) were inoculated with activated sludge (30 mgTSS/L) and incubated in a mineral medium under aerobic conditions for 28 days. After 28 days no mineralization of nC60 was observed. This was not due to inhibition of the biomass, since addition of 5 mg/L sodium acetate was completely mineralized within a few days. Even with this additional carbon source no mineralization of nC60 was observed after an additional 20 days. Based on these results, aged nC60 can be classified as not ready biodegradable according to the OECD test procedure.

**TH 211**

**Bacterial test battery for risk assessment of fine particles originating from the combustion of wood**

IR Gutiérrez
TUHH, HAMBURG, Germany

Due to the increased use of renewable energy sources within the last decade, fine particle exhaust from the combustion of wood has become a relevant issue in human and environmental health risk assessment. The aim of this project was the development of bacterial screening tests that can be applied to fine particles as a whole. Hence these tests account for the bioavailability of contaminants adsorbed to the surface of particles. Three well-established bacterial tests were modified: The bacterial contact test (ISO 10871), the Umu test (ISO 13829) and the YES test. All tests are low in costs and can be performed within one day. The bacterial contact assay accounts for cytotoxicity of sediments by measuring the dehydrogenase activity in the aerobic bacterium Arthrobacter globiformis. By means of a genetically modified Salmonella strain genotoxicity of aquatic samples or extracts is determined in the Umu test. In our laboratories both tests have been successfully adapted for the evaluation of fine dust. In the YES test transgenic yeast reports estrogenicity of aquatic samples or extracts. Currently it is amended for the application with particles. To validate the adapted methods, fine dust in suspension, originating from wood briquettes, was examined in logarithmic concentrations from 0.001 to 10 mg/mL. The control was 1 mg/mL of Minusil 5, a crystalline quartz sand which has been proven to be non-toxic to both bacteria and yeast. 0.01- 10 mg/mL of the fine dust suspension triggered a concentration-dependent cytotoxicity in the bacterial contact assay compared to the control. No genotoxic effect was observed in the Umu test. Besides suspensions filters covered with fine particles were gained in the burning of beeches logs and were evaluated in the assays. They caused cytotoxicity and genotoxicity in the bacterial contact and the Umu test respectively compared to blank filters.

**Fullerene exposure to earthworms: from individual to population effects**

MJC van der Ploeg[1], NW van der Brink[2], JM Baveco[2], A van der Hout[2], R Bakker[3], IMCM Rietjens[4]
[1]WUR, WAGENINGEN, The Netherlands
[2]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[3]RIKILT, Wageningen UR, WAGENINGEN, The Netherlands
[4]Division Toxicology, Wageningen University, WAGENINGEN, The Netherlands

At present environmental risks of nanoparticles are still mostly unknown. Knowledge is especially lacking about possible effects on soil organisms and soil ecosystems. However, this knowledge is of importance because soil ecosystems may be exposed to nanoparticles and residence times of nanoparticles in soil may be long. We therefore conducted a study in which effects of nanoparticles on soil organisms were assessed. In this study, Lumbricus rubellus earthworms were exposed to fullerene C60 nanoparticles (nominal concentrations 0, 15.4 and 154 mg/kg soil), which were added to the soil. The particles, in soil extract, were visualized with TEM and showed aggregates of approximately 10 nm. Adult earthworms were exposed to C60 for 4 weeks and their offspring was exposed from cocoon to adulthood. Mortality, growth and reproduction were assessed at the level of the individual earthworm. These individual endpoints demonstrated that C60 exposure affected cocoon production, juvenile growth rate and mortality significantly. The results on individual parameters were used to model effects at the population level. The population model demonstrated reduced population growth rate with increasing C60 concentrations and a shift in stage structure for C60 exposed populations, with these populations moving towards a larger proportion of juveniles. This study indicates that C60 exposure may seriously affect earthworm populations. Furthermore, it was demonstrated that juveniles were more sensitive to C60 exposure than adults.

**TH 213**

**Influence of the surfactant properties on the coagulation kinetics of functionalized engineered nanoparticles in water system**

JF Liu, S Legros, F Von der Kammer, T Hofmann
Center of Earth Sciences, University of Vienna, VIENNA, Austria

As derivatives of engineered nanoparticles (ENPs), functionalized ENPs (FENPs) are widely used in biomedical, catalysis, and electronics fields.This proliferation induces a risk concerning the release of FENPs into the environment. To date, scientific effort has focused on evaluating the toxicity of ENPs but much less attention has been given to exposure assessment especially of FENPs in the environment. The objective of this study is to assess the fate of FENPs in aquatic environment. Functionalized gold nanoparticles (FGNPs) are employed as a proxy for FENPs. We investigated the effects of environmental parameters (pH, NaCl and natural organic matter (NOM) concentrations) on the coagulation kinetics of FGNPs by dynamic light scattering (DLS). In addition, we investigated the effect of size, surfactant type and FGNPs concentration by studying 30 and 100 nm citrate stabilized (CIT30 and CIT100) and 30 nm 11-mercaptoundecanoic acid stabilized (C1130) at concentrations of 5 ppm, 10 ppm and 20 ppm.
First, the coagulation rate of CIT30 and CIT100 showed the same linear relationship with FGNPs number concentration, but the relationship is different for C1130. Second, FGNPs showed high critical coagulation concentration (CCC) in the presence of the NaCl: C1130 (0.2 M) > CIT100 (0.1 M) > CIT30 (0.08 M). FGNPs are thus little influenced in their aggregation behavior by monovalent 1:1 salts. CCCs of CIT30 and CIT100 were similar; hence the particles size does not change the effect of NaCl. Conversely, C1130 showed a much higher CCC than CIT30 and stronger electrosteric repulsion was observed for longer surfactant chain such as 11-mercaptoundecanoic acid. Third, CIT30 and CIT100 aggregated only at pH < 3.0 whereas C1130 aggregated at pH < 5.7. FGNPs are thus stable on a wider range of pH that is not influ-

enced by the particle size. Nevertheless, the FGNPs show fast aggregation only at pH below the pKa of their surface functional acid group. Finally, addition of NOM decreased the coagulation rate of CIT30 and CIT100, but had surprisingly no effect on C1130 even at a NOM concentration of 100 mg/L. This might be attributed to the different bonding mechanisms between the core of the FGNPs and the different surfactants.
Those results indicate that the physico-chemical properties of the surfactant have more significant influence on the coagulation behaviour than the composition and size of the particles or some of the currently considered environmental parameters.

**TH 214**

**Sedimentation and dissolution of nanomaterials in natural waters**

TK Quik[1], I Velzeboer[2], AA Koelmans[3], D van de Meent[4]
[1]National Institute for Public Health and the Environment (RIVM), BILTHOVEN, The Netherlands
[2]IMARES, IJMUIDEN, The Netherlands
[3]Aquatic Ecology and Water Quality Management Group, Wageningen University, WAGENINGEN, The Netherlands
[4]Radboud University Nijmegen, Institute for Wetland and Water Research, NIJMEGEN, The Netherlands

The behavior and fate of nanoparticles needs to be understood as part of their risk assessment. Sedimentation and dissolution are thought to be the main removal processes that are specific for nanomaterials. We studied the sedimentation behavior of silver, silica coated silver, ceria and fullerene nanoparticles. These particles were suspended at three concentrations, 0.5, 2.5 and 10 mg/L in 6 different natural water types. Water types and properties ranged from freshwater to seawater, from <0.1 to 25 mgC/L natural organic matter and from pH 4 to 8. Sedimentation was measured by quantifying the concentration of nanoparticles during a 15 day settling period by ICP-MS (metals) and $UV_{vis}$ (fullerenes). Additionally, the particle size distribution and zeta potential were measured at different time points. In the same aquatic matrices after a 15 day equilibration period, the dissolution was measured by centrifugal filtration at 3 kDa. Results show that the silver nanoparticles capped with polyvinylpyrrolidone were extremely stable even in sea water. In comparison, the other three nanoparticles showed increased aggregation and sedimentation with increasing ionic strength. The relevance of these findings for developing and validating aquatic fate models for nanomaterials is discussed.

**TH 215**

**Ecotoxicological characterization of carbon nanotubes according to standardized procedures used for the assessment of chemicals in the aquatic environment**

F Mouchet[1], FM Mouchet[1], CG Gancet[2], FB Bourdiol[1], AP Perrault[1], EP Pinelli[1], EF Flahaut[3], LG Gauthier[1], JCB Boutonnet[2]
[1]ECOLAB, CASTANET TOLOSANE, France
[2]ARKEMA, LACQ, France
[3]CIRIMAT, TOULOUSE, France

Carbon nanotubes (CNT), with an annual world production reaching several hundred tons, are a special category of nanomaterials with exceptional characteristic and numerous applications. Considering their current and future production, it is likely that some of them may contaminate the environment during each step of their life cycle (production, use and disposal), and especially the aquatic compartment which concentrates all kinds of pollutions. Thus, CNT should receive considerable attention as new, unknown and potentially hazardous nanomaterials. Nevertheless, little is known about their potential ecotoxicity, especially on aquatic organisms, with only few studies available.
Investigations of the environmental risk assessment related to the dispersion of Multi-walled carbon nanotubes (MWNT, Graphistrength C100) into the environment, synthesized by ARKEMA, were conducted in the framework of the Joint Research Laboratory NAUTILE (Nanotubes & Ecotoxicology).
In the regulatory scheme of ecotoxicological studies carried out to evaluate the ecotoxicity of a substance (REACH regulation), the approach taken by existing regulations is based on conventional and standardized bioassays and procedures (OECD guidelines). In this context, the potential impact of industrial raw MWNT was thus investigated using organisms belonging to different trophic levels: decomposers (bacteria), primary producers (photosynthetic green algae, Pseudokirchneriella subcapitata), primary consumers (invertebrates Daphnia magna and Crangon crangon) and secondary consumers (fish and amphibians, Xenopus laevis and Danio rerio), using classical ecotoxicological standardized procedures used to evaluate chemicals in the aquatic media.
The results indicated growth inhibition in amphibians exposed to 50 mg/L of MWNT. No toxicity in fish and daphnia up to 100 mg/L was observed. Toxicity was observed in the marine shrimp according the protocol of the "sea test"(but in the presence of an organic carrier). A notable effect has also been demonstrated at high concentrations with the growth inhibition test in algae (ErC50 = 120 mg/L, NOEC = 10 mg/L).

**Amorphous nanosilica induce ROS generation and DNA damage in keratinocyte**

Y Tomoaki[1], H Nabeshi[1], T Yoshida[1], T Hirai[1], S Tochigi[1], T Akase[1], M Uji[1], K Ichihashi[1], T Imazawa[2], K Nagano[2], Y Abe[2], H Kamada[2], Y Yoshioka[3], N Itoh[1], S Tsunoda[2], Y Tsutsumi[1]
[1]Graduate School of Pharmaceutical Sciences, Osaka University, SUITA, Japan
[2]Laboratory of Biopharmaceutical Research (LBR), National Institute of Biomedical, OSAKA, Japan
[3]MEI center, Osaka University, OSAKA, Japan

Nanometer-size materials, such as amorphous silica particles (nSP), which are used as functional additives in cosmetics and foods, have quickly become essential to daily life. However, concerns over the potentially harmful effects of nanomaterials have been raised precisely because they possess novel properties that are different from those of microsized materials. A sufficient understanding of the relationship between the physicochemical characteristics of nanomaterials governing their toxicity and the identification of factors that influence their associated hazards are essential for the development of safer nanomaterials. Because the main focus of nanotoxicology research has been on hazard identification, however, linkage analysis between physicochemical properties and nanotoxicologies has been long on indicating a need for nanotoxicological study but short on developing the safer nanomaterials. In the light of this situation, the aim of this study was to investigate the relationship between particle size and in vitro hazard of nSP, especially focusing on DNA damage, using human keratinocyte cells (HaCaT). Specifically, we evaluated the relationship between particle size of nSP and the in vitro biological effects. Our results indicate that exposure to nSP of 70 nm diameter (nSP70) induced an elevated level of reactive oxygen species (ROS), leading to DNA damage. A markedly reduced response was observed using submicron-sized silica particles of 300 and 1000 nm diameter. In addition, cytochalasin D-treatment reduced nSP70-mediated ROS generation and DNA damage, suggesting that endocytosis is involved in nSP70-mediated cellular effects. Thus, particle size affects amorphous silica-induced ROS generation and DNA damage of HaCaT cells. Thus, particle size affects amorphous silica-induced ROS generation and DNA damage of HaCaT cells. We believe clarification of the endocytosis pathway of nSP will provide useful information for hazard assessment as well as the design of safer forms of nSPs.

**Evaluation of immune modulating effect of orally administrated amorphous silica nanoparticles**

T Yoshida[1], TY Yoshikawa[1], HN Nabeshi[1], TH Hirai[1], ST Tochigi[1], TA Akase[1], MU Uji[1], KI Ichihashi[1], TI Imazawa[2], KN Nagano[2], YA Abe[2], HK Kamada[2], NI Itoh[1], YY Yoshioka[2], ST Tsunoda[2], YT Tsutsumi[1]
[1]Graduate school of Pharmaceutical Sciences, Osaka University, OSAKA, Japan
[2]National Institute of Biomedical Innovation (NiBio), OSAKA, Japan

Summary:
Recently, the development of nanomaterials (NMs) with particle sizes below 100 nm is promoted extensively. These NMs have been already used in various applications such as cosmetics, medicines and foods, and become essential to our daily life. Thus, the exposure against NMs are unavoidable for us. Under this circumstance, there is increasing concern regarding the potential health risks by the unique mechanical properties of NMs. In most cases, however, the safety evaluation of NMs has been insufficient for ensuring their safety. In this regards, using amorphous nanosilica particles (nSPs), we are studying relationship between in vivo/in vitro distribution of nSPs and hazard. Because of nSPs has been frequently used as food additive, here, we examined in vivo distribution and biological influences of orally administered nSPs. We used 3 various sizes of nSPs with diameters of 30, 300 or 1000 nm (nSP30, nSP300 or mSP1000). Firstly, mice were orally exposed with nSPs for 28 days and we performed absorption test of nSPs by transmission electron microscopy (TEM) analysis. As a result, only nSP30 migrated to blood through gut and reached spleen. This fact suggested that nSP30 influence immune system. Next, to evaluate immune-modulating effect of nSPs, mice were orally exposed to ovalbumin (OVA) plus nSPs for 4 times at weekly interval, and the levels of OVA-specific response were determined. We found that oral exposure of OVA plus nSP30 tended to induce higher level of OVA-specific immunoglobulin (Ig) G and OVA-specific release of IFN-γ from splenocytes than OVA plus nSP300 or mSP1000. We also demonstrated that the levels of OVA-specific IgE levels causing type 1 allergy were enhanced in mice exposed to OVA plus nSP30. These results indicated that migration of nSPs below 100 nm to spleen could induce immune-modulating effect such as food allergy. Now, to create safer forms of nSPs, we investigate immune response related to physicochemical properties of nSPs. We believe that these data should provide basic information that can help risk analysis of NMs.

[3]MEI center, OSAKA, Japan
[4]NiBio, OSAKA, Japan

Summary:
Nanomaterials acquire revolutionary functions depending on nano size. Recently, Nanomaterials are applied to various fields as innovative materials. Particularly, carbon nanotubes (CNTs) begin to use in car parts and TV display, therefore, CNTs are close for our life. On the other hand, CNTs has filamentous shape like asbestos which induce mesothelioma. Because of this, it is thought that CNTs may have some problems. However, the knowledgement about safety of CNTs is still not enough.
Consequently, we evaluated the biological response, such as cytotoxity, DNA damage and inflammation by different-sized multiwalled CNTs (MWCNTs) and single-walled CNTs (SWCNTs). There is insufficient report about biological response against different-sized and shaped CNTs previously.
Macrophage cells, alveolar epithelial cells and mesothelial cells have possibility that exposure to CNTs, when human inhale it. At first, we examined cytotoxicity of CNTs on these cells. As a result, CNTs induced cytotoxicity in all cells. DNA damage caused by CNTs was evaluated by Comet assay. MWCNT caused stronger DNA damage than SWCNT, and the long and thick size/shape of MWCNT have significantly induced DNA damage. We then examined the CNTs-induced inflammatory responses. All of CNTs induced IL-1_ production in human macrophage cells. For further investigation of inflammation, C57BL/6 mice were intraperitoneally administered with various kinds of CNTs and counted total cell numbers in abdominal lavage fluid. As in the case of Comet assay, the long and thick size/shape of MWCNT-exposed mice exhibits increased total cell numbers. These results indicate that long and thick MWCNT are likely to cause severe biological effects and may lead to be the augmentation of carcinogenicity.
In order to management the risk of CNTs, we will investigate the kinetics in details and modify the CNTs to safety form at a future date.

**Genotoxic effects of nano-sized TiO2 particles in isolated leukocytes and fibroblasts. A comparison between human and dolphin (Tursiops truncatus) susceptibility.**

M Bernardeschi[1], P Guidi[1], V Scarcelli[1], P Lucchesi[1], S Tendi[1], L Marsili[2], G Frenzilli[1], MC Fossi[2], M Nigro[1]
[1]University of Pisa, PISA, Italy
[2]University of Siena, SIENA, Italy

Many studies on NPs toxicity have been focused on their potential effects on human health, but scarce information are available on the susceptibility of endangered species, such as marine mammals. A possible accidental way of exposure to NPs during their industrial production is the skin; TiO2 NPs, present in solar creams are able to migrate to the corneal tissue and known to interfere with the immune system. This study is aimed to assess the profitability of isolated leukocytes for evaluating the potential genotoxic effects of NPs on toothed cetaceans and human lymphocytes and fibroblasts. The bottle-nose dolphin Tursiops truncatus was selected as study species being commonly reared in captivity. Previous studies had underlined a different susceptibility of human and dolphins leukocytes to pollutant exposure. In order to make a comparison human and dolphin blood, human (HuDE), murine (3T3) and dolphin fibroblast isolated from skin biopsies were used in this study. Blood samples from four males and a female specimens were achieved by the Adriatic SeaWorld “Oltremare”(Riccione, Italy). Human blood samples were taken from two healty male volunteers (24-30 years old), and processed as follows. Leukocytes were isolated by the lyses procedure and exposed in vitro to TiO2 (rutile and anatase) Nps.

Three experimental times of exposure (4, 24, 48h) and three doses (20, 50, 100 μg/ml) were tested. Genotoxicity was assessed by the Comet Assay, detecting DNA strand breaks. Cell viability was also assed by the Trypan Blue test. In order to assess aggregation, particles were observed with a Jeol 100 SX transmission electron microscope (TEM). Transmission electron micrograph showed that anatase and rutile particles coalesced in RPMI solution, forming variously sized aggregates after sonication, likely explaining a comparable behaviour of the two compounds both in dolphin and human cells. Results of the Comet assay showed that both the crystalline forms of TiO2 induced DNA fragmentation on a group basis. A marked variability among specimens was also detected. An higher susceptibility to TiO2 NPs exposure was assessed for dolphin leukocytes in comparison with human cells, speaking in favour of a particular attention to be paid to cetaceans endangered species .

**Biological effects of exposure to engineered nanoparticles in Saccharomyces cerevisiae**

N Bayat[1], SC Cristobal[2]
[1]Stockholm University, STOCKHOLM, Sweden
[2]Linköping University, LINKÖPING, Sweden

Nanoparticles (NP) are particles of mater between 1-100 nanometers (nm). They exhibit different properties compared their bulk form due to the large surface to volume atoms ratio, and therefore have extensive application in many fields such as cosmetics and medicine. However, the small size of nanoparticles, comparable with the molecular machinery of cells, may affect normal physiological functions of cells and cause cyto- and genotoxicity and thus pose unknown risks to human health. The overall goal of our research is to better understand those potential adverse biological, and health effects that accumulation of nanoparticles may cause after chronic exposures. In this regard the biological effects of exposure of the yeast Saccharomyces cerevisiae to the nanoparticles TiO2, ZnO, CuO, single walled carbon nanotubes and Ag are assessed. The findings are then compared to the effects of exposure to the respective bulk form of the nanoparticles. The nanoparticles are characterized and their potential cyto- and genotoxicity are studied using a green fluorescent protein modified yeast-based screening system. The interaction between cells and nanoparticles are then analyzed more in detail using transmission electron microscopy (TEM) and finally the reasons for the potential toxicity (i.e. DNA breakage or oxidative stress) is studied by using comet assay and cell-free reactive oxygen production assay.

Our results show that TiO2-NP, ZnO and CuO-NP all show high cytotoxicity while Ag shows both cyto- and genotoxicity. At concentration of 31,25 mg/l, the nanoparticles do not produce any significant amount of reactive oxygen species. The TEM images confirm our preliminary data and show that the effects of the nanoparticles differ from each other. The main effect seems to be on the increase, and changes in size and shape of the yeast cell vacuoles. The cell walls are not broken due to the exposure, suggesting that the nanoparticless succeed in entering the cells despite the rigid cell wall and lack of endocytosis. Difference in cell wall size and presence of lipid droplets are also seen in the images. The TiO2 and ZnO bulk material are not cytotoxic, while CuO-bulk showed some genotoxicity. In conclusion, the nanoparticles affect yeast cells extensively, with more cytotoxicity than genotoxicity. More research is needed to understand the reasons for toxicity and the localization of the nanoparticles inside the cells.

**TH 221**

**Cell-nanoparticle interactions and cytotoxic effects in human lung cells depend on particle properties and aggregation state**

E Moschini[1], P Mantecca[1], D Gallinotti[1], U Fascio[2], M Gualtieri[1], M Camatini[1]
[1]University of Milano Bicocca, MILAN, Italy
[2]University of Milan, MILAN, Italy

The rapid increase and wide distribution of engineered nanomaterials, occurred in the last decade, suggest that human exposure to nanoparticles (NPs) is almost unavoidable. Thus the interactions with the biological systems and the potential adverse health effects must be better understood. Inhalation represents the main exposure route for humans, both in outdoor and indoor environment, but also the application of NP-containing consumer products has to be carefully evaluated. Metal oxides are a class of nanomaterials abundantly used in several industrial sectors and high concentrations of these NPs have been monitored in the sites surrounding factories. Previous in vitro studies confirmed metal nanoxides as powerful cytotoxic agents, thanks to their capacity to induce oxidative stress and DNA damage. Moreover, differences in particle size, aggregation and chemical properties may determine the extent of the cellular reactions to NP exposure and the mechanism by which NPs are taken up by epithelial cells.

This study aimed to associate the main cytotoxic effects induced on human lung epithelial cells (A549) with the physico-chemical properties and hydrodynamic behaviour of CuO and TiO2 NPs. After being characterised by TEM and DLS, NP suspensions were administered to cell cultures. Biochemical and morphological analyses were performed to evaluate stress responses and the cellular mechanisms involved in cell-particle interactions at different exposure times. CuO strongly diminished cell viability in a dose- and time-dependent manner. Metal ions dissolution contribute to the cytotoxicity but does not completely explain the high mortality observed. The effects of CuO were promoted by a rapid internalization of NPs, either surrounded by vesicles or free in the cytoplasm. Ultrastructural alterations were soon visible, mainly at cell membrane level, and oxidised lipids suggested that membrane systems may constitute a primary target.

In contrast TiO2 -treated cells resulted engulfed by particles internalised by endosomal vesicles but this phenomena failed to affect viability and cell ultrastructure. Besides the extremely high oxidative potential of Cu2+, these findings pointed out that the NP size and surface charge, coupled with the level and modality of particle aggregation, play a pivotal role in establishing the endocytic pathway, and thus the subcellular NP localization, which ultimately lead to different toxic potential.

**TH 222**

**Effect of detonation nanodiamonds on fungi**

MN Maslov[1], VA Terekhova[1], D Khundzhua[1], S Patsaeva[1], TM Gubarevich[2]
[1]Moscow State University, MOSCOW, Russian Federation
[2]Physics Institute, MINSK, Republic of Belarus

Nanodiamonds (NDs) are already widely used in various industries. But their bioactivity to different components of environment is still unknown. The goal of this work is to investigate the bioactivity of detonation NDs towards fungi by measuring growth of mycelia and spectral characteristics of micromycete culture fluids. Two samples of Ural NDs (size of free particles 15 and 100 nm) manufactured at the company “SKN”(Snezhinsk, Russia) were investigated. The effect of NDs (at 0.05 mg/ml) on fungi (Alternaria arternata, Cladosporium cladosporioides and Fusarium oxysporum) was assessed by comparing changes in biomass and spectral characteristics of metabolites released by fungi into growth medium treated with NDs and without NDs (control cultures).

Fluorescence emission spectra and quantum yield QY of filtered culture fluid were measured by luminescence spectrometer Solar CM 2203 under excitation at 270, 310 and 355 nm. Absorption spectra were measured using spectrophotometer Unico within spectral range 200[3DOTS]900 nm. It was found that the growth of fungi depends on size of nanoparticles. Maximum mycelia biomass observed at 15 nm NDs. More remarkable this effect was on the light-colored fungi. Dark-colored species of weakly respond to the virtues of nanodiamonds. Growth of mycelia biomass of A. alternata and Cl. cladosporioides correlated with the optical density of culture fluid. Addition of NDs to nutrient medium causes more rapid culture growth and hence higher concentration of metabolites. Shift of fluorescence emission maximum towards longer wavelengths, decrease of fluorescence QY may indicate the formation of larger aggregates of fluorescing metabolites.

The results of experimental investigation demonstrated that :1) NDs of 15 nm size are more effective on the growth of fungal biomass stimulation than NDs of 100 nm; 2) light-colored fungi are more sensitive to NDs than dark-colored species;3) the presence of NDs reduces the fluorescence quantum yield of fungal metabolites in culture fluid, which is associated with an increase in size of the macromolecules in the medium; 4) increase in the size of the macromolecules due either to the fact that the fungi in the presence of NDs emit exometabolites of higher molecular weight, or with the adhesion of metabolites on the surface of NDs (without depending on the size of NDs).

The research was supported by the Russian Education and Science Ministry (GK 02.740.11.06993)

## NM03 - Risk assessment and risk management of nanomaterials

**TH 226**

**Assessing the risks for aquatic organisms posed by waterborne copper and silver nanoparticles**

NH Hsieh
National Taiwan University, TAIPEI, Taiwan

The increasing use of engineered nanomaterials in numerous industrial applications and consumer products are including the potential risk for human health and the ecological sustainability. The purpose of this study was to develop a risk-based probability model to predict the risks of nanoecotoxicity toward aquatic organisms posed by waterborne copper and silver nanoparticles (Cu/Ag NPs). Published experimental evidence based on Cu/Ag NP-zebrafish (Danio rerio) systems was adopted as the study data. Toxicodynamic based Hill model was used to reconstruct a concentration-mortality response profile. To estimate the exposure thresholds, the Weibull predictive model was employed. The derived probabilistic model can predict the risk of environmentally relevant Cu/Ag NPs for major Taiwanese rivers with predicted environmental concentrations. The results indicated that estimated thresholds of 95% confidence interval (95% CI) were 0.10~0.48 mg $L^{-1}$ for Cu NPs and 2.69~2.73 mg $L^{-1}$ for Ag NPs. The probabilities of a risk quotient (RQ) of > 1 ranged 17%~81% for zebrafish exposed to Cu NPs. This study found that Ag NPs exposure scenarios had no significant risks to zebrafish (RQ << 0.1). Results of this study imply that zebrafish can be used as a suitable bioindicator to monitor nanoecotoxicity of environmentally relevant Cu/Ag NPs that pose potential adverse effects toward aquatic organisms.

**TH 227**

**Comparative toxicity of silver nitrate and silver nanoparticles to representative species of an aquatic trophic chain**

FA Ribeiro, AMVM Soares, SMP Loureiro
University of Aveiro, AVEIRO, Portugal

Nanotechnology field is growing with consequent release of manufactured nanomaterials and nanoparticles to the environment. Silver NP’s are used as antibacterial agents in biotechnology and bioengineering as well as in textile industry and consumer products. In this study we compared the sensibility of thee different aquatic species to silver nitrate and silver nanoparticles and aimed to relate differences in toxicity to the differences in particle sizes and processes of uptake and distribution inside the organisms. Growth inhibition bioassay with the green algae Pseudokirchneriella subcapitata was performed according to the OECD 201 guideline with adapatations. Immobilisation assays with Daphnia magna was conducted under the OECD 202 guideline (OECD, 2004). Feeding inhibition assessment of Daphnia magna was conducted according to the methodology described in McWilliam and Baird (2001) and reproduction assay was conducted following the OECD 211 guideline (OECD, 1998). The zebrafish (Danio rerio) assay was in accordance with the guideline on fish embryo toxicity (FET) test (OECD, 2006). Zebrafish embryo were collected within 30 minutes after natural mating and selected under a stereomicroscope for the suitability of the eggs. The endpoints assessed were the number of coagulated eggs, irregularities in somite formation, tail detachment and the heart beat of larvae. We found no significant differences on the inhibition of growth of P. subcapitata exposed to silver nitrate and silver nanoparticle. Daphnia magna neonates were more sensitive to AgNO3 than to the AgNP, with a 48h-LC50 value ten times greater for AgNP. Fish embryo development was also studied under exposure to AgNO3 and AgNP and abnormalities were observed in embryo exposed to silver when compared to the control animals. The hatching rate was decreased in silver exposed embryo, and among injuries observed were abnormal notochord development, edema and weak heart beating rates. In conclusions, we addressed some of the effects of silver nanoparticles to three different aquatic species and it was possible to observe differences in toxicity between AgNO3 and AgNP. However, we believe that the toxicity profile of these compounds would be better understood under the investigation of their uptake and distribution inside the organisms, which is an ongoing work.

### TH 228

**Long-term effects of iron-based nanoparticles at population level (Project Fe-NANOSIT)**

K Foit[1], I Kirst[2], M Liess[2]
[1]Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[2]Helmholtz Centre for Environmental Research, System Ecotoxicology, LEIPZIG, Germany

General aim of the project Fe-NANOSIT is the development of novel methods for the purification of contaminated ground- and industrial wastewaters based on nanoparticles (NPs) and nanocomposit structures. The project includes (i) the development and production of reactive NPs and nanocatalysts, (ii) detailed particle characterization, (iii) demonstration of the technological solutions at field scale, and (iv) detailed risk assessment following a multi-tiered approach from the cell to the population level.

For a risk assessment at population level, we apply the automated test system NANOCOSM, which analyses populations of Daphnia magna. The abundance and size structure of populations are quantified by image analysis. The NANOCOSM system allows the investigation of stressed population in the presence of intraspecific competition, which is a very important factor involved in the dynamics of natural populations. Hence, the NANOCOSM system enables a highly sensitive monitoring of long-term effects and recovery processes after exposure to NPs.

### TH 229

**Toxicity review on Al2O3, TiO2, ZrO2, SiO2, MWCNT and CeO2 nanoparticles**

S Scalbi, G Barberio, P Buttol, P Masoni
ENEA, BOLOGNA, Italy

The LCA & Ecodesign laboratory of ENEA is in charge of the assessment of nanofluid coolants impacts on the environment, health and safety (EHS), across their entire life cycle, for NanoHex (enhanced nano-fluid heat exchange) project (www.nanohex.eu). The NanoHex project, financed by Seventh Framework Programme for collaborative projects, is developing a high-performance coolant for adoption by industry in heat exchange systems using the enhanced thermal properties of nanofluids (NFs). The promising laboratory based nanotechnology results are translating into pilot-lines for the cooling of electronics primarily targeting Data Centres & Power Electronics.

The EHS assessment is being performed by the joint application of Risk Assessment (RA) and Life Cycle Assessment (LCA). The choice of the methods results from two main reasons: the recommendations in the Action Plan 'Nanosciences and nanotechnologies: An action plan for Europe 2005-2009' and the issues related to the sustainability of the emerging technologies (Sustainability Assessment of Technologies -SAT ).

The article presents the results of a literature review on toxicity of the candidate nanoparticles (NPs) for NanoHex application in NFs, in order to consider the prevention and reduction of possible impacts of the new materials as well as technological performance.

Available studies of scientific community are not sufficient to characterize the effect of NPs and define a "hazard hierarchy"between different NPs because, at date, the difference among the procedures and results of toxicity tests are too broad. Nevertheless, some useful information about the toxicity can be drawn by the survey proposed in this work to consider impacts related to the toxicity besides the enhanced thermo-hydraulic properties of NFs based on NPs.

Further investigations are required to understand the behaviour of NanoHex selected NFs starting from the main NPs parameters (physical-chemical characteristics of NPs such as dimension, shape, crystalline form, z-potential and type of experimental tests such as in vivo or in vitro).

### TH 230

**Designing environmental friendly nanoparticles with Nano-QSAR**

T Puzyn[1], A Gajewicz[1], B Rasulev[2], A Michalkova[2], A Toropov[2], D Leszczynska[2], J Leszczynski[2]
[1]University of Gdansk, GDANSK, Poland
[2]Interdisciplinary Center for Nanotoxicity, Jackson State University, JACKSON, MS, United States of America

New approaches that concern the study of materials having at least one dimension below 100 nm, called nanoscience and nanotechnology, are rapidly expanding. Particles in these size ranges, may exhibit properties drastically different from their larger counterparts having the same chemical composition. This enables novel, profitable applications of nanoparticles.

Together with an increasing role of nanotechnology in our every-day-life, we can also expect increasing emissions and increasing levels of novel nanoparticles in the environmental compartments. Thus, development of novel techniques that enable to design environmentally safe nanoparticles is of high interest.

Novel, fast and inexpensive procedures for designing nanoparticles with the expected properties as well as for performing a comprehensive human and environmental risk assessment can be developed without the need of extensive empirical and animal testing. Instead, a group of Quantitative Structure-Activity and Structure-Property Relationships methods (QSAR and QSPR, respectively) can be employed.

In this presentation we will demonstrate new contributions of our group to Nano-QSAR and Nano-QSPR methodology. The presentation will be focused on the four priority areas: (i) collecting and curating available experimental data; (ii) developing appropriate nano-structural descriptors; (iii) studying interactions between nanoparticles and biological systems; (iv) existing and newly developed Nano-QSARs and Nano-QSPRs.

### TH 231

**Iron-based nanoparticles and nanocomposit structures for removal of contaminants in ground- and industrial wastewaters (Project Fe-NANOSIT)**

K Foit[1], S Scholz[2], K Mackenzie[3], M Liess[4], A Potthoff[5], J Bruns[6], D Lippok[7], K Duis[8], F Seitz[9], M Gelinsky[10], S Oswald[11]

[10]Technical University of Dresden, if WW and Max Bergmann Center of Biomaterials, DRESDEN, Germany
[11]University of Potsdam, Institute of Earth and Environmental Science, POTSDAM-GOLM, Germany

General aim of the project Fe-NANOSIT is the development of novel methods for the purification of contaminated ground- and industrial wastewaters based on nanoparticles (NPs) and nanocomposit structures. The project includes (i) the development and production of reactive NPs and nanocatalysts, (ii) detailed particle characterization, (iii) ecotoxicological risk assessment and (iv) demonstration of technological solutions for the remediation of contaminated water recourses at field scale. Studies of possible environmental hazards caused by the particles play an important role since a sustainable technology development can only be warranted when risks for the environment can be excluded or fully controlled.

Groundwater treatment:

For the purification of contaminated groundwaters, a nano-structured composite material has been developed which combines the reactivity of zero-valent iron deposits with the sorption properties of the colloidal activated carbon carrier (Carbo-Iron). Carbo-Iron is applicable for injection into contaminated aquifers in order to form sorption/reaction barriers by controlled subsurface deposition directly within the flow passages of the contaminated water. Carbo-Iron's properties have been designed to target both: plume control and source remediation.

Waste water treatment:

Reactive nanocatalysts are studied for two target applications in the treatment of industrial wastewater: the Pd-catalyzed hydrodehalogenation as reductive treatment and particle-catalyzed Fenton-like oxidation of persistent non-halogenated pollutants as well as oxidation using magnetic photocatalysts. Highly-active Pd/magnetite and Fe-based magnetic nanocatalysts are designed, characterized and tested for their performance in the target reactions. All of the particles are supposed to be removed from the treated water streams and are subjected to recycling and regeneration processes.

Before implementing the particles into any technological development process, all of the particles under study are included into a strict risk assessment scheme which will be described in detail in this presentation.

### TH 232

**A proposed protocol for estimating the potential release of nanoparticles from nano-based coatings: the NANOHOUSE project**

A Brunelli[1], S Zuin[2], A Ferrari[3], D Cervellati[3], G Pojana[1], A Marcomini[1], F Tardif[4]
[1]University Ca' Foscari of Venice, VENICE, Italy
[2]Venice Research Consortium, VENICE, Italy
[3]GFC Chimica, FERRARA, Italy
[4]Commissariat à l'Energie Atomique et aux Energies Alternatives, GRENOBLE, France

Nanotechnologies utilizing engineered nanoparticles (ENPs) have been envisaged to become a flourishing industry with an expected annual turnover over 1.5 trillion euros by 2015 (Savolainen et al., 2010). "The Project on Emerging Nanotechnologies"has estimated that more than 1000 nano-products are marketed now, with a new entry every 3-4 week (http://www.nanotech-project.org). ENPs, since their unique features, are applied in many fields and products (e.g., textile, coatings, composites, medicine, etc.). An inevitable consequence of this constantly using of nano-based products is the potential human and environmental exposure to ENPs (Nowack and Bucheli, 2007; Kaegi et al., 2010). However, although the toxicity of some ENPs has been widely studied in both *in vitro* and *in vivo* assays, there still is a lack of information concerning ENPs release from nano-based products. Hence it is necessary to estimate their potential releases throughout the whole product life cycle.

Within the FP7 EU-funded NANOHOUSE project (*Life Cycle of Nanoparticle-based products used in house coating*; www-nanohouse.cea.fr), aiming at developing appropriate solutions for a safe and sustainable use of nano-based coating according to Life Cycle Thinking, the potential release of ENPs from selected nano-based paints by "wet route"is being evaluated. In detail, within the WP2 - Source identification, an experimental protocol has been proposed to estimate release from selected paints containing $TiO_2$, Ag and $SiO_2$ ENPs. The proposed protocol has been defined taking into account literature results, available standards (e.g.. ISO, ASTM) and input from project partners. In this work, the experimental protocol will be presented and discussed, highlighting: (i) type of panels coated with nano-based paints and their initial conditioning; (ii) pre-treatment of panels to simulate their weathering (i.e. accelerated weathering tests such as Taber test and UV exposure); (iii) leaching test applied on weathered and un-weathered panels to verify possible ENPs release; (iv) characterization methods and techniques needed to investigate ENPs in collected leaching liquid samples. Moreover, a special attention will be paid to available leaching standards able to estimate migration rate of ENPs, and characterization techniques/methods necessary to quantify ENPs release.

**The safety assessment of amorphous nanosilica on developmental and reproductive toxicity**

K Yamashita[1], Y Yoshioka[2], K Higashisaka[1], M Fujimura[1], Y Morishita[1], P Huiyan[1], T Ogura[1], K Mimura[2], M Nozaki[2], H Nabeschi[1], K Nagano[3], Y Abe[3], H Kamada[3], S Tsunoda[3], N Itoh[4], I Yanagihara[2], KS Saito[5], T Yoshikawa[1], Y Tsutsumi[4]
[1]Osaka University, OSAKA, Japan
[2]MEI center, Osaka University, OSAKA, Japan
[3]Laboratory of Biopharmaceutical Research (LBR), National Institute of Biomedical, OSAKA, Japan
[4]Graduate School of Pharmaceutical Sciences, Osaka University, OSAKA, Japan
[5]National Institute for Environmental Studies, TSUKUBA, Japan

Recently, many nanomaterials (NMs) with innovative functions have been developed and already used in several fields. However, knowledge concerning the potential safety of NMs is still fragmentary. Especially, few studies have examined the effect of NMs on maintenance of pregnancy. Therefore it is essential to examine the effect of NMs on fetuses and pregnancies. In this study, we examined the reproductive toxicity of nanosilica particles with different size and surface modification for developing NMs with safety. Pregnant BALB/c mice were treated with silica particles with a diameter of 70, 300 or 1000 nm (nSP70, nSP300 or mSP1000, respectively) via intravenous injection. At first, we examined the influence of silica particles on fetuses. nSP70-treated pregnant mice showed the increase of fetal resorption rates and decrease of fetal weights compared to control mice, suggesting that nSP70 induced the miscarriage and fetal growth restriction. In contrast, nSP300 and mSP1000 did not induce these pregnant complications. Furthermore, we showed that nSP70 with functional COOH or NH2 surface modification group did not induce miscarriage and fetal growth restriction. These results suggest that appropriate surface modification suppresses these pregnancy complications. Next we attempted to clarify the mechanism of miscarriage and fetal growth restriction induced by nSP70. Sections of placentas were stained with hematoxylin and eosin. We observed variable structural abnormalities of placenta in nSP70-treated mice, although placentas of nSP300- and mSP1000-treated pregnant

mice did not show any significant abnormalities compared to control mice. These results suggest that nSP70 induce the structural abnormalities to placenta. Therefore we consider that the dysfunction of placenta is one mechanism of pregnant complications induced by nSP70. We believe that the knowledge obtained by these studies might provide basic and useful information for developing NMs with safety.

It has been recognized that production and use of engineered nanoparticles (ENPs) are addressed by the EU REACH Regulation n. 1907/2006 that gives industries the responsibility of the Chemical
Safety Assessment (CSA) for any produced or imported industrial substance. The required CSA follows the traditional Risk Assessment (RA) framework for chemicals, including Hazard Assessment, Exposure Assessment and Risk Characterisation steps. Since the application of the traditional RA framework to ENPs is hampered by methodological concerns and data gaps, a novel approach for RA and prioritization of ENPs, including uncertainty evaluation, is being developed within the FP7-funded ENPRA project. The whole procedure will follow the Weight of Evidence (WoE) approach and will integrate experimental/estimated exposure and effect data provided by project partners or available in the literature that refer to a panel of 9 ENPs including titanium dioxide, zinc oxide, silver and carbon nanotubes. Among the experimental data required for RA purposes, the physical and chemical characterization of ENPs seems to be a critical point, on the basis of available literature data. Only a correct combination of adequate measurement techniques allows adequately characterizing a certain ENP and therefore avoiding the misinterpretation of the toxicological tests to be carried out for RA purposes. The set of techniques and needed information strongly depends on the investigated ENP, and only an expert evaluation allows their adequate selection and application. Additional critical issues are associated with the absence of reliable particle standards, the lack of reproducible administration protocols and the performance of a 'secondary' characterization of ENPs (i.e. behaviour under real conditions) in biological media during and after administration. Within the ENPRA project many efforts are addressed to investigate and solve these open issues within a RA perspective.

## RA05 - Integrated science: Key to risk assessment

**TH 238**
**To contract a pyrene-based physiologically based pharmacokinetic (PBPK) model for predicting urinary 1- hydroxypyrene (1-OHP) levels in human**
SC Chen
Chung Shan Medical University, TAICHUNG, Taiwan
The objectives of this study are to characterize the concentration-time profiles in target organs and tissues by a pyrene-based physiologically based pharmacokinetic (PBPK) model, and to collect the published data of metabolism biomarkers (urinary 1- hydroxypyrene (1-OHP) levels) for model validation. We adopted the pyrene data from Tsai et al. (2004) for PAHs concentrations measured at highway to all station to account for the traffic pollution sources. The variation of urinary 1-OHP levels between post-shift and pre-shift exposure were measured. The input pyrene concentration and 1-OHP concentration of exposure groups were 105 ng m-3 and 2.12 μmol of 1-OHP/mol of creatinine, respectively. For simulating the inhalation pharmacokinetics of pyrene, we use a basic human compartment structure that has been previously used by Chiang and Liao (2006). The tissue compartments included in the model are: alveolus, lung, richly perfused tissues (brain, gut, kidney, spleen, and heart), fat, slowly perfused tissues (bone, muscle, and skin), and liver. Each tissue compartment is interconnected by arterial and venous blood. The PBPK model will be verified by comparing the predictions of urinary 1-OHP levels with the measured published data. The results shows the simulated highest time-course concentrations of pyrene were in fat (4.32[GREEKX]$10^{-5}$ mg/l blood) at day 5, followed by rapidly perfused tissues (6.04[GREEKX]$10^{-6}$ mg/l blood), slowly perfused tissues (3.56[GREEKX]$10^{-6}$ mg/l blood), liver (1.34[GREEKX]$10^{-6}$ mg/l blood), blood (3.83[GREEKX]$10^{-7}$ mg/l blood), and lung (6.64[GREEKX]$10^{-7}$ mg/l blood). Model validation by t-test statistical method shows that there is no significant difference between model prediction and experimental 1-OHP concentration in urinary.

**TH 239**
**Assessing arsenic exposure and influenza A (H1N1) infection-associated lung function exacerbations risks**
YH Cheng[1], CM Liao[1], CP Chio[1], NH Hsieh[1], WY Chen[1], SC Chen[2]
[1]National Taiwan University, TAIPEI, Taiwan
[2]Chung Shan Medical University, TAICHUNG, Taiwan
Arsenic (As) is ubiquitous in the environment and known to lead to many human health problems related to pulmonary diseases. Recently, the animal experiment showed that As would significantly increase influenza viral titer. In this study, we are trying to link arsenic exposure and influenza A (H1N1) infection-associated lung function exacerbation and assess the risk based on mechanistic models. First, we apply the homogeneous Poisson process to obtain the relationship between viral load and percent predicted forced expiratory volume in the first second ($FEV_1$). Then, we construct the viral load-percent predicted $FEV_1$ and arsenic exposure-percent predicted $FEV_1$ relationships to link the As exposure and viral load. The result shows that 625 μg $L^{-1}$ As increment leads to 1 viral load (log TCID50 $mL^{-1}$) increment. Second, we apply the Hill model to best fit the relationship of viral load and respiratory symptoms scores (RSS). Finally, a Hill-based model is also adapted to construct the response of RSS as the function of As exposure and influenza A (H1N1) infection. Given the amount of viral load in a specific day post infection (PI) and site-specific arsenic distribution, we could estimate the change of RSS and assess the risk under different levels of RSS. Our results show that West Bengal (India) has the most severe lung exacerbation risk due to the highest As concentration distribution (RSS: 0.11-0.51 (Day 0 PI); 0.28-0.76 (Day 1 PI); 0.60-0.91 (Day 2 PI)) followed by Taiwan, USA, Mexico, and Brazil, respectively.

**TH 240**
**Lead human exposure to industrial emission and health risk assessment for selected area of Casablanca: a pilot phase in Morocco**
M Idrissi Belkasmi[1], N Benjelloun[2], S Amaziane[3], R Soulaymani Bencheikh[4], A Soulaymani[5]
[1]Ibn Tofail University, RABAT, Morocco
[2]B2IS, Department of research, CASABLANCA, Morocco
[3]DSPR, Department of Environment, RABAT, Morocco
[4]Faculty of Medicine and Pharmacy, RABAT, Morocco
[5]Laboratory of Genetics and Biometrics, Ibn Tofail University, KENITRA, Morocco
INERIS (French National institute for industrial environment and risks) methodology is used here to calculate the human health risk associated with lead emission exposure, from lead fondry and Battery Manufacturing Plants located in two communities namely: Sidi Bernoussi and Ain Sebaa in the region of Casablanca.
Inhalation and ingestion of lead-contaminated dust are identified as major exposure routes. Used Human Toxicity Values were chosen based on the first 3 Data bases (WHO, ATSDR, EPA). Data from sources and lead emission were obtained according to two approaches: actual direct measurement and modelling. Thus, four scenarios were built: Population of Sidi Bernoussi bordering the Battery Manufacturing Plants within a distance of 100 m, 450 m and 500 m and the general population located at 1,8 km of the sources of pollution. For the four scenarios, we calculated the Hazard Quotient (HQ) for the noncarcinogenicity effects and assessment of Unit Risk for Carcinogenic effects. Probabilistic risk assessment is also conducted to account for uncertainty and variability in the analysis.
For the noncancerogenic effects, ingestion of deposit lead was only considered for specific sub group of population (6 years of age and less).
In the absence of national blood lead surveillance program, Blood Lead Level (BLL) modelling Methods was performed to predict results in child.
Among the four scenarios considered, the calculated risk values were several times higher than the generally acceptable risk mainly in children from a shantytown. Effort must be taken to implement screening strategies to reduce childhood lead exposure.

**Substance flow analysis for micropollutants management in urban watersheds**
N Chevre[1], S Coutu[2], HP Bader[3], R Scheidegger[3], L Rossi[2]
[1]Université de Lausanne, LAUSANNE, Switzerland
[2]EPFL, LAUSANNE, Switzerland
[3]Eawag, DUEBENDORF, Switzerland
Micropollutants released by cities into water are of increasing concern as they are suspected of inducing long-term effects on both aquatic organisms and humans. Substances found in the urban water cycle have different sources in the urban area and different fates in this cycle. For example, the pollutants emitted from traffic, like copper or PAHs get to surface water during rain events often without any treatment. Pharmaceuticals resulting from human medical treatments get to surface water mainly through wastewater treatment plants, where they are only partly treated and eliminated. Once in the receiving waters (lakes, rivers, groundwater), these substances may reenter the cycle through drinking water. It is therefore crucial to study the behaviour of micropollutants in the urban water cycle and to get flexible tools for urban water management. Substance flow analysis (SFA) was recently proposed as instrument for water pollution management in urban water systems. In this study, we propose to test the application of surface flow analysis for various classes of micropollutants to evaluate its application to urban water management. We chose the city of Lausanne as case study since the receiving water of this city (Lake Geneva) is an important source of drinking water for the surrounding population. Moreover a profound system-knowledge and many data were available, both on the sewer system and the water quality. We focused our study on some heavy metals, and some pharmaceuticals. For copper, the results show that around 1500 kg enter the aquatic compartment yearly. This amount contributes to sediment enrichment, which may pose a long-term risk for the benthic organisms. The major sources (total of 73%) of copper in receiving surface water are roofs and contact lines of trolleybuses. Thus technical solutions have to be found to manage this specific source of contamination. Application of SFA approach to pharmaceuticals reveals that combined sewer overflows represent an important source of contamination. These results will help in defining the best management strategy to limit Lake Geneva contamination. SFA is thus a promising tool for integrated urban water management.

**A novel risk assessment approach for the prioritisation of emerging substances and its application to 500 organic microcontaminants**
PC von der Ohe[1], V Dulio[2], J Slobodnik[3], E de Deckere[4], R Kühne[1], G Schüürmann[1], W Brack[1]
[1]UFZ - Helmholtz-Centre for Environ Res, LEIPZIG, Germany
[2]INERIS, VERNEUIL-EN-HALATTE, France
[3]Environmental Institute, KOS, Slovak Republic
[4]University of Antwerp, ANTWERP, Belgium
Given the huge number of chemicals in commerce, there is a need of prioritising chemicals for risk assessment and monitoring. This study is the first to assess the risk of 500 organic substances based on observations in the four European river basins of the Elbe, Scheldt, Danube and Llobregat. A decision tree is introduced that first classifies chemicals into six categories depending on the information available. The priority within each category is then evaluated based on two indicators, the Frequency of Exceedance and the Extent of Exceedance of Predicted No-Effect Concentrations (PNECs). These two indictors are based on maximum environmental concentrations (MEC), rather than commonly used statistically based averages (Predicted Effect Concentration, PEC), and compared to the lowest acute-based ($PNEC_{acute}$) or chronic-based thresholds ($PNEC_{chronic}$). For 56% of the compounds, PNECs were available from existing risk assessments, and the

majority of these PNECs were derived from chronic toxicity data or simulated ecosystem studies (mesocosm) with rather low assessment factors. The limitations of this concept for risk assessment purposes are discussed. For the remainder, provisional PNECs (P-PNECs) were established from QSAR models for acute toxicity to the standard test organisms *Daphnia magna, Pimephales promelas* and *Selenastrum capricornutum*. The prioritisation revealed that about three-quarter of the 44 substances with MEC / PNEC ratios above ten were pesticides.

**Environmental assessment for pharmaceuticals under the National Environmental Policy Act**

EA Mcvey
US Food and Drug Administration, SILVER SPRING, United States of America

The fate of pharmaceuticals in the environment has been studied for more than 50 years, with the presence and potential effects acknowledged shortly thereafter (Soulides et al. 1962; Voets et al. 1976; Peele et al. 1981; Lee & Arnold 1983; Grimes et al. 1984). It has gradually become apparent that risk assessments developed for the usual chemical contaminants cannot be applied carte blanche to pharmaceuticals, because they are developed to be highly active and specific in biological systems at low levels (Sybesma 1992; Stan & Heberer 1997; Halling-Sorensen et al. 1998; Daughton & Ternes 1999). Therefore, when applying risk assessment models to the environmental assessment of pharmaceuticals, regulators must take into account not only the complexity of the entity to be protected (the ecosystem at large), but also the complexity of the regulated article (pharmaceuticals).
Under the United States' National Environmental Policy Act (NEPA), before performing any action, a federal agency must assess the environmental impact of that action by preparing an Environmental Assessment (EA), followed by a Finding of No Significant Impact (FONSI), or an Environmental Impact Statement (EIS). An EA is a "concise"(i.e. 10-12 pages) document that assesses the potential environmental impact of an action. From the EA, regulators then determine whether a more in-depth EIS is required, or whether there can be a FONSI. If it is determined that an EIS is needed, a longer process begins to create a (in most cases) massive document which takes into account all possible environmental impacts of an action, including cultural and social impacts and those relating to environmental justice. The Act encourages multidisciplinary approach to risk assessment, by requiring this very broad and extensive view of environmental assessment, and by encouraging cooperation between various Federal entities to create an EIS.

**TH 245**

**Using 'intelligent testing' ideas to design a targeted fish full life-cycle test: a case study**

H Panter[1], YC Glennon[1], J Robinson[1], A Hargreaves[2], RM Murray-Smith[1]
[1]Brixham Environmental Laboratory, BRIXHAM, United Kingdom
[2]AstraZeneca, MACCLESFIELD CHESHIRE, United Kingdom

For evaluating the potential ecotoxicity to fish of human pharmaceuticals, particularly potential 'endocrine disruptors', a fish full life-cycle test is deemed to be the "gold standard", as it covers all life-stages and measures long-term effects. However, by making the best use of mode of action, preclinical and clinical pharmacological and toxicological data (data generated during drug development from non-human mammals and humans), it may be possible to tailor the experimental design to focus on the most sensitive life-stages and biological endpoints. From an ethical perspective, such considerations have the potential to reduce the number of animals required for testing. In knowing the therapeutic dose and predicted environmental concentration, test concentrations could also be selected such that a range-finding study is not required.
This presentation provides a real example of how the existing data for an active pharmaceutical ingredient, bicalutamide, was used to design a targeted fish chronic study and to focus measurements where effects would be most likely to be seen. The results provided good quality data for risk assessment purposes and the study used approximately half the number of animals normally tested in a fish full life-cycle study and at a considerably reduced cost and time requirement.

**TH 246**

**Non-traditional endpoints put to the test: a question of relevance and reliability**

E Mihaich[1], AT Hall[2], LS Ortego[2], CA Staples[3], N Caspers[4], GM Klecka[5], SS Dimond[6], SG Hentges[7]
[1]ER2 for SABIC Innovative Plastics, DURHAM, NC, United States of America

[6]SABIC Innovative Plastics, BEDFORD, NH, United States of America
[7]American Chemistry Council, WASHINGTON, DC, United States of America

The apical endpoints of survival, growth, and reproduction have long been the mainstay of environmental toxicology research as they integrate effects at the organism level. Yet, as science progresses the use of biomarker endpoints in early hazard assessment is becoming more common. The challenge is in relating the biomarker with an adverse effect that is relevant and reproducible. Bisphenol A (BPA), is an important high production volume compound used in the production of epoxy resins and polycarbonate plastics. It is also one of the most studied compounds, particularly for potential endocrine interactions. The database of ecotoxicological test results for BPA includes traditional guideline acute and chronic data addressing population level effects of survival, growth and reproduction, as well as a variety of studies with secondary and often unique sublethal or biomarker-type endpoints. For example, a number of highly replicated fish life-cycle and multi-generational tests in both freshwater and marine species have examined growth, development and reproductive success in combination with biomarker endpoints such as vitellogenin, gonadosomatic index, and gonad histology. In addition, analyses of sperm quality, gonad development, vitellogenin, genomic markers, and many other non-traditional endpoints have been reported in the literature, often evaluated in isolation of a link with more traditional endpoints. In determining the utility and relevance of these additional studies and their various endpoints in an environmental risk assessment framework, a clear understanding of the relationship between biomarker and sublethal findings, which may or may not be adverse, to population relevant assessment endpoints must be established and data quality and reliability must be determined. The evaluation of such existing information, including both traditional and non-traditional endpoints should be done in a weight of evidence approach in order to reach a scientifically defensible risk determination. In so doing, potential adverse impacts of the compound can be defined and subsequently used as measures of effects that are directly related to the assessment endpoints for a sound and robust risk assessment. A case study describing this approach for the evaluation and use of both traditional and non-traditional endpoints in a weight of evidence assessment will be presented using examples from the extensive database of fish studies available for BPA.

**TH 247**

**How non-standard test methods and data analysis tools can benefit to ecological risk assessment of chemicals?**

V Ducrot[1], S Charles[2], ARR Péry[3], L Lagadic[1]
[1]INRA, RENNES, France
[2]Université Lyon 1, VILLEURBANNE, France
[3]INERIS, VERNEUIL-EN-HALATTE, France

Regulation mostly relies upon the results of standard toxicity tests that have been validated for a reduced set of species and endpoints. This pragmatic strategy ensures the reliability of toxicological data. Yet, current practices might not appropriately cover the broad range of toxicant mode of action (*e.g.,* endocrine disruptors - EDCs). In particular, the standard approach may fail to provide realistic risk forecasts when the test design is not sensitive enough to highlight toxicity and when the various standard tests provide conflicting results.
Through two case studies, we explain why the standard approach may not allow assessing properly the risk of reprotoxic pesticides in invertebrates. The first case study illustrates current issues in risk assessment of EDCs. In this context, we show how non-standard partial life-cycle (PLC) tests allow identifying sensitive development phases/endpoints to EDCs (*e.g.,* anti-androgens) along the life-cycle of *Lymnaea stagnalis*, a candidate species for the development of forthcoming OECD test guidelines. We also show how non-standard data analysis methods, such as mixed effect models, can be used to avoid underestimation of EDCs toxicity. The second case study illustrates how a non-standard approach can contribute to provide complementary data when standard approaches led to conflicting risk forecasts. In this context, we repeatedly exposed *L. stagnalis* to pulses of diquat and monitored life-cycle traits. We show how non-standard full life-cycle (FLC) tests allow assessing effective diquat concentrations more realistically and why non-standard models, such as TK-TD models, are relevant to characterise the time-course of biological responses to complex exposure patterns. For each case study, we show how to derive relevant effects criteria and include them in the regulatory risk assessment process. We then investigate whether including this additional data might modify current risk forecasts for the studied compounds.
This study illustrates how non-standard test procedures of different nature may contribute to ecological risk assessment of chemicals, when standard procedure are lacking or provide conflicting results. Most importantly, the use of some simple but relevant PLC and FLC tests methods with *L. stagnalis* should be promoted when standard approaches are suspected to provide unrealistic risk forecasts.

**TH 248**

**The role of interspecific competition on the response of Daphnia magna to pesticides**

I Dolciotti, B Martin, M Liess
UFZ, LEIPZIG, Germany

Most of the tests to address toxicity of pesticides are made on experimental organisms, typically Daphnia magna for fresh water, cultured individually. These tests are not realistic and many studies showed the inadequacy of this current practice in ecotoxicology. Animals potentially struggle in interspecific or intraspecific competition, interactions that are likely to be of crucial importance to obtain a response to toxicants' activity. Thus in ecotoxicology a subject for inquiry should be the role such biotic interactions play in determining the response to stressors.
The focus of this study is to understand the importance of competition on Daphnia magna after pesticide applications. Competitions between different species of cladocerans have been already investigated by several ecology studies. Daphnids respond with life history changes to the presence of competitors, which can influence their sensitivity to a chemical stress. However little is known about what the presence of a species of a complete different systematic group can cause.
A laboratory mesocosm study on population of Daphnia magna competing with larvae of Culex pipiens showed a delay in recovery after multiple pesticide applications.
To understand the relative roles of the direct influence of competition on vulnerability to a pesticide, versus the influence of life history adaptation, a reproduction test (OECD guideline 211) was also conducted. We investigated mothers (F0) living singly or with three C.pipiens specimens in 50 ml of medium and their offspring (F1). Both were contaminated at the same levels of the pesticide pirimicarb used for the mesocosm experiment. Results showed a delay in growth and reproduction and an increased sensitivity to the contamination for the competition-experienced F0 daphnids, confirming the results obtained in the mesocosm study.
Animals were kept in semi-static test system with high amount of food, thus probably Daphnia magna might have perceived the presence of competitors and then adapted its life strategy at this new condition. What it is now needed to understand is how this change affects the sensibility to contaminants.
The interaction between toxicants and biological interaction is rarely investigated but we proved that interspecific interactions can negatively affect the sensitivity of one of the most common test organism in ecotoxicology. Therefore such interactions must be considered when conducting an ecological risk assessment.

**TH 249**

**Competition delays the recovery from toxicant stress**

K Foit[1], O Kaske[2], M Liess[2]
[1]Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[2]Helmholtz Centre for Environmental Research, System Ecotoxicology, LEIPZIG, Germany

Recovery from toxicant stress is important to assess the field relevance of effects. Positive effects on recovery often occur after pesticide-induced mortality relieves competition pressure. We investigated how persistent competition pressure alters effects and the recovery of species.
Model communities of Daphnia (*Daphnia magna*) and Culex larvae (*Culex pipiens molestus*) were pulse exposed (48 h) to the pyrethroid Fenvalerate. Abundance and biomass of aquatic populations were monitored by non-invasive image analysis; adult mosquitoes were counted manually.
Short-term effects due to exposure were increased for both species by intraspecific competition. Long-term effects were exacerbated by interspecific competition: After pulse exposure close to the acute LC50 of 1 µg/L, the recovery of Daphnia was impaired by persistent competition with surviving Culex larvae for 31 days. Culex larvae profited from the slow recovery of Daphnia with an increased emergence until day 47 after pesticide pulse.
We conclude that in natural systems where competition is present, such competitive processes may prolong the recovery of the community structure. Hence, natural communities may be disturbed longer than predicted from mono species tests alone. To achieve a realistic pressure of

competition in test systems at population and community levels, we recommend initiating them with several generation times before contamination.

**TH 250**

**Traits and stress - keys to identify community effects of low levels of toxicants in test systems**

EF Liess, M Beketov, M Kattwinkel
UFZ, LEIPZIG, Germany

Community effects of low toxicant concentrations are obscured by a multitude of environmental factors and biological interactions. To resolve this issue for community test systems, we propose a trait-based approach to detect toxic effects. A long-term experiment with outdoor stream mesocosms was conducted. It was established 2-year before contamination to allow the development of biotic interactions within the community. Following pulse contamination with the insecticide thiacloprid, communities were monitored for additional 2 years to observe long-term effects. Species were aggregated into trait-based groups that reflected stressor-specific vulnerability of populations to toxicant exposure. This reduced intrareplicate variation and increased the ability to detect toxicant related effects. Species with low intrinsic sensitivity showed only transient effects at the highest thiacloprid concentration of 100 µg/L. Sensitive multivoltine species showed transient effects at 3.3 µg/L. Sensitive univoltine species were affected at 0.1 µg/L and did not recover during the year after contamination. The new indicator SPEARmesocosm was calculated as the relative abundance of sensitive univoltine taxa. It detected long-term effects for five species at concentrations that were 1000 times below the concentration at which long-term effects of thiacloprid were detected by the PRC (Principal Response Curve) approach traditionally applied for mesocosms. We also found that species that were stressed, as indicated by a decline in abundance in control streams, were affected more strongly by thiacloprid than nonstressed species. We conclude that the grouping of species according to toxicant-related traits enables identification and prediction of community response to low levels of toxicants

**TH 251**

**Ecological Risk Assessment of estuarine contaminated sediments: the Exposure-Dose-Response framework**

A Iero[1], W Maher[1], A Chariton[2]
[1]University of Canberra, ACT, Australia
[2]Centre for Environmental Contaminants Research (CECR); CSIRO Land and Water, BANGOR NSW, Australia

Sediment Ecological Risk Assessment has often been conducted integrating exposure and effects data using qualitative judgement to weight the different Lines of Evidence. To identify the Lines of Evidence more suitable in evaluating the impairment of sediment environments contaminated by metals, Lines of Evidence have been explored in the Exposure-Dose-Response framework. Data including sediment chemistry, bioaccumulation, toxicity, and biomarkers for molluscs, crustaceans and fish and benthic community assemblages were mined from the literature and from available databases. Data were gathered only for estuarine sediment environments contaminated by copper, cadmium, lead and zinc. The collected data were compared with sediment quality guidelines and explored for relationships within the Exposure-Dose-Response framework. The behaviour of the molar sum of the four metals was investigated for its possible use as a concise indicator of metal exposure and dose and for its relationships with Response. The Exposure-Dose-Response approach was also applied to the Lines of Evidence gathered from Lake Macquarie, an estuarine lagoon on the East Coast of Australia, historically contaminated by copper, cadmium, zinc, lead and selenium. The molar sum of the four metals showed to be a good indicator of contamination and bioaccumulation in relation to response. Dose-Response relationships were shown to be stronger than Exposure-Response relationships in the mined and Lake Macquarie data sets, by-passing the confounding factors due to bioavailability of metals in sediment. Molluscs and fish showed more consistent Exposure-Dose and Dose-Response relationships than crustaceans.

**TH 252**

**Silkworm as a bio-indicator model in ecotoxicological studies on Cadmium (CD)**

O Panzarino[1], P Vernile[2], G Bari[2], R Terzano[2], M Spagnuolo[2], E de Lillo[2]
[1]Faculty of Agriculture, BARI, Italy
[2]Department of Agroforestal and Environmental Biology and Chemistry, University o, BARI, Italy

Xenobiotic risk evaluation largely concerns the international scientific and social communities in order to assess sustainable threshold levels of pollution. Different available bioassays for ecotoxicological studies focused mainly on organisms such as earthworms, mussels and snails while only few insect species have been used up to date. This research aims at setting up protocols for testing some relevant biomarkers on Bombyx mori L. (Lepidoptera: Bombycidae) used as model. This insect species was chosen because it is easily reared under controlled environmental conditions by feeding on mulberry leaves or artificial diet.

Silkworm artificial diet was spiked with 0.01, 0.1, 1 and 10 ppm of Cd. Three microcosms were set up for each treatment and for control.

Twelve larvae of silkworm at the last instars were fed on artificial diet and exposed to pollutant for 6 days at 28°C with 65% relative humidity (RH) and a light:dark ratio of 15:9. After exposure, specimens of B. mori were opportunely treated to assess the metallothionein content, the DNA damage (comet assay), and the bioaccumulation of Cd.

The metallothionein content showed a significant difference between the treatment with the highest Cd dose and the control, while the comet assay showed a dose-response effect.

These first results seem to be promising to use silkworm as a starting model to promote other insects, more relevant from an environmental point of view, as bio-indicators. The application of other biomarkers and the collection of further data for confirming these preliminary information is foreseen in the next steps of this research.

**TH 253**

**Using a soil-water flume on pesticide ecological risk assessment under Mediterranean exposure scenarios**

PAS Leitão[1], M Moreira Dos Santos[2], R Ribeiro[2], MJ Cerejeira[1], P van den Brink[3], JP Sousa[2]
[1]Instituto Superior de Agronomia, Technical University of Lisbon, LISBOA, Portugal
[2]IMAR-CMA, Department of Life Sciences, University of Coimbra, COIMBRA, Portugal
[3]Alterra and Wageningen University, P. O. box 47, 6700AA, WAGENINGEN, The Netherlands

Integrated in a broader study on the fate and effects of plant protection products under Mediterranean conditions results on fate of three PPPs and their effects on aquatic and soil organisms are presented. Samples for both assessments were collected using a recently developed laboratory soil-water simulator allowing simulation of pesticide application, irrigation and collection of different matrix samples (soil, leachate and run-off). Model pesticides were chlorothalonil, ethoprophos and azoxystrobin, used in their commercial formulations and selected based on the result of acceptance in inclusion in Annex I of Directive 91/414/EEC and as being regularly used in Portuguese model crop systems (potato, maize, onion).

Different scenarios for each pesticide were created using reference soil from an agricultural area of Central Portugal. Simulator experiments ran under Mediterranean climatic conditions, and considered the specific crop type, mode of application and irrigation regime for each pesticide. Based on data from previous laboratory tests, soil samples for testing with soil organisms were collected only for ethoprophos, but leachate and run-off samples were collected for the three pesticides. Data gathered from all matrices will be compared with data obtained from laboratory tests aiming to refine effect assessment data obtained in lower tiers. Furthermore run-off matrices will be used as contamination source on higher tier aquatic microcosms.

This study contributes to fulfil the need for integrated (water and soil) studies, especially mimicking more realistic exposure scenarios This will also lead to a refinement of methodologies to assess quality standards that will contribute to decision-making aiming at a sustainable use of pesticides towards water, soil and biodiversity protection, contributing to reduce soil degradation and water contamination at a national level.

## MOPC1 - Amphibians and reptiles in ERA (review)

### MOPC1-1

**A Review of the Inclusion of Amphibians and Reptiles in Ecological Risk Assessments**

KR Campbell[1], SD Deacon[2], JT Ipock[1]
[1]ENVIRON International Corp., TAMPA, United States of America
[2]ENVIRON UK, Ltd, WILTSHIRE, United Kingdom

To be realistic and robust, ecological risk assessments (ERA) should account for potential harm to all the relevant components of the ecosystems being evaluated. Amphibians and reptiles are important components of terrestrial and aquatic ecosystems; they drive important abiotic and biotic processes, which underpin the delivery of ecosystem services. In addition, some species of herpetofauna are legally protected both nationally and internationally. Amphibians and reptiles are excellent indicators of the health of the aquatic and terrestrial habitats in which they live.
In particular, amphibians are sensitive to environmental disturbance because of their biphasic life history, physiological characteristics, and specific microhabitat requirements; reptiles play a complex role in food webs where they can be predators or prey of invertebrates and vertebrates.
In addition to contaminants, numerous other stressors affect the world's herpetofauna, including habitat degradation and loss, introduced species, global warming, and diseases. Publicly available literature was reviewed to determine the current status of including amphibians and reptiles in ERA. It was confirmed that seven amphibian ERA have been conducted on stressors ranging from ultraviolet radiation, acidic deposition, and organic, inorganic and nutrient contaminants. Fewer ERA included risks to reptiles; two ERA have been conducted for turtles where the risk of contaminants, as well as anthropogenic and physical stressors, was assessed. In conservation studies, four ecological assessments evaluated the impacts of non-native reptile introductions to native amphibians and reptiles. It was concluded that while amphibians and reptiles are key to providing many ecosystem services, the results of our review demonstrate that they are still rarely included in ecological risk assessments. However, with the establishment of the SETAC Ecotoxicology of Amphibians and Reptiles Advisory Group in 2010, it is hoped that amphibians and reptiles are included in all future applicable ERA.

### MOPC1-2

**Is it necessary to include reptiles in the risk assessment of plant protection products?**

R Luttik[1], S Fryday[2]
[1]RIVM, BILTHOVEN, The Netherlands
[2]The Food and Environment Research Agency, SAND HUTTON, United Kingdom

In the proposal for data requirements under the new Regulation (EC) No 1107/2009 of the European Parliament and of the Council concerning the placing of plant protection products (PPP) on the market it is proposed to include reptiles in the risk assessment for PPPs. This means that for each PPP it would be necessary to test a reptilian species, but from an animal welfare point of view this is undesirable. The purpose of this poster is to open a discussion on whether reptilian risk assessment should be included in the risk assessment process or whether we have evidence that this would not be necessary.
Fryday and Thompson (2009) reviewed information that might be suitable for assessing the possible exposure of reptiles to PPPs:
_ Many reptilian species can be found at the edges of fields and in hedgerows adjacent to fields. Therefore they could be exposed to PPPs via contaminated food in a similar fashion to birds and small mammals.
_ Exposure via contaminated food will be similar to that of birds except that a reptile is likely to consume more than ten times less of the same food type.. Therefore it can be predicted that exposure of reptiles through food will be less than for a similar-sized bird. The comparison may be valid for small species, like turtles and lizards, which may eat every day during periods of activity. In the case of snakes the comparison is more difficult due to the punctuated feeding pattern where they will eat a large prey item on one day and not feed again for several days or more. In these circumstances maximum daily exposure may therefore be far greater than that predicted for other species. More data on feeding patterns is needed to allow risk assessment for these species.
_ The review of toxicity data confirmed that very little acute toxicity data suitable for comparison with birds is available in the literature. For the five pesticides and one rodenticide for which acute toxicity data was available, reptiles were less sensitive than birds for four compounds and more sensitive to the remainder. Should sufficient data become available in future then consideration could be given to whether data from other species such as birds could be used to predict risk to reptiles.
Tentative hypothesis: Assuming reptiles have similar sensitivity to pesticides to that of birds, dietary risk for reptiles is covered in risk assessment for birds.

### MOPC1-3

**Variation in sensitivity of amphibians to toxic and non-toxic stressors**

A Fedorenkova[1], JA Vonk[2], HJR Lenders[1], AM Breure[2], AJ Hendriks[1]
[1]Radboud University Nijmegen, NIJMEGEN, The Netherlands
[2]Dutch National Institute for Public Health and the Environment, BILTHOVEN, The Netherlands

Amphibian populations are declining around the world. Identifying the major causes of their decline is important to explain why amphibians are at risk and how to preserve them. Causes that may underlie amphibian declines include habitat loss, global warming, acidification, fertilizers, pesticides, toxic chemicals, invasive species, and infectious diseases. Loss of suitable habitat is considered to be the largest factor contributing to this decline. However, remaining habitats might be less suitable due to chemical pollution. In this study, the influence of acidification, nitrogen fertilizer ($NH_4NO_3$), heavy metals (Cd, Cu) and two insecticides on amphibians are evaluated to determine their sensitivity to these stressors. Data were derived from the database of the Dutch Institute for Public Health and the Environment, e-toxBase, as $LC_{50}$ (mg/L) for Anura species. The fact that species differ in their sensitivity to the same stressor allows for the use of Species Sensitivity Distribution (SSD). SSDs are probabilistic models to analyze the variation of species sensitivity for one particular or a set of stressors. In log-logistic distributions, variation in sensitivity of species is described by the slope of SSD (β, parameter proportional to the standard deviation of distribution) and the average toxicity over species is described by the parameter ±/__sample mean of log-transformed values). To study the influence of different stressors on the variation within a population of amphibians, the difference between slopes was compared. The shallowest concentration-effect curve corresponds to β values of 0.65 for cadmium and 0.57 for copper (α is 9.3 and 4.3, respectively). The β for $NH_4NO_3$ equals to 0.41 (α=1.9), for insecticide camphechlor 0.36 (α=0.5) and for azinphos-methyl 0.39 (α=2.9). For acidification the curve is the steepest with the β value of 0.15 (α= pH 3.7), meaning that variation in sensitivity to acidity is the smallest. Previous studies on toxic stressors show that, in general, within a taxonomic order compounds with a specific mode of action have steeper slopes than that with a non-specific mode of action. Here, β values for insecticides are similar to the values characteristic to compounds with narcosis mode of action (β~0.4). This may imply that these insecticides have no specific mode of action on amphibians. The SSD analysis allows to rank the stressors according to the sensitivity of amphibians and identify the major threat causing their decline.

### MOPC1-4

**Evaluation of the embryotoxic potential of xenobiotics in Xenopus laevis using molecular approaches**

L San Segundo, F Martini, G Carbonell, C Fernández, MV Pablos
INIA (Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria), MADRID, Spain

The aim of this work is to explore the validity of molecular endpoints as suitable biomarkers to evaluate the embryotoxic potential of contaminants and complex mixtures on a *Xenopus laevis* embryo assay. For this purpose, the effects of two contaminants of environmental concern (Bisphenol A and Chlorpyrifos), one emerging pollutant (Methylparaben) and several effluents from wastewater treatment plants around the city of Madrid (Spain) have been evaluated in a new frog embryo assay. The parameters considered in this test are lethality, embryo malformations, whole body length at 96 hours of exposure and mRNA expression of different genes involved in the embryonic development at 4, 24 and 96 hours of exposure. The response (inhibition or overexpression) of the studied genes will be compared with the morphological parameters in order to investigate the sensitivity of molecular endpoints for the early detection of sublethal effects. This work has been funded by Spanish projects CONSOLIDER-INGENIO (TRAGUA) CSD2006-00044 and RTA2010-00004-C02-00. L. San Segundo is a doctoral student supported by a FPI fellowship from Spanish INIA.

### MOPC1-5

**Assessment of ecotoxicological status of the Mediterranean population of Caretta caretta (Linneo, 1758) based on classes of age**

M Giannetti, I Caliani, S Casini, T Campani, D Coppola, S Maltese, S Ancora, N Bianchi, L Marsili, MC Fossi
University of Siena, SIENA, Italy

The loggerhead turtle (Caretta caretta) represents the most common sea turtle in the Mediterranean Sea. This species is a long-living (70-80 years) omnivore species that feeds on molluscs, crustaceans and fish potential subjected by threats deriving by contaminants. In addition to the accumulation of pollutants from food the threats for the Mediterranean population of this species are fishing, nesting beaches degradation and solid wastes. For all these reasons since 1996 the loggerhead turtle is listed as "Endangered"on the IUCN Red List of Threatened Species. Therefore, there is a need to develop sensitive tools to investigate the health status of the Mediterranean population of this species. The purpose of this study was to evaluate the ecotoxicological status of Caretta caretta through the responses of a set of biomarkers and the analysis of contaminants levels (PAHs, OCs and heavy metals) in blood, skin biopsies and carapax samples. Between 2008 and 2010 were collected 50 specimens of loggerhead turtles in several Italian rescue centers and during a survey in Spain (free-ranging specimens). Oxidative stress was evaluated on plasma samples by lipid peroxidation (LPO); potential genotoxic effects were investigated by Comet assay and ENA (erythrocytic nuclear abnormalities) assay in whole blood. Butyrylcholinesterase (BChE) activity was detected in plasma as biomarker of neurotoxicity. The presence and induction of CYP1A was detected by Western blot (WB) analysis in skin biopsies as biomarker of exposure to planar molecules. The results were processed by classes of age to evaluate a possible relationship between the specimens age and the different biomarkers responses and contaminants bioaccumulation. In accordance with Casale et al., (2009) the specimens were classified into three age categories (I: specimens from 0 to 5 years; II: from 5 to 10 years; III: more than 10 years) depending on the Curved Carapace Length (CCL) through the use of von Bertalanffy growth-model. The results of total PAHs, carcinogenic PAHs and OCs levels, lipid peroxidation, Hg levels and the frequency of micronuclei and total number of cells with nuclear abnormalities showed increasing values from I to III category to suggest a potential accumulation of contaminants with increasing of specimens age. The data obtained from this multi-trial approach represents a further sight that highlights the potential ecotoxicological risk of the Mediterranean population of Caretta caretta.

### MOPC1-6

**Effects of mosquito control measures on mortality and whole-body corticosterone levels in tadpoles of four Southeast Asian amphibian species**

MB Murphy[1], P Lam[1], S Niu[2], D Dudgeon[2], NE Karraker[2]
[1]City University of Hong Kong, KOWLOON, Hongkong
[2]University of Hong Kong, HONG KONG, Hongkong

Mosquito control methods include both chemical and biological approaches, and are commonly applied in wetlands and marshes that also serve as amphibian habitats. In Hong Kong, mosquito control measures are applied by local authorities in urban and rural areas to control mosquito-borne diseases. In this study, the toxicological and ecological effects of three mosquito control methods used in Hong Kong, larvicidal oil, the organophosphate insecticide temephos, and the bacterium *Bacillus thuringiensis*, on tadpoles of four native wetland-breeding Southeast Asian amphibian species (the ornate pigmy frog [*Microhyla ornata*], paddy frog [*Fejervarya limnocharis*], Asian common toad [*Bufo melanostictus*], and brown tree frog [*Polypedates megacephalus*]) were determined in a mesocosm exposure. Eighty 84-L plastic containers (55 L water/container) were set up and allowed to be colonized by local insect fauna for 30 days prior to commencing the exposure. The mesocosms were randomized by species, treatment, and replicate (n=5; 40 tadpoles per container). Tadpoles were exposed to one of four treatments: freshwater control, 4.70 ml larvicidal oil, 10.70 g temephos, or 1.60 ml B. thuringiensis per container for 28 days. Larvicidal oil and *B. thuringiensis* were re-applied every seven days, while temephos was applied only once at the beginning of the exposure. Effects on tadpole survival and whole-body corticosterone levels were investigated, as well as impacts on the aquatic insect community in the mesocosms.
Tadpole survival in the mesocosms was highly dependent on the presence of Odonate predators. Odonate abundance was reduced by the temephos treatment, which had a positive effect on tadpole survival. The larvicidal oil was found to be toxic to the tested species. Whole-body corticosterone levels were determined by enzyme-linked immunosorbent assay following tadpole homogenization and extraction. The effects of the three mosquito control methods on whole-body cortiscosterone levels will be discussed.

**MOPC1-7**

**Sensitivity of embryos and tadpoles of the green frog Pelophylax perezi (Seoane, 1885) to lethal levels of copper**

BRF Santos[1], R Pereira[2], R Ribeiro[3], AMVM Soares[2], I Lopes[2]
[1]University of Aveiro, AVEIRO, Portugal
[2]CESAM & Departamento de Biologia, Universidade de Aveiro, AVEIRO, Portugal
[3]IMAR - Instituto do Mar, Departamento de Zoologia, Universidade de Coimbra, COIMBRA, Portugal

Metals are well described as responsible for survival reduction and development disturbance on several stages of aquatic organisms when present at high concentrations. This work aimed to compare the sensitivity of embryos and tadpoles of green frog *Pelophylax perezi* (Seoane,1885) to lethal levels of the essential metal copper. Eggs and tadpoles were collected at a coastal freshwater pond in Northern Portugal. Eggs were kept in the artificial medium FETAX until reaching the Gosner stages 9-11. Afterwards, jelly-coat was removed and they were exposed to a gradient of copper concentrations (0 to 3.2 mg Cu L-1) until the 96 h. Survival and malformations rate, time to eclosion and larvae body length after the eclosion were monitored during the assay. Tadpoles were kept for at least 24 hrs in FETAX and, at the Gosner stage 25-28, were exposed to a copper gradient (0 to 2.4 mg Cu L-1), for 96 hrs. At the end of the assay survival was checked.
For embryos, the 96h-LC50 and 96h-LC20 were > 3.2 and 1.4 mg Cu L-1, respectively. The 96h-EC50 and 96h-EC20 for malformations were > 3.2 and 1.2 mg Cu L-1, respectively. Significant differences were observed on the body length in the three highest copper concentrations but no differences were found in time to eclosion. For tadpoles the LC50,96h was 0.9 mg Cu L-1, revealing that this life stage of *P. perezi* is more sensitive to copper than embryos, and, thus, suggesting that though assays with larval stages should be abolish from risk assessment, an exhaustive evaluation of embryo relatively to tadpoles sensitivities should be carried out, to allow the use of scientifically sound safety factors, aiming at avoiding risk of under- or overestimation.

**MOPC1-8**

**Lethal and sublethal effects of nitrogen pollution on anuran larvae**

P Ilha[1], LC Schiesari[2]
[1]Instituto de Biociências - Universidade de São Paulo, SÃO PAULO, Brazil
[2]Environmental Management - University of São Paulo, SÃO PAULO, Brazil

Human activities dramatically increased the amount of inorganic nitrogen released in ecosystems through the application of fertilizers in agriculture, the generation of human and livestock waste, and the combustion of fossil fuels. This nitrogen eventually reaches water bodies where it can, in the form of nitrate, nitrite and ammonium, be toxic to aquatic organisms. Our objective was to test in the laboratory if prolonged exposure of anuran larvae to inorganic nitrogen at low and environmentally relevant concentrations could affect survival, growth, development and behavior. Tadpoles of *Hypsiboas faber* (Anura, Hylidae) were exposed to 0, 2.5 and 10 mgN/L of nitrate, nitrite and ammonium during 21 days in a static renewal test. We demonstrated that if there is extended exposure even relatively low concentrations of inorganic nitrogen can cause lethal and sublethal effects on anuran larvae. Nitrate, the most abundant N form in nature, has low toxicity when compared to nitrite and ammonium, causing no effects even in the largest manipulated concentration. Tadpoles exposed to 10 mgN-nitrite/L had survivorship 20% and mass 12% lower than controls. However, it is unlikely that the concentrations of nitrite we manipulated in the laboratory are common in nature, especially under aerobic conditions. On the other hand, 10 mgN-ammonium/L reduced survivorship in 10% and activity rate in 22% relative to controls. This concentration is within the upper range of concentrations observed in nature. This study contributes to the development of ecotoxicology in Brazil by establishing the basis for the employment of native amphibians as model experimental system. Future studies that aim to assess the environmental risk of nitrogen contamination should monitor concentrations in natural habitats and evaluate the effects of synergistic interactions between inorganic nitrogen and other physical, chemical or biological stressors to amphibian larvae.

## MOPC2 - New developments and perspectives in Life Cycle Sustainability Assessment

**MOPC2-1**

**Life cycle based indicators for quantifying and monitoring the environmental impact of European Union**

M Goralczyk, MA Wolf, D Pennington
European Commission - DG Joint Research Centre, ISPRA, Italy

Sustainable development is an underlying objective of the European Union treaties. It is mainstreamed to the European Union policies, along with the approach chosen to facilitate meeting this objective"'life cycle thinking. So far, the tools necessary to measure the progress towards this ambitious goal have been missing. Therefore, the JRC/ESTAT in consultation with DG ENV and the EEA developed a new type of life cycle based indicators for quantifying and monitoring the environmental impact of the European Union. This paper presents the framework for the life cycle based indicators.
These indicators serve the implementation of modern life-cycle based environmental policies, like the Sustainable Consumption and Production Action Plan (COM(2008) 397), the Thematic Strategy on the Sustainable Use of Natural Resources(COM(2005) 670), and the Thematic Strategy on Prevention and Recycling of Waste (COM(2005) 666).
Life cycle based indicators are essential to monitor progress and objectives towards sustainable consumption and production, with particular focus on the separation of environmental impacts from economic growth. The indicators take into account the impacts and resources consumed, both inside and outside the EU, that are associated with goods and services consumed and the wastes produced.
The life cycle based monitoring indicators include:
- Decoupling Indicators (resource efficiency indicators) which measure the total environmental impact of European Union in relation to the resources used.
- Basket-of-Product Indicators which informs about the environmental impact indicators for products, covering a representative selection of goods and services consumed in the EU.
- Waste Management Indicators cover the entire waste management chain for most relevant waste types generated and treated in the EU.
The indicators will be used to monitor progress towards sustainable development in the policy areas of resources, consumption and production, and waste, allowing the detailed analysis of the European production and consumption. They will support the sustainable use of natural resources without shifting of burdens in a globalised economy as well as foster material and energy resource efficiency and reduced environmental pressure of waste management.

**MOPC2-2**

**Feasibility of current SLCA methodology for technology assessment**

E Zschieschang[1], A Lehmann[2], L Schebek[3], M Finkbeiner[2]
[1]Karlsruhe Institute of Technology (KIT), KARLSRUHE, Germany
[2]Technical University Berlin, Department of Environmental Technology, BERLIN, Germany
[3]KIT, Institute of Technology Assessment and Systems Analysis, KARLSRUHE, Germany

Life cycle thinking within sustainability assessment of products so far mainly addresses environmental aspects (Life Cycle Assessment). However, assessing economic and social aspects gain increasing attention; the latter especially since the publication of the UNEP-SETAC Guidelines for Social Life Cycle assessment (SLCA) of products in 2009.
Based on two case studies on sustainability assessment of technologies for water respectively fuel provision in developing countries, social aspects along the life cycle of those technologies were identified. Special focus was laid on the "use-phase"of technologies respectively the production phase of the services provided.
It is discussed if the assessment of technologies is actually within the scope of SLCA, which focuses on products. Since it consequently was considered to be, current SLCA-methodologies - summarized in the UNEP/SETAC Guidelines - were analyzed with regard to suitable impact categories and indicators for describing the identified social sustainability aspects.
The paper thus examines the basic applicability of SLCA guidelines to address social aspects and indicators which are considered as relevant to evaluate the "sustainability performance"of technologies. Finally, possible additional social indicators for technology assessment within management systems are proposed, giving an outlook on how further development of SLCA methodologies could look like.

**MOPC2-3**

**New guideline for sustainable chemicals management**

CTF Blum[1], D Bunke[2], A Reihlen[3], S Walter-Rhode[1]
[1]Ferderal Environment Agency (Germany), DESSAU-ROβLAU, Germany
[2]Öko-Institut e.V., 79100 FREIBURG, Germany
[3]Oekopol GmbH, HAMBURG, Germany

Today's chemicals management has the responsibility to avoid long-term and irre-versible damage to human health and environment. Existing data of a chemical pro-vides important information for the producer and the applicant to decide whether a chemical is able to perform distinct functionalities. Additionally, existing concepts dealing with the assessment of chemicals impact on health and environment are mostly restricted to special applications. However, it is necessary to develop a new approach for industrial operators to address all aspects of sustainability in production and usage of chemicals.
Therefore, based on the analysis of three existing concepts, the guideline "Criteria for Sustainable Chemicals"for producers and operators was developed. In this guideline, substance characteristics were accounted for by distinct substance-orientated assessment criteria in terms of hazardous properties, exposure assess-ment and risk characterisation. Additionally, application-orientated assessment crite-ria were established to refer to methods of processing and use.
In this new guideline not only inherent and intrinsic properties and potential sub-stance exposure were addressed. Also aspects of sustainability of chemicals along their whole life-span were accounted for: emission and transport, resource and en-ergy demand as well as social implications. Overall, the guideline was designed as a level-adapted risk reduction concept with 15 substance- and application-orientated assessment criteria with focus on relevance, applicability and underlying information.
For the first time, a guideline concentrates on essentials for a holistic sustainable chemicals management and therefore helps producers and operators to green their chemical portfolio as well as their internal processes.

**MOPC2-4**

**Development of inventory database aimed at sustainability assessment considering environmental, economic and social aspects**

K Horiguchi, N Itsubo
Tokyo City University, YOKOHAMA, Japan

As sustainable and prosperous global society is pursued, LCA aiming at environmental aspect is expected to expand considering sustainability such as social and economic aspects. Although several studies of life cycle social impact assessment have been proposed, the existing inventory databases consider mainly environmental aspect.
In this study, we developed inventory database focused on triple bottom line, which contains environmental, economic and social aspects, using input-output analysis. On the environmental aspect, natural resources, water resources and biodiversity as well as climate change is considered. On the economic aspects, a framework considering the effect of production inducement is designed. Third, on social aspects, labor inducement effect is evaluated. In addition, we have a plan to include labor accident in our database.

**MOPC2-5**

**Methodological development of regional sustainability analysis**

K Szita Toth[1], J Roncz[1], A Nyíri[2]
[1]University of Miskolc/Faculty of Economics,, MISKOLC-EGYETEMVÁROS, Hungary
[2]NORRIA North Hungarian Regional Innovation Agency, MISKOLC, Hungary

Recently the methodological aspects of the sustainability LCA induce increasingly bigger interest among LCA researchers. Many assessments connect to sustainable product systems, renewable resource system or regional and local sustainable models. This paper describes an applied method of a regional sustainability assessment. It is based partly on LCA and partly on sectors mutual relationship.
The basic concept of our analysis is built on the LCA standards ISO 14040 and ISO 14044 but it is supplemented by economic and social elements, because according to our concept all (three) pillar of sustainability should be integrated into the assessment. In the development of the concept we used the following models as a starting point (EIOA, MFA, REEIO, CALCAS, GEM-E3, EVR) selecting their advantage to build a measurable, relatively simplified, transparent, and coherent model specified to our region (at NUTS 2 level) that represents an underdeveloped, a former heavy-industrial centre.
In this model LCA is built on a matrix structure, the environmental impacts have been aggregated as an environmental performance index, while we measure the economic and social impacts by scenario and trend analysis. For system border we chose the region's geographical border, the function unit is the unit of GDP produced in the region. The data analysed in the model generated from regional material flow and sector specific production data statistics.
The model does not integrate the whole economical activity; it focuses for those sectors, which have a more considerable role in the development of the region and can determinate its sustain-

able path. It involves:
- sectors which cover the 80 percent of the environmental load focusing on the largest polluter producers at company level - environmental aspect;
- sectors where the added value is the highest - economic aspect,
- sectors which employs the most- social aspect.
The selection of the dominant sectors is based on long term statistical data analysis provided by the Hungarian Statistical Office.
Conclusion
Recently we are working at the elaboration of a demonstrative project, which can represent and verify the model's viability and its adaptability through an example of a selected sector's evaluation. This can help us characterise the further steps and directions to improve the model and sustainability assessment.

**MOPC2-6**
**Selection of LCA-based environmental criteria for multi-criteria decision support in a biorefinery context**
G Liard[1], P Lesage[1], P Stuart[2], R Samson[1], MB Amor[3]
[1]CIRAIG, MONTREAL, Canada
[2]NSERC, MONTREAL, Canada
[3]CIRAIG-École Polytechnique de Montreal, MONTREAL (QC), Canada
Triticale is a non-food crop that can grow on marginal lands. It may therefore be an interesting candidate for biorefinery feedstock. To help identify sustainable pathways for three different products made from triticale: ethanol, polylactic acid (PLA) and thermoplastic starch (TPS), a multi-criteria decision-making (MCDM) panel is conducted which will consider four aspects: product portfolio competitiveness, technico-economics, biomass procurement and environmental impacts. Given the number of aspects considered, the number of criteria per aspect should be as few as possible while remaining representative, comprehensive and easy to understand. Consequential Life cycle assessment (C-LCA) has been chosen to calculate the environmental impacts of each scenario, taking into account affected processes and indirect land use change (iLUC). Because the study is limited to the context of Alberta, the triticale scenario will be compared to wheat and corn scenarios, which are the most common local feedstock for biorefineries.
The C-LCA midpoint categories impacts and interpretation will be presented to a preliminary panel along with a productivity-weighted measure of land use that represents the potential competition with food. In this preliminary panel, the weighting of the different impacts will be assessed, enabling to calculate a smaller set of criteria adapted to the biorefinery context in Alberta for the environment aspect. This presentation will present the LCA-based criteria definition for the environmental aspect and its integration in the overall MCDM panel.

## MOPC3 - Data-driven, knowledge-based, and QSAR modelling in ecotoxicological assessment

**MOPC3-1**
**An uncertainty-based framework for the integration of data from different sources in ecotoxicological risk assessment**
E Boriani[1], A Fernandez[2], A Lombardo[1], E Benfenati[1]
[1]Mario Negri Research Institute, MILAN, Italy
[2]Departament d'Enginyeria Quimica Universitat Rovira i Virgili, TARRAGONA, Spain
Estimation of risks caused by environmental stressors involves uncertainties. These uncertainties might have impact on the results of the risk assessment and, thus, to the decision making if risk assessment is supporting a decision making process. Therefore it is important to recognize and quantify uncertainties during the risk assessment process. The identification and characterization of uncertainty sources are two capital issues to develop a transparent and objective decision support system to both integrate different data and perform any risk assessment analysis.
BCF has been used as a benchmark endpoint to develop a decision support framework based on uncertainty values obtained from the differences between experimental and predicted BCF values for a training set of chemicals. BCF data has been treated as a continuous endpoint and the uncertainty of each predictive test method has been obtained following the same methodology. As a result of such analysis it is possible to obtain a point estimate for the mean error of the method and, what is more relevant, a confidence interval for the mean error which gives an idea of the uncertainty of each method tested on a new substance.
The uncertainty values relative to the alternative methods are compared next. This gives a realistic expectation of the possibility to use a certain value for a specific endpoint. The relevance of a method in the final risk characterization may be expressed in terms of its uncertainty. The advantage of this approach is that different methods can easily be compared and a clear objective procedure is defined and applied unambiguously.

**MOPC3-2**
**SMILES-based QSAR model for bioconcentration factor**
A Toropov[1], P Toropova[1], E Benfenati[1], G Gini[2]
[1]Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy
[2]Politecnico di Milano, MILAN, Italy
The Simplified Molecular Input Line Entry System (SMILES) has been used as a representation of the molecular structure to build up quantitative structure - property relationships (QSPR) for the prediction of the logarithm of bioconcentration factor (logBCF) of a large set of organic compounds (n=473). Quite good predictions of logBCF for external test sets (n=105) have been obtained for three random splits into subtraining, calibration, and test sets, in spite of lower statistical quality of the models for the subtraining set. An attempt to explain this phenomenon from a probabilistic point of view is discussed. This is also useful to evaluate principles for the definition of the applicability domain for these models. A new global SMILES invariant ATOMPAIR (calculated with CORAL software, http:/www.insilico.eu/CORAL) has been examined as a potential tool for improvement of the statistical quality of the logBCF prediction.

**MOPC3-3**
**QSAR for toxicity of aromatic aldehydes to Tetrahymena pyriformis using correlation weights of physicochemical situations**
A Toropov[1], P Toropova[1], E Benfenati[1], G Gini[2]
[1]Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy
[2]Politecnico di Milano, MILAN, Italy
A physicochemical situation in the molecular structure can be represented by means of a (0,1)-descriptors, where 0 is the indicator of absence and 1 is the indicator of presence. For each physicochemical situations and each molecular fragment that can be calculated from the simplified molecular input line entry system (SMILES), correlation weights, producing a maximum correlation coefficient between the endpoint and the optimal descriptor, can be obtained by the Monte Carlo technique. This approach has been used for the QSAR model of the toxicity of aromatic aldehydes to Tetrahymena pyriformis (-logC, C is the 50% growth inhibitory concentration). The model is characterized by the n=35, R2=0.63, Q2=0.58, RMSE=0.287, F=56 (sub-training set); n=23, R2=0.88, R2pred=0.87, RMSE=0.290, F=166 (calibration set); and n=19, R2=0.89, R2pred=0.86, RMSE=0.210, F=138 (test set). It has shown that the model is both robust and convenient for the physicochemical interpretations. The described calculation can be carried out with CORAL software available on the Internet (http:/www.insilico.eu/CORAL).

**MOPC3-4**
**QSAR models for toxicity of organic substances to Daphnia magna built up by using the CORAL freeware**
A Toropov[1], P Toropova[1], E Benfenati[1], G Gini[2]
[1]Istituto di Ricerche Farmacologiche Mario Negri, MILAN, Italy
[2]Politecnico di Milano, MILAN, Italy
CORAL (CORrelations And Logic) is a freeware available on the Internet. This freeware is designed to build up quantitative structure - property/activity relationships (QSPRs/QSARs). The molecular structure for CORAL should be represented by the simplified molecular input line entry system (SMILES). Optimal descriptors calculated with SMILES are a mathematical function of the presence or absence of SMILES elements. The element is one or two symbols which cannot be examined separately (e.g., 'Cl', 'Br', etc.). The basic idea of our approach is to calculate correlation weights for each element or combination of the elements by the Monte Carlo method. These coefficients serve to calculate the descriptor correlated with the endpoint for the training set, hoping that this correlation will also hold for the external test set. These descriptors can be improved by taking into account global physicochemical situations in molecules. An example of the physicochemical situation is the presence of oxygen, nitrogen, and sulphur. Another illustration of the mentioned situations is the presence of oxygen and nitrogen accompanied but no sulphur. One can calculate these situations with SMILES and represent them by descriptors combine 0 (absence) and 1 (presence). Using this software we developed a model for the prediction of the toxicity to Daphnia magna (LD50). The statistical characteristics of this model are the following: n=114, r2=0.7082, q2=0.6969, s=1.04, F=272 (subtraining set); n=108, r2=0.7366, r2pred=0.7238, s=0.877, F=296 (calibration set); and n= 75, r2=0.7897, r2pred=0.7790, s=0.847, F=274 (test set).

**MOPC3-5**
**Classification scheme for screening metabolic half-lives of organic chemicals in fish**
W Janzen, R Kühne, G Schüürmann
Helmholtz Centre for Environmental Research GmbH - UFZ, LEIPZIG, Germany
For the regulation of chemical substances under REACH, the bioconcentration factor (BCF) is an animal-intensive and high-cost endpoint. So far, in silico alternatives to experimental testing focus on the octanol/water partition coefficient as predictor for the passive-diffusive uptake and storage in the organism. Recently, a fragment-based scheme for predicting metabolic half-lives from molecular structure has been introduced, enabling the possible extent of BCF reduction due to biotransformation to less hydrophobic metabolites. Estimation of metabolic half-lives is also needed for multimedia fate modelling.
In the present communication, a new classification scheme is introduced that enables the discrimination between fast-, intermediate- and slow-metabolizing compounds based on their structural features and associated property profiles.
Normalized estimated values for whole-body in vivo metabolic half-lives ($\tau$1/2) for fish of about 600 organic compounds for scheme developing were taken from the work of Arnot et al. 2009. Rules for a classification scheme where developed using physical-chemical and molecular properties and structure fragments, all of which were generated with our in-house software ChemProp (Schüürmann et al. 1996).
The proposed classification scheme allows a screening-level assessment of metabolic biotransformation half-lives for organic chemicals in fish, and can be integrated into existent schemes for predicting BCF as additional correcting factor.

**MOPC3-6**
**Reactive toxicity of michal acceptors: quantitative prediction based on quantum chemical reaction barriers**
D Mulliner, G Schüürmann
Helmholtz Centre for Environmental Research, LEIPZIG, Germany
One important property to predict reactive toxicity of Michael acceptors is their electrophilic reactivity towards thiols. For a set of 35 $\alpha,\beta$-unsaturated aldehydes, ketones and esters, quantum chemical transition-state calculations including consideration of different conformers have been performed for their model reaction with $CH_3SH$ as surrogate of glutathione (GSH), focusing on an addition pathway with initial protonation of the carbonyl oxygen. The GSH-thiol reactivity in terms of logarithmic second-order rate constants, $\log k_{GSH}$, can be predicted with the calculated reaction barriers, $\Delta E^{\ddagger}$, with $r^2$ (squared correlation coefficient ) = 0.96 if combined with an indicator variable $I\alpha$ to discriminate between $\alpha$-H and $\alpha$-substituted derivatives. For an augmented set of 46 $\alpha,\beta$-unsaturated carbonyls aquatic toxicity quantified as logarithmic 50% growth inhibition after 48-h exposure, $\log EC_{50}$, of the ciliates Tetrahymena pyriformis were taken from literature. Class-specific regression models for predicting $\log EC_{50}$ were developed using a combination of $\log K_{ow}$ (logarithmic octanol/water partition coefficient) and predicted $\log k_{GSH}$ or calculated $\Delta E^{\ddagger}$ and $I\alpha$ yielding $r^2$ values up to 0.96 (aldehydes), 0.92 (ketones), and 0.83 (esters), respectively. Our results confirm the recently reported difference in hydrophobicity and reactivity contributions to the aquatic toxicity of Michael acceptors between aldehydes, ketones and esters. The derived regression models appear useful as in silico tools for screening the electrophilic reactivity and toxicity of $\alpha,\beta$-unsaturated carbonyls in the context of integrated testing strategies for REACH, enabling an early discrimination between narcosis-level and reactive toxicants.

## MOPC4 - Innovative approaches of toxicant identification and structure elucidation

**MOPC4-1**
**Effect-directed analysis (EDA) of transformation products of triclosan formed during (photo)oxidative processes**
H Mestankova, N Bramaz, K Schirmer, B Escher, U von Gunten, S Canonica
EAWAG, DÜBENDORF, Switzerland
Transformation processes in the aquatic environment and in water treatment systems may signifi-

cantly change the toxicity in comparison to the parent compound. For an overall risk assessment, the toxicity of the transformation products should be investigated. The direct identification of the transformation products, their synthesis if they are not readily available, and evaluation of their toxicity, is a rather tedious and expensive procedure. As an alternative, an effect-driven approach allows the priority setting for further identification and evaluation of toxicity. Here, the toxicity of the mixture of transformation products is tested and specific transformation products are identified only if the toxicity does not follow the degradation kinetics of the parent compound, which indicates that the transformation product is more toxic than parent, presumably because a new toxicophore is formed.
This screening-level approach will be illustrated on the example of the antimicrobial agent triclosan (5-chloro-2-(2,4-dichlorophenoxy)phenol). The toxicity of transformation products was investigated during four (photo)oxidative processes (direct phototransformation, triplet-induced photosensitized oxidation, oxidation by hydroxyl radicals and ozone). In a first step, we followed the evolution of the specific toxicity of the parent compound (growth inhibition of E. coli) during its degradation. The specific toxicity decreased proportionally with the decrease of triclosan concentration. We concluded that the antibacterial activity of the degradation products was insignificant in comparison to the toxicity of triclosan. In addition, the induction of cytochrome CYP1A, measured as EROD activity in fish liver cells, was analysed in order to detect dioxin-like compounds. Our work confirmed formation of 2,8-dichlorodibenzodioxin (2,8-DCDD) during direct photodegradation of triclosan. The dioxin-like activity measured by the EROD assay corresponded to the concentration of 2,8-DCDD measured by HPLC analysis. Moreover, we revealed the formation of CYP1A-inducers during ozonation which could not be explained by 2,8-DCDD. Therefore, this degradation mixture was fractionated according to hydrophobicity by preparative HPLC and the active fraction localized by application of the bioassay, whereupon the toxic compound is identified.
Our approach can be used as a first step in toxicity assessment of transformation products and facilitates identification of toxic products formed.

### MOPC4-2

**What are the constituents of heavy fuel oil that cause toxicity to fish?**

PV Hodson[1], J Adams[1], J Bornstein[1], RS Brown[1], B Hollebone[2]
[1]Queen's University, KINGSTON, Canada
[2]Environment Canada, OTTAWA, Canada

Heavy fuel oil (HFO or Bunker C) is a thick, viscous residue of refining that is used in large heating plants, industrial processes, and ships as an inexpensive source of energy. Compared to crude oil, it contains much smaller proportions of low molecular weight alkanes and mono- and diaromatics, and higher proportions of high molecular weight PAH, waxes, resins, and asphaltenes. Because it is transported by truck and rail in relatively small quantities, there is a high frequency of shipments, and a high risk of spillage. In aquatic ecosystems, Bunker C tends to sink because it has a specific gravity close to 1.0, and brief weathering or contact with sediments accelerates sinking, usually as large blobs or tar balls. Little is known about toxicity, although a spill in Wabamum Lake, Alberta contaminated whitefish spawning shoals and impaired embryo survival. Our lab tests have demonstrated that HFO is more toxic to fish embryos than crude oil, in proportion to its higher concentrations of PAH. We have used embryo toxicity as a tool for an effects driven fractionation of HFO to test the hypothesis that it is PAH in HFO that are responsible for toxicity. This paper will present our progress in fractionation, chemical analyses, and toxicity testing.

### MOPC4-3

**Identification and compartmentalization study of emerging EDCs in an impacted river system by using an EDA approach**

N Creusot[1], MH Dévier[2], JM Porcher[1], H Budzinski[2], S Aït-Aïssa[1]
[1]INERIS, VERNEUIL EN HALATTE, France
[2]ISM, LPTC, TALENCE, France

The last decade dealt with the increasing occurrence of emerging pollutants (e.g. hormones, pharmaceuticals) that trigger adverse effects in river systems. Thus, strategies for their identification are needed. Effect directed analysis (EDA) approach aims at identifying such adverse chemicals. Its current use is the most often restricted to dioxin (AhR), estrogen (ER) or androgen (AR) receptors pathways while recent evidences suggested that others signalling pathways (e.g. PXR) involved in endocrine regulation can be disrupted. Hence identifying environmental active pollutants on these other pathways will enhance risk knowledge on endocrine disruption in situ.
We report here the use of a battery of in vitro reporter gene bioassays including classical and emerging pathways to characterize the contamination of both sediment and surface water (polar organic integrative sampler (POCIS) and semi permeable membrane device (SPMD)). This allowed to integrate a wide range of active chemicals and to assess their distribution between river compartments. To isolate and identify these chemicals, a two-step fractionation was then used. This overall approach was applied to a river site under mixed anthropogenic pressure where fish are impacted.
The bioassay profiling revealed estrogenic, anti-androgenic, dioxin-like and PXR-like activities in sediment while very strong estrogenic and PXR-like activities were measured in POCIS as regard to what reported scientific litterature. Bioanalysis of SPMD extracts is under progress. A first fractionation of sediment extract led to 4 fractions. F3 (polar) exerted only strong estrogenic and PXR-like activity while dioxin-like was mainly detected in F1 and F2. This demonstrated the occurrence of semi-polar to polar ligands of ER and PXR in sediments. Then F3 was hyperfractionated, estrogenic activity was mainly detected at the same elution time as BPA and 17β-E2 while PXR-like activity was mainly detected in less polar fractions.
In summary, this study demonstrates the usefullness of an EDA approach based on a multi-receptors/muti-compartment approach to assess and identify a diversity of EDCs and to study their distribution between water compartment The active fractions will be investigated using accurate mass spectrometric techniques while further fractionation strategies will be adressed on POCIS extracts. Purification on purified nuclear receptor column will be also tested on active fractionation for an optimized identification.

### MOPC4-4

**Automated strategies to identify compounds based on mass spectrometry and calculated properties**

EL Schymanski[1], C Gallampois[2], M Meringer[3], W Brack[1]
[1]UFZ - Helmholtz Centre for Environmental Research, LEIPZIG, Germany
[2]Linköping University, LINKÖPING, Sweden
[3]DLR - German Aerospace Centre, MUNICH, Germany

The identification of active compounds in complex environmental samples using integrated chemical and biological approaches often relies on chromatographic separation followed by mass spectrometric detection due to sample amount and purity. Effects often cannot be fully explained by compounds identified using mass spectral databases alone and it follows that many compounds (e.g. transformation products or emerging pollutants) not within the databases may be responsible for the unexplained activity. An alternative to database searching is to use structure generation approaches to generate all possible compounds matching the analytical data and then reduce these candidates by progressive exclusion based on calculated properties. The identification of compounds based on gas chromatography-electron impact-mass spectrometry (GC-EI-MS) and structure generation techniques has been improved by combining a number of strategies into a programmed sequence. This builds on the mass spectral interpretation and structure generation procedures in the program MOLGEN-MS by the calculation of additional data following structure generation, such as the boiling point, octanol-water partitioning coefficient and steric energy. Several exclusion criteria were applied progressively to eliminate candidates that did not match the analytical information available. The effectiveness of the proposed sequence was tested on a case-study of 29 structures of formula $C_{12}H_{10}O_2$, which showed that the combination of mass spectral interpretation and the additional exclusion criteria reduced the number of possible candidates down to the correct set of substitutional isomers in most cases. The method was then tested on unknown spectra isolated during mutagenicity-based effect-directed analysis (EDA) on river water sampled using blue rayon as a passive sampler in the Elbe River in the Czech Republic. Two compounds were identified in an active fraction using structure generation techniques based on GC-EI-MS spectra, confirmed analytically using both GC and LC-based techniques. These compounds were not responsible for the sample mutagenicity, but no additional spectra of interest were found using GC-based analysis. LC-Orbitrap-MS/MS analysis of the same samples revealed tens to hundreds of peaks of interest following subtraction of the blanks, highlighting the need to incorporate LC-based methods into EDA studies and develop similar database-independent identification strategies for $MS^{(n)}$ spectra.

### MOPC4-5

**Contaminants identified in sewage Effluent using an LC/ ToF fast screening approach**

G Bondoux, E Riches, P Hancock, J Morphet
Waters, GUYANCOURT, France

In recent times the use of pesticides, herbicides and fungicides has steadily increased, in an effort to meet global food demands. A percentage of such chemicals applied to crops will, inevitably, end up leaching into the surrounding soil and waterways. Strict environmental monitoring is mandated, which endeavours to safeguard the environment and protect plants and wildlife from harm as a result of exposure to these types of chemicals.
A novel QTof instrument coupled with ACQUITY UPLC, along with the Waters ToF Screening Pesticide Database, and POSI±IVE software data processing, was used to rapidly screen treated sewage effluent that had been extracted using SPE Waters' OASIS HLB cartridges. A generic screening UPLC gradient was used, with a total run time of 2 minutes. The mobile phases used were 10 mM ammonium acetate solution in water and 10 mM ammonium acetate in methanol. Extracted sewage effluent was successfully screened for pesticide contaminants at ultra-trace level. Use of the MSE functionality of the QTof instrument enabled the acquisition of exact mass data for both precursor and fragment ions in one screening run, with a high level of reproducibility. The RMS variation in acquired exact mass across a peak for thiabendazole was 1.5 ppm. This provides increased confidence in the detection and identification of compounds present, as result of the accurate and precise exact mass data acquired, and also allowed the use of very narrow chromatographic extraction windows, as low as 0.5 mDa in some instances.
In addition, the use of ChromaLynx XS software for non-targeted spectral deconvolution enabled further discovery and identification of a non-targeted pharmaceutical compound in natural river water during a pesticide screening run. This was confirmed by examination of the high energy MSE fragment ion data, which exhibited characteristic fragments at the retention time for that compound.

### MOPC4-6

**Utilizing novel software algorithms to streamline LC-MS analysis for targeted and non-targeted screening in environmental applications**

F Schousen, KA Akervik, ND Duczak
Thermo Fisher Scientific, SAN JOSE, United States of America

The availability of full scan ultra high resolution LC-MS instruments allows for rapid analyses of samples without the need to develop specific MS methods for target components. At the same time, it is possible to re-interrogate the same dataset for the identity of unknown or unexpected components since full scan data is acquired over the entire chromatographic run. Historically, significant time has been devoted to manual data mining required when searching for unexpected components. We describe the use of software for environmental screening applications to improve processing throughput of ultra-high-resolution, accurate-mass LC-MS data. The software incorporates several novel algorithms for data processing, including advanced component detection, parameter-less peak integration, and intelligent elemental composition determination.
In addition to these algorithms, automated library and database searching can be enabled to facilitate identification and throughput. The software can be used to screen and report targeted components in an automated fashion and at the same time obtain information on potential unexpected or unknown contaminants in samples

## TUPC1 - Integrated testing strategies (ITS) for bioaccumulation

### TUPC1-1

**Integrated Testing Strategy (ITS) to optimise the assessment of bioconcentration under REACH framework**

A Lombardo[1], A Roncaglioni[1], M Nendza[2], H Segner[3], S Jeram[4], E Benfenati[1]
[1]Istituto di Ricerche Farmacologiche "Mario Negri", MILAN, Italy
[2]Analytisches Laboratorium, LUHNSTEDT, Germany
[3]University of Bern, BERN, Switzerland
[4]Institute of Public Health of the Republic of Slovenia, LJUBLJANA, Slovenia

Aim of the REACH legislation is human and environmental protection. To achieve this goal the use of available information results achieved by alternative methods are preferred, not only to save animals but also to increase the information robustness. To optimize the choice of the methods to satisfy all REACH requirements, an ITS (Integrated Testing Strategy) is recommended. It combines the available knowledge about the target chemical (identity, exposure, effects) with alternative information: non-optimal in-vivo data (e.g. BMF or BAF data), values from testing (in-vitro) and non-testing (e.g. QSAR and read-across) methods.
In this work an ITS for bioconcentration assessment has been developed beyond the REACH requirements and the official guidelines. The ITS for bioconcentration assessment takes into consideration: 1) annual production tonnage, 2) experimental information (including in-vivo and in-

vitro data), 3) physicochemical properties, and 4) data from non-testing methods. As one component, this ITS contains a waiving scheme to identify the compounds that can be safely considered non bioaccumulative (nB). This waiving scheme is made up of two logP-based worst-case QSARs and a decision tree based on physicochemical properties. The performance of the waiving scheme was tested using a large dataset. More than 50% of the nB compounds can be classified this way. The ITS allows to further reduce the number of compounds needing an in-vivo test using alternative methods. The ITS presented here is implemented in a web tool to help users in the decision-making process.
Financial support by the OSIRIS project (GOCE-CT-2007-037017) is gratefully acknowledged.

### TUPC1-2

**Screening for low aquatic bioaccumulation: physico-chemical constraints**

M Nendza, T Herbst
Analytisches Laboratorium, LUHNSTEDT, Germany

Physico-chemical properties related to the bioavailability of xenobiotics in aquatic environments have been tested for their ability to identify chemicals with low bioconcentration potential. Cut-offs in lipophilicity (log KOW < 3 or > 10), solubility and volatility (log Henry constant < -11 [atm/(mol/L)]), degradability (ready biodegradability, hydrolysis) and ionisation (> 5% ionisation at pH 7) have been adopted and combined into a decision tree based on 382 industrial chemicals [1]. The 5-parameter classification scheme was externally validated with 49 pesticides and successfully confirmed with 83 bioaccumulative compounds. The applicability domain of the model has been described in terms of chemical classes (excluding polybrominated compounds (> 4 Br), organometallics, compounds with perfluorinated fragments, substances with an acyclic alkyl moiety (chain length > C7) and thiols) and ranges of physico-chemical properties. The present tool [2] allows to securely de-prioritise more than 50% chemicals of low concern with regard to the B criterion (BCF < 2000). Bioassays with compounds with these physico-chemical constraints may be waived because testing may be technically not possible and does not appear scientifically necessary in PBT and risk assessments.

### TUPC1-3

**Use of conditional inference trees in support of B and non-B classification for aaiving of experimental BCF testing**

SE Strempel[1], M Nendza[2], M Scheringer[1], K Hungerbühler[1]
[1]ETH Zürich, ZÜRICH, Switzerland
[2]Analytisches Laboratorium für Umweltuntersuchungen und Auftragsforschung, LUHNSTEDT, Germany

Under the European REACH regulation substances of very high concern, including persistent, bioaccumulative and toxic (PBT) chemicals, require authorization and their use may be restricted. According to Annex XIII of REACH, the bioconcentration factor (BCF) may be used as a surrogate to characterize bioaccumulation potential. To improve animal welfare and reduce costs of experimental testing of chemicals, QSARs are accepted by the legislation to identify bioaccumulation potential. Here we present a scheme for identifying chemicals for potential waiving of experimental BCF studies that extends an initial decision scheme based on physicochemical properties (1), that uses 382 chemicals from the CEFIC database (2) as training set and classifies the chemicals into "non-B"and "undecidable"using 5 descriptors. Conditional inference trees (3) (cTree) separate the variable selection from the splitting procedure, reduce overfitting and avoid selection bias towards explanatory variables with many possible splits. After analysis of multiple collinearities and variable importance 10 variables were selected to construct the cTree. This tree classifies the remaining 179 undecidable chemicals from (1) into B, non-B, and still undecidable. Ctrees show also how a classification was obtained: the paths from the root to a particular leaf detail the rules to classify substances. From the 179 chemicals, 37% (45/122) of the non-B chemicals and 19% (11/57) of the B chemicals could be correctly classified, the remaining 123 chemicals are still undeciable. In combination with the initial decision scheme based on physicochemical properties, 60-70% of chemicals could be proposed for waiving their experimental BCF tests and therefore the work presented here has the potential to contribute to monetary savings as well as saving of animal lives in the framework of REACH.

### TUPC1-4

**A cost-based classifier for bioaccumulation assay waiving**

R Rallo, A Fernandez, F Giralt
URV, TARRAGONA, Spain

The development of robust and reliable models for bioassay waiving requires the development of robust classifiers able to distinguish between active and non-active chemicals with high sensitivity. Different types of information such as physicochemical properties or molecular descriptors have been reported in the literature as the basis to develop QSAR models to predict the bioaccumulation potential of chemicals (Zhao et al., 2008).This work explores the feasibility of using a cost-based learning scheme to develop high sensitivity classifiers suitable to be used as the basis for waiving bioassays.The data set used in this work corresponds to an experimental data obtained according to official guidelines (Dimitrov et al., 2005) that contains logBCF information for 511 chemicals. This dataset was filtered and cleaned and final database containing 473 chemicals was obtained. The dataset covers a wide range of logBCF (-1.0 to 4.85) where chemicals have been identified as either B or nonB according to Annex XIII of REACH (i.e., chemicals with BCF>2000 are considered as having highly bioaccumulation potential). The resulting dataset after applying the logBCF threshold is highly imbalanced (i.e., 391 nonB chemicals (82.6%) and 82 B substances (17.4%)). The best classifier was obtained from the combination of an alternating decision tree (ADTree) with a cost-sensitive wrapper (Metacost). To avoid false negatives (i.e., 100% sensitivity) the required false positive to false negative cost ratio was 1:25. Similar results were obtained using Atom Center Fragments (ACF). The current work shows that the use of cost-sensitive learning schemes facilitates the tuning of the performance of classifiers based on the cost assigned to false negative classifications. This is especially useful when dealing with unbalanced data sets as well as for the development of assay waiving models that require the development of high sensitivity classifiers.

### TUPC1-5

**Models to estimate the BCF from octanol/water partition coefficient - validation and applicability domain**

R Kühne[1], RU Ebert[1], S Strempel[2], M Scheringer[2], G Schüürmann[1]
[1]Helmholtz Centre for Environmental Research - UFZ, LEIPZIG, Germany
[2]ETH Zürich, Institute for Chemical and Bioengineering, ZÜRICH, Switzerland

The software system ChemProp provides several models to estimate the bioconcentration factor in fish from the octanol/water partition coefficient. In turn, the octanol/water partition coefficient can either be taken from experimental values, or calculated from the chemical structure. For models with known training sets, the applicability domain is checked. A data set with experimental data independent from the model training sets is used to estimate the uncertainty of the predictions. A refinement is provided by a result correction derived from the estimation errors for chemicals of this data set that are similar to the test compound. A separate external test set is applied to validate the performance of the implemented models and their uncertainty estimation.
This study is financially supported by the EU Integrated Project OSIRIS (contract No. 037017).

### TUPC1-7

**An assessment of the bioaccumulation model in EUSES**

EM Undeman, MS Mclachlan
Stockholm University, STOCKHOLM, Sweden

Assessment of environmental exposure is an essential element of chemical risk assessment. The decision support instrument European Union System for the Evaluation of Substances (EUSES) is currently recommended for government authorities, research institutes and chemical companies within the EU to carry out quantitative model based exposure assessments when appropriate monitoring data are lacking. However, the algorithms employed in the bioaccumulation module of this model are more than 10 years old and our scientific understanding of bioaccumulation has progressed considerably since then. This study presents a comparison between estimates of human daily intake by EUSES and a new steady state food chain model (OSIRIS) which employs more recently published process descriptions. Calculations were made for a wide range of chemicals defined by their octanol-air ($K_{OA}$) and octanol-water ($K_{OW}$) partitioning properties. This model comparison showed that the greatest differences between the models were for chemicals with high $K_{OW}$ and high $K_{OA}$ due to differences in estimation of bioaccumulation in fish and root crops. Predicted concentrations in fish were up to four orders of magnitude lower in EUSES. One reason is that dietary uptake is not considered in this model, but also due to a generally lower predicted bioconcentration factor for high $K_{OW}$ compounds. EUSES predicted much higher concentrations of hydrophobic compounds in root crops because it assumes chemical equilibrium between the roots and the soil compartment, whereas the OSIRIS model treats root accumulation as a mass-transfer limited process.

### TUPC1-8

**Integrated testing strategies (ITS) for bioaccumulation: 3R-directed optimization of in vivo BCF testing**

E Segner[1], L Lany[1], M Hawliczek[1], M Nendza[2], A Lombardo[3], A Roncaglioni[3], E Benfentai[3]
[1]University of Bern, BERN, Switzerland
[2]Analytsiches Laboratorium, LUHNSTEDT, Germany
[3]Pharmacological research Institute Mario Negri, MILANO, Italy

Under REACH, assessment of the bioconcentration potential is required for chemicals with a log Kow greater than 3 if it is produced or imported in quantities greater than 100 t/year. The gold standard for the determination of the bioconcentration factor (BCF) is the OECD Test Guideline 305 with fish, which is demanding in terms of resources, costs and number of animals. Integrated? Testing Strategies (ITS) for bioaccumulation assessment take advantage of a variety of information sources in order to estimate whether a chemical is bioaccumulative (B, BCF > 2000) or very bioaccumulative (vB, BCF > 5000). Although the ITS aims to come to a conclusive statement on the BCF of a test substance solely on the basis of non-animal (in silico, in vitro) data, for a number of substances still the in vivo test may have to be performed. Here, we discuss potential approaches to further develop the existing BCF test guidelines by refining the test and by reducing the animal needs for the test. Possibilities to optimize the OECD TG 305 with respect to the 3R principles include reduction of sampling frequency for determination of the kinetic parameters as well as the reduction of test concentrations (only one instead of two concentrations). Another option is to explore the utility of fish embryos for bioaccumulation testing. Embryos, due to their yolk content, readily absorb xenobiotics, and they posses already a functional metabolic capacity. Thus, the Fish Embryo Test (FET), hwich is currently under valdiation as alternative to the acute fish lethality test, may serve at the same time as a BCF test, or at least a BCF screen. A similar double use of a test to determine both toxicty and bioaccumulation may also be possible for fish early life stage tests. However, the potential of these approaches for 3R-directed optimization of in vivo BCF testing remains largely un-exploited to date.
Financial support by the OSIRIS project (GOCE-CT-2007-037017) is gratefully acknowledged

## TUPC2 - Life cycle thinking in the waste management sector: one solution fits all?

### TUPC2-1

**LCA software for evaluating the environmental performance of municipal solid waste management systems: a comparison**

MD Bovea, D Bernad-Beltrán
Universitat Jaume I, CASTELLÓN, Spain

Within the last years, a number of LCA software has been developed to evaluate the environmental behavior of municipal solid waste (MSW) management systems. These tools can be applied as life cycle management tools by technical managers responsible for incorporating environmental criteria into the decision making process when selecting a waste management system for a municipality. However, these software present very different functionalities and characteristics, and therefore may provide different results. In this paper, a comprehensive comparative analysis of six LCA tools specifically applied to waste management systems has been developed: IWM-2 (Integrated Waste Management), IWMMM (Integrated Waste Management Model for Municipalities), WARM (WAste Reduction Model), LCA-IWM (LCA-Integrated Waste Management), WISARD (Waste Integrated Systems for Assessment of Recovery and Disposal) and EASE-WASTE (Environmental Assessment of Solid Waste Systems and Technologies). This analysis was conducted at three levels: 1) modeling and assessment of a complex MSW management system in each software in order to examine whether there are differences in the obtained results in terms of overall impact of the MSW management system; 2) modeling and assessment of alternative MSW management systems in each software in order to analyze whether the preference order is maintained; and 3) analysis of the life cycle inventory applied in each software for each waste management treatment in order to justify the differences obtained in the previous comparisons.

**TUPC2-2**

**LCA as a decision support tool for waste management planning in Lombardia Region**

M Grosso[1], L Rigamonti[1], P Zerbinati[2], P Belotti[2], D de Simone[3], M Severgnini[3], L Tasca[3]
[1]Politecnico di Milano, MILANO, Italy
[2]Regione Lombardia, MILANO, Italy
[3]Cestec, MILANO, Italy

Waste management plans play a key role in achieving sustainable development by saving resources and recovering materials and energy from waste. Their aim is to provide a planning framework for the following: compliance with waste policy and target achievement; outline of waste characteristics and sufficient treatment capacity for managing waste; control of technological measures; outline of economy and investment requirements.

Life cycle assessment (LCA) has been chosen by Regione Lombardia as a strategic support decision tool in the preparation of its new waste management plan, which will address 2015 as the target year for the implementation. The goal is to use the life cycle thinking approach to assess the current regional situation and thus to give useful strategic indications for the future waste management.

Regione Lombardia is among the most advanced in Italy, as well as in Europe, for municipal waste management. In the year 2009 the total production of about 5 millions ton (500 kg per capita per year) was split between 48% of source separation for material recovery, 32% of energy recovery (mainly via incineration), 16% of mechanical-biological pre-treatment (MBT) and only a negligible amount to landfill.

The project started in November 2010 and it will be finished by the end of 2011. By bearing in mind that a "status part"(i.e. assessment of the state-of-the-art of waste management) and a "planning part"(i.e. definition of future developments in waste management) are the key elements of a plan, the first phase of the study consists in the analysis of the present management of municipal waste in Lombardia (baseline scenario). This implies the identification of all the fluxes of materials (both the source-separated fractions and the unsorted residual waste - URW) in terms of quantity, characteristics and destination, together with the characterisation of the most important treatment plants, in terms of their capacity, energy and materials consumption, emissions in the environment, energy and materials recovery.

The critical analysis of the results of the baseline scenario will allow to design some possible scenarios for the year 2015, with the final goal of a further improvement of the environmental performances of the regional system.

In parallel with the regional assessment, three more detailed LCAs will be carried out for the evaluation of three provinces within Lombardia, characterised by a different approach on waste management.

**TUPC2-3**

**Screening environmental and human health impacts of municipal solid waste management in Asian cities**

J Potting[1], J van Buuren[1], SH Gheewala[2]
[1]Wageningen University, WAGENINGEN, The Netherlands
[2]King Mongkut's University of Technology Thonburi, BANGKOK, Thailand

Solid waste management has become a major environmental problem for the fast growing towns and cities of developing Asian countries. Asia generates annually roughly 4.4 billion tons of solid waste (SW) that consists for 0.8 billion tons of municipal solid waste (MSW). Present solid waste management in most Asian countries is disastrous. There is an urgent need in Asia for municipal solid waste management (MSWM) systems that effectively separate and process hazardous and non-hazardous waste in a healthy and environmentally sound way.

Municipal waste composition in Asia is broadly similar, though slightly influenced by climatic and cultural variations, and clearly differing between high income countries versus middle and low income countries. This enables a screening environmental and human health impact assessment and comparison based in quantitative and semi-quantitative information that matches enough across Asian countries at the same time contrasts enough between MSWM services and technologies and involved environmental and human health impacts. The screening assessment combines life cycle assessment with elements from risk assessment and environmental impact assessment. Quantitative and semi-quantitative information needed for the screening assessment is abstracted from the fast amount of relative certain information stored in existing databases and full (life cycle) assessments.

Asian MSWM stakeholders will be greatly helped with a screening assessment of existing and available MSWM services and technologies and their potential environmental and human health impacts. This facilitates them to evaluate and compare MSWM services and technologies on a screening level, before going into more details for the relevant ones in their specific MSWM context. The presentation will present and underpin the screening assessment approach illustrated with examples.

**TUPC2-4**

**Life cycle inventory of a new technology for the inertization of MSWI fly ashes**

G Tomasoni, A Alberti, C Cantaboni, P Cocca, F Marciano, D Rossi
Università degli Studi di Brescia, BRESCIA, Italy

The quantity of fly ashes produced by municipal solid waste incineration (MSWI) is a significant percentage of municipal solid waste incinerated. Fly ashes are an hazardous waste, since they contain large quantities of soluble salts (NaCl, KCl, calcium compounds) and significant amounts of toxic heavy metals (Pb, Zn, Cr, Cu, Ni, Cd) in forms that may easily leach out.

Fly ashes inertization can facilitate their recycling as a secondary material instead of landfilling. The best available techniques for the inertization of fly ashes can be grouped into three categories: separation processes, solidification/stabilization processes and thermal processes.

Among the solidification/stabilization processes is the COSMOS process, recently developed at the Chem4Thech laboratory of the Università degli Studi di Brescia (northern Italy). This process combines the stabilization of the metals in a solid matrix with a successive washing treatment. Recently, the European Commission has funded, with the Life+ program, a project called "COSMOS project"(LIFE08 ENV/IT/000434), that has the objective to demonstrate the industrial applicability of the COSMOS process, including the assessment of the possible environmental advantages. More information about the COSMOS project can be found here: http://www.cosmos.csmt.it.

Within the COSMOS project, with the aim to compare the environmental performance of the COSMOS process with viable alternatives, a comparative life cycle assessment (LCA) is being conducted.

In this work, the methodology and the main results of the life cycle inventory phase of the LCA of the COSMOS process will be presented. Of great interest for the life cycle inventory phase is the availability as a source of primary data of a pilot plant for the COSMOS inertization process funded through the COSMOS project.

**TUPC2-5**

**Estrategies for improving the life cycle management of construction and demolition waste in Spain**

E Moliner, C Muñoz, D Garraín, JV Sanfélix, V Franco, R Vidal
Engineering Design Group - Universitat Jaume I, CASTELLÓN, Spain

Spain is one of the major producers of construction and demolition (C&D) waste in the European Union, however, presents a low level of C&D waste recovery (lower than 40%) which is well below the target level established by the Waste Framework Directive -Directive 2008/98/CE- by 2020 (minimum of 70% by weight of non-hazardous C&D waste).

In order to correct the current situation and meet the requirements of the Directive 2008/98/CE is necessary to lay down a model of sustainable construction. This requires the application of ecological principles able to maximize resource efficiency and minimize waste in construction processes, use and end of life of buildings and infrastructure. One of the main challenges for the construction industry is the production and use of construction materials based on the recycling of these same materials, in order to closing the loop of materials and to minimize waste generation. Those countries with a shortage of raw materials and/or space to build landfills are the most advantaged in terms of prevention, reuse and recycling of C&D waste (e.g. Holland, Belgium or Denmark, all of them reach C&D waste recovery rates above 80%).

This work presents the drawbacks of C&D waste management in Spain and expounds some strategies to improve the current situation, some of which are being promoted in other countries with satisfactory results. We propose strategies to deal effectively with waste management throughout the entire life cycle of construction, from design, planning and execution of construction projects until the end of life of buildings and infrastructure, in order to minimize waste generation and to establish a closed cycle construction.

Firstly, we present some waste minimization strategies to incorporate at the early stages of project (design and planning considering waste minimization). Secondly, we detail some measures to reduce waste generation during project implementation and to improve the efficiency of subsequent treatments (material control, separate collection on-site and selective demolition). Thirdly, we describe new high-efficient recovery technologies (integrated treatment plants). Finally, we discuss some measures to boost the competitiveness of the market for recycled products (establishing quality standards, defining applications for recycled products, etc.), emphasizing the role of Government to promote the development of the measures raised (taxes for landfilling, incentives for recycling, etc.).

**TUPC2-6**

**Reduction of environmental impacts in the production process of Portland cement by using Refuse Derived Fuel (RDF)**

L Zampori, G Dotelli, G Cantarella
Politecnico di Milano, MILAN, Italy

Waste management is one of the biggest environmental issues and still a key topic for a sustainable society. Then, a possible alternative is the use of wastes as fuels for high energy consuming industries, then allowing to lower the overall emissions.

This study highlights the environmental advantages deriving from the use of Refuse Derived Fuel (RDF), partially substituting the use of conventional fossil fuels in the production of a Portland cement clinker. It is known that, due to the high production volumes and consumption, especially by fast growing countries, such as China and India, cement is one of the most impacting materials on the environment. For such a purpose the production process of a Portlan cement (CEM II/A-LL 242.5R) was studied by LCA, by following the ISO 14040 and 14044 regulations. The study followed "from cradle-to-gate"perspective and considered three different functional units in order to exploit the main outputs of the system: i) 1 ton of clinker, ii) 1 ton of cement, iii) 40 bags (25 kg each) of cement. The indicator used were GWP100 (IPCC 2007) and Eco-Indicator 99 (2001). The system was coincident to everything was connected to the production process; in the study only human resources and impacts linked to the costruction and end-of-life of machinery and transportations were neglected.

RDF is a dry grinded solid fuel obtained from the treatment of urban solid wastes. In the Robilante plant, where the cement is produced, two different factories making RDF are present: I.D.E.A. Granda that produces high-quality RDF and Ecodeco that produces normal RDF. The first one has a heating value of about 5000 kcal/kg, while the second of 4500 kcal/kg.

Both GWP100 and Eco-Indicator 99 agree that the use of RDF allows a considerable reduction of the impacts on the environment. In particular Eco-Indicator 99 states that the overall reduction was about 25%, while GWP100 detected a lowering of the CO2-equivalent emissions of about 8%. The stage involving the higher impacts is the production of clinker, since during the production of the cement, the addition of other raw materials such as gypsum and limestone allows a reduction of the overall impacts. The use of paper bag considered in the study gave credits in terms of CO2 equivalent.

## TUPC3 - Carbon-based nanomaterials in the environment: tools for detection, quantification, and characterization

**TUPC3-2**

**Towards the isolation, separation and quantification of condensed carbonaceous nanoparticles in soil and sediments**

DX Flores-Cervantes, TD Bucheli
Forschungsanstalt Agroscope Reckenholz Tänikon ART, ZÜRICH, Switzerland

Due to their unique chemical and physical properties, the use and mass production of condensed carbonaceous nanoparticles (CCNs), such as carbon nanotubes (CNTs) and fullerenes (C60) is on the rise. Correspondingly, concerns regarding the potential environmental and human health effects of CCNs are also increasing. However, the lack of methodologies to quantify and differentiate between various forms of CCNs in complex matrices has prevented us from assessing the potential impacts of their release into the environment. Here we present the on-going development of a method to isolate, separate and quantify different forms of naturally occurring and man-made CCNs in soils and sediments. Our approach consists of: 1) extracting from the natural matrix the CCN isolated during a chemo-thermal oxidation treatment (CTO-375); 2) fractionating the extract into different CCN (CNTs, C60s, and soot) forms by size exclusion chromatography (SEC); and 3) quantifying and characterizing the isolated fractions via optical techniques, spectroscopy, and/or elemental analysis. This far we have adapted the CTO-375 method for large sample sizes (recoveries of spiked CCN between 97 and 155%) and have tested the CTO-375 for isolating mixtures of CNTs, C60s and soot in soil and sediment matrices. We have also developed a method to solvent extract native and spiked CCNs from CTO-375 treated soil and sediments with extraction efficiencies up to 57 ± 15% for individual solvents and 121 ± 32% when multiple solvents were used successively. Finally, we have also tested diverse identification/characterization methods to differentiate between the CCN types found in the extracts. Most of them are not selective enough to identify different CCN types in our batch extracts, but it is likely that after fractionation the characterization/identification of cleaner and more concentrated CCN subfractions will be easier. Our next targets are: a) to evaluate size exclusion chromatography (SEC) to separate and fractionate the extracted material; b) to couple and test the whole system together; c) to test the methodology on real samples.

### TUPC3-3

**Testing the resistance of fullerenes to chemothermal oxidation used to isolate soots from environmental samples**

DX Flores-Cervantes, TD Bucheli
Forschungsanstalt Agroscope Reckenholz Tänikon ART, ZÜRICH, Switzerland

Due to potential breakthroughs in a broad range of applications for manufactured carbonaceous nanoparticles (MCNPs) over the past two decades, the use and mass production of materials such as carbon nanotubes (CNTs) and fullerenes is on the rise. However, research regarding the fate and transport of these materials in the environment has been limited due to the lack of a method to quantify MCNPs in complex environmental matrices. Here we tested the resistance of five different fullerenes to chemothermal oxidation at 375 °C, a method that has been widely used and tested for quantify black carbon (BC) in soils and sediments, and was recently tested for isolating CNTs in spiked soils and sediments that contained naturally occurring BC. Of the fullerenes tested, C60 was the one that survived CTO-375 the most (50%) while C70 was the one with the lowest survival rate (< 1%). Standard additions of C60s to soil and sediment yielded recoveries between 18 and 45%. Although lower than some of the recoveries that have been observed for soot and CNTs, these results demonstrate the capability of CTO-375 to isolate C60s from solid environmental matrices. Contrary to what would be expected, standard additions of C70, C76/78, and C84 yielded higher survival rates when added to soil and sediment samples than in their pure form. These results indicate that the mineral matrices from the soil and sediment may have a catalytic effect towards C60s and a protective effect towards C70, C76/78, and C84.

### TUPC3-4

**Occurrence of fullerenes in aerosols from the Mediterranean Sea atmosphere**

J Sanchis, N Berrojalbiz, G Caballero, J Dachs, M Farre, D Barceló
IDAEA-CSIC, BARCELONA, Spain

Carbon-based nanoparticles are present in the environment due to different causes including natural events, incidental sources, as industrial and combustion processes, and during the recent years due to the use and production of carbon based nanomaterials for nanotechnological applications. Therefore, occurrence assessment of carbon-based nanoparticles is required for determining their environmental cycling and impacts.

This work describes the development, optimization and validation of a liquid chromatography coupled to mass spectrometry (LC-MS) method for the determination of a selection of fullerenes in environmental samples. The presented method has been applied to the study of the occurrence of natural and synthetic fullerenes (C60, C70, N-methylfulleropyrrolidine, C60 pyrrolidine tris-acid ethyl ester, [6,6]-Phenyl-C61 butyric acid butyl ester and [6,6]-Thienyl C61 butyric acid methyl ester) in airborne samples from the Mediterranean Sea. This new method reached sensitivities in the pg/m3 range, with repeatabilities between 1,8% and 13,2%.

While the presence of fullerenes in wastewater [1] and its occurrence in the atmospheric particulate (mainly associated with coal combustion processes [2] and domestic kitchen stoves burning natural gas/air and propane gas/air mixtures [3]) have already been reported, to our knowledge, this work is the first study to be about the occurrence and quantification of fullerenes in sea airborne.The results can be reasonably related to incidental emission and posterior atmospheric transport and deposition, underpinning the need of studying the possible risks associated to the presence of carbon nanoparticles in the environment and the need of evaluating the possible consequences of their ubiquitous distribution, which is facilitated by long range atmospheric transport.

### TUPC3-5

**Characterization and toxicity tests of multiwalled carbon nanotubes and cyclodextrin polymers on selected test organisms**

W Nyembe[1], V Wepener[1], BB Mamba[1], N Musee[2]
[1]University of Johannesburg, JOHANNESBURG, South Africa
[2]CSIR, PRETORIA, South Africa

The escalating use of engineered nanomaterials has since led to the need to study their possible adverse effects to the environment. The key in carrying this out is in their full characterization and testing on living organisms of different trophic levels. In our laboratories, selected carbon-based nanomaterials in the likes of pristine multi-walled carbon nanotubes (MWCNTs), oxidised multi-walled carbon nanotubes (oxMWCNTs), cyclodetrin polymers pCDs, and cyclodextrin-multiawalled carbon nanotube polymers (CD-oxMWCNTs) were exposed to Daphnia pulex (water flea), Vibrio fisheri (luminescent bacteria), Selenastrum capricornutum (algae) and Poecilia reticulatae (fish). The nanomaterials were characterized and their toxicities were observed on these test organisms. The toxicities were explained in the light of the nanomaterials' characterization. The particle size distribution was found to be the same for both pristine and oxidised MW-CNTs (14.5-93.7 nm). The FTIR showed that the acid oxidation used to produce oxMWCNTs introduced new functional groups that made these nanomaterials more toxic than their pristine counterparts. The EDX showed some residual Fe-catalyst impurities in the pristine MWCNTs and TEM showed amorphous carbon which was not observed in the oxMWCNTs. The toxicities observed also showed oxMWCNTs were more toxic than pristine MWCNTs. The surface charges of pristine MWCNTs were 0 mV and oxMWCNTs was 3.4 mV, thus pristine MWCNTs agglomerated while oxMWCNTs dispersed well in water. The SEM images of these materials showed a fibrous appearance. The polymers were polymerized using hexamethylene diisocyanate (HMDI) as a linker showed that their particle sizes were comparable yet the toxicity of CD-oxMWCNT was higher than that of pCDs through the tested organisms. Their charges were 0 and 0.7 mV, respectively. Their particle size distribution was 10-79.2 nm. The SEM images of the nanomaterials showed a somewhat razor sharp, flaky appearance of CD-oxMWCNTs while that of pCD was only flaky. The conclusions drawn were that the primary factor of nanomaterials' toxicity is their size. The surface charge or absence of it thereof, is also important in the materials's toxicity since it determines its mode of penetration into the organism. Full characterization is therefore, key into the understanding of interaction of nanomaterials and the environment.

### TUPC3-6

**Sorption of hydrophobic and very hydrophobic PAHs onto carbon nanotubes in the low concentration range**

M Kah[1], X Zhang[1], MTO Jonker[2], T Hofmann[1]
[1]University of Vienna, VIENNA, Austria
[2]IRAS, University of Utrecht, UTRECHT, The Netherlands

Production of CNTs is expected to increase rapidly in the future and CNT release into the environment has been shown. Understanding the interactions between organic contaminants and CNTs is therefore essential for evaluating the potential environmental impact. Although a great deal of work has been published in the past years, data is still limited in terms of compounds, concentrations and conditions investigated. This can be mainly explained by some limitations associated with classical batch setups, traditionally used to measure sorption. First, the high sorption capacity of CNTs results in extremely low concentration of sorbates remaining in the aqueous phase. Second, classical separation techniques (e.g. centrifugation or filtration) are often not adequate to efficiently separate the CNTs and liquid phase under conditions where CNTs may be partially dispersed (e.g. presence of humic acids). Questions thus remain open on the possible succession of sorption mechanisms occurring over a range of concentration and environmental conditions.

In the present study, we applied a passive sampling method (POM-SPE) previously validated for sorbents with similar characteristics as CNTs to investigate aspects of sorption that have not been studied to date. The first objective was to gain a better understanding of the interactions between polycyclic aromatic hydrocarbons (PAHs) and CNTs over a range of concentrations. Sorption isotherms of phenanthrene and pyrene were measured over six to seven orders of magnitude. In the low concentration range (pg/L), sorption of both PAHs was linear on a non-logarithmic scale. Sorption can thus be described using a single sorption coefficient over several orders of magnitude. Isotherm fitting over the whole concentration range showed that the CNT sorption capacity was directly related to their surface area. Sorption coefficients for 13 PAHs (11 of which were never reported to date) were also measured using the passive sampling method. Conversely to results previously reported at higher concentrations, no competition seemed to occur in the low concentration range. Sorption affinity also appeared to be directly related to the hydrophobicity of the compounds (Kow) which is extremely valuable for the development of predictive equations. Further experiments are currently undergoing to study sorption under conditions in which CNTs are dispersed and to analyse how sorption characteristics are affected.

## TUPC4 - Hazard assessment for the marine environment and regulation

### TUPC4-2

**Marine ecotoxicology testing: towards a standardised suite of chronic methodologies for chemical risk assessment**

C Simpson, DH Leverett
WCA environment, FARINGDON, United Kingdom

Several European regulatory regimes include requirements for the hazard assessment of chemicals in marine (water and sediment) systems, but few specify the ecotoxicology test methods that should be used. In particular there is a lack of consensus on the methods that should be used to assess chronic marine toxicity. The absence of a standardised suite of chronic marine tests has led to a reliance on those (usually few) academic studies available in the open literature, or on the use of "read-across"from freshwater testing data. Chronic marine chemical hazard assessment can therefore be hampered by the low quantity/ quality of appropriate ecotoxicology data, or by differences in the fate and behaviour of chemicals and the physiology of receptors in freshwater and marine systems. Effects specific to marine systems and organisms can be missed, and the uncertainties inherent in "read-across"from freshwater data to marine receptors require the application of large safety factors to any toxicity thresholds derived in this way. Chronic marine ecotoxicology testing methodologies have been developed for use in marine monitoring programmes (e.g. OSPAR JAMP/CEMP) and for assessing the hazards posed by industrial discharges (e.g. OSPAR Whole Effluent Assessment) but these methods have not been widely applied in single chemical hazard assessments. This may be because, in validation terms, the techniques are considered to be relatively immature compared to the freshwater methods, or because of the potential challenges in adapting the methods for use with more rigorous single-chemical testing systems. This poster evaluates those chronic marine ecotoxicology methods currently prescribed for use in European marine monitoring programmes and assesses their potential for adaptation for use in regulatory chemical hazard assessments. The available methods are compared using the criteria set out in the comprehensive validation assessment framework developed by the European Commission's FP6 NORMAN Network (with a focus on single-chemical testing). Based on the outcomes of these evaluations a standardised suite of chronic marine ecotoxicology tests is proposed, along with suggestions for optimizing their performance for use in chemical hazard assessments for marine water and sediment.

### TUPC4-3

**Integrated assessment of bioeffects monitoring data in the Baltic Sea - a case study with flounder, eelpout and herring**

U Kammann, N Fricke, M Gschwind, T Lang
Johann Heinrich von Thuenen-Institut, HAMBURG, Germany

In the light of the EU Marine Strategy, integrated monitoring and assessment receive increasing attention. Data for integrated assessments are converted to a traffic light system, enabling comparison of multiple bioeffects on a common scale. Threshold values are adjusted for fish species as well as for bioeffect methods. If different species are combined in one approach, they should be comparably sensitive to the parameter measured in general. In a case study with data on PAH metabolites in bile, fish diseases, liver histopathology, and vitellogenin measured in flounder (*Platichthys flesus*), eelpout (*Zoarces vivipa*rus), and herring (*Clupea hare*ngus) from the Baltic Sea this approach was tested. The data were collected during sampling campaigns of the pan-Baltic BONUS+ project BEAST which is targeted at developing integrated measures of chemical pollution and tools to detect and understand human-induced pressures on the Baltic Sea ecosystem. The results will contribute to science-based recommendations for the implementation of an integrated chemical-biological effects monitoring strategy for the assessment of ecosystem health.

**TUPC4-4**

**The derivation of a marine predicted no effect concentration for bisphenol A: the case for a species sensitivity distribution approach under REACH**

E Mihaich[1], CA Staples[2], LS Ortego[3], GM Klecka[4], N Caspers[5], SS Dimond[6], SG Hentges[7]
[1]ER2 for SABIC Innovative Plastics, DURHAM, NC, United States of America
[2]Assessment Technologies, Inc., KESWICK, VA, United States of America
[3]Bayer CropScience, RESEARCH TRIANGLE PARK, NC, United States of America
[4]Dow Chemical Corporation, MIDLAND, MI, United States of America
[5]Currenta, LEVERKUSEN, Germany
[6]SABIC Innovative Plastics, BEDFORD, NH, United States of America
[7]American Chemistry Council, WASHINGTON, DC, United States of America

REACH guidance allows for the derivation of predicted no-effect concentrations (PNEC) based on (1) the traditional "assessment factor"approach that divides no observed effect concentrations (NOEC) of sensitive key species by a factor of typically 10 to 1000 and, (2) species sensitivity distribution (SSD) approaches when data exists for at least 8 taxonomic groups. Statistically based approaches, such as SSD, make use of the full distribution of available no-effect values, taking into account the variability that might be observed between taxonomic groups. Current European Chemicals Agency guidance developed for REACH provides specific procedures on the use of the SSD approach for the assessment of freshwater, while not so for marine water. Marine environments are considered to be more diverse and thus greater uncertainty may exist in the extrapolation between species responses. Therefore, within the guidance, calculations of PNEC for the marine environment are typically addressed using assessment factors of 10 to 10,000, depending on the number of acceptable toxicity tests available. Since freshwater and marine data can be combined in the assessment factor approach to derive a PNEC for marine water, this same practice should be appropriate for developing a marine PNEC using the SSD approach. This is especially true when high quality chronic freshwater and marine data exist for multiple taxonomic groups. Bisphenol A (BPA), is an important high production volume compound used in the production of epoxy resins and polycarbonate plastics. With the addition of new chronic marine aquatic toxicity studies using the sheepshead minnow (Cyprinodon variegatus) and the mysid shrimp (Americamysis bahia), BPA now has an extensive toxicity database of both freshwater and marine organisms from diverse taxonomic groups. Freshwater and marine PNEC for BPA were derived using both the traditional assessment factor and an SSD-based approach. PNEC derived using assessment factor and SSD-based approaches are compared and will be used to revise the risk characterization for BPA in freshwater and marine environments for submission of the "technical dossier"under the REACH regulation.

**TUPC4-5**

**Deriving a safe level for copper in the marine environment**

KWJ Long[1], KM Delbeke[2], EM Foekema[3], P van Sprang[4]
[1]RCL, BILSTON GLEN, United Kingdom
[2]European Copper Institute, BRUSSELS, Belgium
[3]IMARES Wageningen UR, DEN HELDER, The Netherlands
[4]ARCHE Consulting, GENT, Belgium

The last five years have seen significant developments in the approaches used to define safe levels for metals. In particular, the better understanding of bioavailability has provided new tools such as the Biotic Ligand Model which have allowed the derivation of 'Predicted No Effect Concentrations' (PNECs) based upon improved use of available data. The approach described shows how these tools can be used to derive a PNEC for copper in the marine environment, and provides information on how the safe level was tested experimentally.

**TUPC4-6**

**Deriving a safe level for copper in marine sediment**

KWJ Long[1], KM Delbeke[2], EM Foekema[3], P van Sprang[4]
[1]RCL, BILSTON GLEN, United Kingdom
[2]European Copper Institute, BRUSSELS, Belgium
[3]IMARES Wageningen UR, DEN HELDER, The Netherlands
[4]ARCHE Consulting, GENT, Belgium

Predicting the effects of metals in the sediment compartment has historically been a challenging task, because of the ameliorating processes which occur in the sediment compartment. The use and applicability of the Equilibrium Partitioning Model to derive safe levels for copper in the marine sediment environment is assessed, and conclusions drawn based upon experimental data available.

**TUPC4-7**

**Marine risk assessment of molybdenum under REACH: generating data, developing of a species sensitivity distribution and PNEC derivation**

DG Heijerick[1], L Regoli[2], S Carey[2]
[1]ARCHE, GENT, Belgium
[2]IMOA, LONDON, United Kingdom

In an effort to generate a robust $PNEC_{marine}$ for risk assessment purposes which is based on the SSD approach, a marine research program was initiated by the REACH Molybdenum-Consortium as part of the REACH dossier preparation. As a first step, the International Molybdenum Association (IMOA) commissioned a thorough evaluation of all existing chronic toxicity data for molybdate in the marine environment. Based on the outcome of this review a testing program was conducted aimed at generating the data necessary to 1) develop a species sensitivity distribution for molybdate, and 2) derive a $HC_{5,50\%}$/PNEC for the marine aquatic compartment.
One reliable chronic data point was identified in open literature for the mussel *Mytilus edulis*. Consequently, nine different tests were conducted at four different testing laboratories, representing eight taxonomic groups that are relevant and typical for the marine environment: the copepod *Acartia tonsa*, the diatom *Phaeodactylum tricornutum*, the oyster *Crassostrea gigas*, the mysid *Americamysis bahia*, the micro-alga *Dunaliella tertiolecta*, the macro-alga *Ceramium tenuicorne*, the sheepshead minnow *Cyprinodon variegatus*, the sea urchin *Strongylocentrotus purpuratus* and the sand dollar *Dendraster excentricus*. Where possible, the chronic toxicity experiments were conducted according to internationally accepted standard testing protocols (e.g., EPA, ASTM, ISO). Dissolved molybdate levels were measured and reported effect levels (NOECs, $EC_{10}$-levels) were based on these measurements.
No-effect levels for dissolved molybdenum were situated between 4.4 mg Mo/L and 1,174 mg Mo/L, i.e., a difference of a factor of 267 between the most and least sensitive species. The mussel *M. edulis* and the copepod *A. tonsa* were the most sensitive species. The least sensitive species were the oyster *C. gigas* and two algal species (*D. tertiolecta*, *C. tenuicorne*). The $HC_{5,50\%}$ (± 95%CL) that was associated with the Log-Normal Distribution that was plotted through the chronic data was 5.74 mg Mo/L (95%CL: 0.58 - 21 mg Mo/L). Application of an assessment factor of 3 on this HC5,50% resulted in a $PNEC_{marine}$ for molybdenum 1.192 mg Mo/L. This value is in line with the Final Chronic Value (FCV) of 1.16 mg Mo/L that was determined according to the USEPA methods, i.e., a method based on the four most sensitive genera - taking into account the size of the toxicity database (n=10).

## WEPC1 - Assessment of the effects of veterinary drugs on dung and soil organisms

**WEPC1-1**

**Higher tier test strategy for dung fauna organisms - from regulatory perspective**

NE Adler[1], J Bachmann[1], J Römbke[2]
[1]UBA Federal Environment Agency, DESSAU, Germany
[2]ECT Oekotoxikologie GmbH, FLOERSHEIM, Germany

According to European legislation, an environmental risk assessment of veterinary pharmaceuticals for dung fauna is required if the substance acts as a parasiticide for the treatment of pasture animals. However, the demonstration of the environmental safety of those substances for dung fauna was strongly hampered by the fact that no standardized tests were available until recently. Therefore, starting with recommendations from the SETAC advisory group DOTTS (Dung Organism Toxicity Test Standardization) test systems for phase II tier A tests on the mortality of dung fly and dung beetle larvae were developed. The dung fly test guideline No. 228 was adopted by OECD on October 2008, while an OECD guidance document for standard laboratory tests with dung beetles is available since 2009. If a risk is identified for dung organisms in phase II tier A of the risk assessment process, a higher tier test strategy is required for tier B - but currently no advice is given for those studies in the existent EMEA and VICH guidelines. No validated higher tier laboratory or semi-field methods are available to assess structural and functional effects of pesticides in dung. Therefore, three workshops took place in 2007, 2008, and 2009 with international dung fauna experts in order to find an appropriate test strategy for higher tier dung fauna (Aveiro group). Possible strategies were discussed and adequate endpoints were defined for higher tier tests. Further on, strategies and endpoints were analysed for their practicability in laboratories considering different dung species, test compounds and endpoints.
The aims of the presentation are:
-To present details of higher tier testing requirements.
-To highlight the current state of knowledge regarding methods for dung organisms and to discuss methods to assess the 'impact' of parasiticides on dung community structure and function.
-To give an overview on higher tier laboratory and field methods which may be appropriate for Tier B dung organism effects studies.
-To discuss modeling approaches for higher tier dung testing.

**WEPC1-2**

**Veterinary drug ivermectin and behaviour of earthworms**

A Torkhani
University of Ljubljana, Biotechnical faculty, LJUBLJANA, Slovenia

Since 1990s behaviour responses of earthworms to contaminated soils have been well documented and two systems for avoidance test were developed (two-chamber and six-chamber system). The avoidance test has been described in ISO 17512-1 since 2008.
Although the effects of many substances on behaviour of earthworms have already been tested the information on influences of veterinary drugs (e.g. avermectins) are still lacking. Avermectins are broad spectrum parasiticides belonging to macrolide endectocides. Nearly all avermectins administered to animals are excreted into cattle manure (98 %). High concentrations of avermectins in soil and feces of treated animals can have negative effects on invertebrates, including earthworms, which play an important role in decomposition of dung on pastures. Studies were already performed to measure effects of avermectins on mortality, reproduction (cocoon production, hatching of juvenile earthworms), bioaccumulation and growth.
We studied the influence of ivermectin (belonging to avermectins) on behaviour of two earthworm species, Eisenia fetida (epigeic species) and Lumbricus terrestris (anecic species). We measured the effect of ivermectin on two earthworm species with avoidance test. The avoidance test was performed with two different soils, Lufa 2.3 natural soil and soil provided by Cinkarna Celje (Slovenia). The same soil was used on both sides of the test vessel. Earthworms Eisenia fetida were exposed to both types of soil, Lumbricus terrestris only to soil provided by Cinkarna Celje. Both soils were spiked with following ivermectin concentrations: 8, 32, 64 and 256 mg kg-1.The results of the avoidance test were presented as the mean number (±SD) of living earthworms in the test soil and the percentage of remaining worms in the test soil. Test soil is considered to be toxic if more than 80 % of earthworms migrate to control soil.
Our study showed that ivermectin, under experimental conditions stipulated by ISO 17512-1, does not have a deterrent effect on earthworms up to the highest concentration tested (256 mg kg-1). The avoidance test with Lumbricus terrestris exposed to soil from Cinkarna Celje showed that in all concentrations more than 20 % of the earthworms stayed in the test soil. We observed the same distribution of worms in the avoidance test with Eisenia fetida exposed to soil from Cinkarna Celje. Eisenia fetida in Lufa 2.3 soil was attracted to soil spiked with 32, 64 and 256 mg ivermectin kg-1 soil.

**WEPC1-3**

**Sublethal effects of two parasiticides on the dung beetle Aphodius constans**

J Roembke[1], JP Lumaret[2], A Scheffczyk[1], N Adler[3]
[1]ECT Oekotoxikologie GmbH, FLOERSHEIM, Germany
[2]University Paul Valery, MONTPELLIER, France
[3]Federal Environment Agency (UBA), DESSAU-ROSSLAU, Germany

Currently, no advice is available how to proceed in case a risk is identified when testing the effects of a parasiticides on dung organisms in Phase II, Tier A laboratory tests. In this contribution we want to present (A) two test ideas using the beetle species Aphodius constans, (B) compare these results with data gained in the larval Emergence Test with the same species published recently as an OECD Guidance paper and, [C] discuss these ideas in the light of the development of a higher-tier test strategy with dung organisms. The main properties of the existing dung beetle test as well as in the elongated larvae test and the adult reproduction test differ primarily in the endpoint measured, the life-stage of the test organisms and the duration of the test. As a general rule, the new tests try to cover more than one life stage and a sub-lethal endpoint, aiming to increase the sensitivity of the test. These methods have already been set-up at two laboratories (ECT GmbH (Germany) and of the University of Montpellier (France)), indicating that the test performance is possible without considerable problems. All tests performed so far were valid according to the (preliminary) criteria proposed so far. Test concentrations were spiked into cattle dung using acetone as a solvent. All concentrations are given as nominal values in mg a.i./ kg dung dry weight (DW). As an example the results obtained in the Adult Reproduction Test, performed with Ivermectin in parallel in the laboratories of ECT GmbH and the University of Montpellier, are as follows: Despite the fact that different concentrations were used in the two tests, the resulting EC50 values were almost the same: 0.29 (0.21 - 0.40) and 0.32 (0.24 - 0.43) mg a.i./ kg dung dry weight (DW) were determined at ECT GmbH and the University of Montpellier, respectively. The corresponding EC50 value obtained in the Elongated Larvae Test at ECT GmbH was 0.26 mg a.i./ kg dung dry weight (DW). Thus, with both new methods a higher sensitivity compared to the established OECD Larvae Test was found. The results obtained in the two laboratories show that the new test methods are practical and sensitive. However, so far only two parasiticides could be tested. In the long run, and assuming standardisation as an OECD guideline is completed, these tests could be used for Phase II, Tier B in case a risk has been identified in lethal laboratory tests in Phase II, Tier A.

**WEPC1-4**

**Lessons learned during the selection of a dung beetle species as a bioassay for insecticidal residues in cattle dung**

J Roembke[1], KD Floate[2], WU Blanckenhorn[3], P Coghlin[2], I Davies[4], J Gray[5], P Höhn[6], N Kadiri[7], JP Lumaret[7], A Scheffczyk[1], T Schmidt[8], A Schwarz[9], T Sekine[9], C Taylor[4], K Taylor[5]
[1]ECT Oekotoxikologie GmbH, FLOERSHEIM, Germany
[2]Lethbridge Research Centre, LETHBRIDGE, Canada
[3]University - Zoological Museum, ZUERICH-IRCHEL, Switzerland
[4]Covance Laboratories Ltd., HARROGATE, United Kingdom
[5]Huntingdon Life Sciences, HUNTINGDON, United Kingdom
[6]Eurofins Agroscience Services GmbH, NIEFERN-ÖSCHELBRONN, Germany
[7]University Paul Valery, MONTPELLIER, France
[8]Harlan Laboratories Ltd., ITINGEN, Switzerland
[9]IBACON GmbH, ROSSDORF, Germany

Pastured animals treated with parasiticides may faecally excrete residues harmful to non-target organisms. European legislation requires parasiticides to be tested for such effects using species of dung-breeding flies and dung-breeding beetles (Scarabaeidae). The latter include species that may be 'dwellers', 'tunnelers', or 'rollers'. Dwellers develop in dung on the soil surface. Tunnelers and rollers develop in dung which is deposit by the parent beetles into the soil. Adult tunnelers bury dung into the soil immediately below the pat, whereas adult rollers bury dung some distance from the pat. The beetle, Aphodius constans, is a dweller species that recently has been approved as a test species for insecticidal residues in dung (OECD 2009). However, results of toxicity tests using A. constans may not extend to tunnelers and (or) rollers. Thus, the tunneler species Onthophagus nuchicornis, recently was evaluated as a second species by members of the SETAC advisory group DOTTS (Dung Organism Toxicity Test Standardization). Preliminary results using adults field-collected in spring, showed O. nuchicornis to have high susceptibility when developing from egg-to-adult in cattle dung containing residues of the parasiticide, ivermectin. These results could not be replicated in a subsequent ring test (8 organizations in five countries), because adults field-collected in autumn failed to exhibit reproductive behaviour. This observation indicates that adult O. nuchicornis require an obligate diapause period prior to mating. A second international ring test is planned for spring 2011 using overwintered beetles.

**WEPC1-5**

**Effect of oral ivermectin application to pony's on the dung colonising insect fauna of a semi-natural pastureland**

J Lahr, RJM van Kats, A van der Hout, DR Lammertsma, A Siepel, DC van der Werf
Wageningen UR, WAGENINGEN, The Netherlands

The use of large herbivores for the management of vegetation in nature conservation areas in The Netherlands creates opportunities for dung insect fauna and wildlife that feeds on these invertebrates. However, the routine application of toxic anthelmintics such as ivermectin to these herbivores potentially affects dung fauna populations. The negative impact of ivermectin and other macrocyclic lactones used in animal husbandry on dung fauna are well documented in the scientific literature. However, it is largely unknown to what extent these effects do also occur in conservation areas. Moreover, past research on the ecological effects of anthelmintics like ivermectin has tended to focus mostly on the insect fauna in cattle dung and less on the possible negative effects in dung of other large herbivores used for conservation purposes such as sheep and particularly horses. We conducted a combined field and laboratory experiment in order to investigate the effects of ivermectin treatment of pony's on the dung colonising insect fauna in The Netherlands. A second goal of the study was to test a method to evaluate the effects of parasiticides on dung insects in the field. The field experiment was conducted in a semi-natural grassland situated in a connective corridor of the Dutch Ecological Main Structure (EHS). The pasture is managed in a non-intensive, organic way and grazed all year round by a small herd of Dartmoor pony's. Dung pats of ivermectin-treated and untreated pony's were left in the field for colonisation and taken to the laboratory to capture emergent insects over the following 3 months. The study demonstrated that oral ivermectin treatment of pony' s at the recommended medical dose has a negative effect on the emergence of some of the most important families of flies that colonise the dung of these animals: Sphaeroceridae, Muscidae and Stratiomyiidae. Although dung beetles are abundant in the study area, very few of them emerged from the pony dung incubated in the laboratory. The exact cause for this remains to be investigated. In general, the study design is suitable to evaluate the effects of parasiticides on dung insects under field conditions such as in testing for higher-tier risk assessment.

**WEPC1-6**

**Effects of antibiotics on microorganisms and the nitrogen cycle in soil**

R Kindler, A Kotzerke, BM Wilke
Technical University Berlin, BERLIN, Germany

The fertility of soil largely depends on the availability of nutrients, particularly on inorganic nitrogen, and thus, on the continuous formation of ammonium and nitrate by soil microorganisms. Consequently, the balanced functioning of all pathways of the nitrogen cycle has to be guarantied in soil.
Veterinary drugs, e.g. antibiotics, enter the environment via manure application and influence the soil organisms and nutrient cycles. The present study gives information on the effects of manure from pigs treated with sulfadiazine (SDZ) and difloxacine (DIF), respectively, on soil microorganisms and the nitrogen pathways (nitrogen mineralization, nitrification, denitrification) in a mesocosm experiment under controlled moisture, temperature and light conditions. SDZ and DIF containing manures were added to an agricultural soil (Orthic Luvisol), respectively. Then, pre-grown maize seedlings were planted and cultivated on the soil. Microbial analyses with focus on the rhizosphere were performed at the beginning and in distinct intervals up to 62 days after manure addition.
The microbial biomass amount and all processes of the nitrogen cycle were stimulated by manure addition. However, the presence of SDZ restricted the enhancing effect of manure significantly. The nitrogen mineralization was influenced temporarily. The potential nitrification and denitrification showed decreased activities in both soil compartments during the whole incubation time. In contrast, DIF applications caused minor effects. This can be attributed to the fast adsorption of the antibiotic.

**WEPC1-7**

**Effects of monensin and lasalocid on heavy metal accumulation in woodlice**

S Zizek[1], R Hrzenjak[1], P Zidar[2]
[1]Veterinary Faculty, University of Ljubljana, LJUBLJANA, Slovenia
[2]Department of Biology, Biotechnical Faculty, University of Ljubljana, LJUBLJANA, Slovenia

Monensin and lasalocid are polyether ionophore antibiotics used in prevention of coccidiosis in the poultry industry and as growth promoters in cattle. They enter the environment via the faeces of treated animals. As ionophores, they affect the passage of ions across cellular membranes and could therefore change the patterns of heavy metal accumulation in soil organisms. These effects were studied on woodlice Porcellio scaber. The animals were exposed to cadmium and lead in the presence of monensin or lasalocid and their Cd and Pb contents were measured. The results imply that ionophore antibiotics could have a marked effect on the accumulation of heavy metals in soil organisms on metal-contaminated sites.

**WEPC1-8**

**Ecological vulnerability of wildlife species for ivermectin**

HJ de Lange, J Lahr
Alterra, Wageningen UR, WAGENINGEN, The Netherlands

The ecological vulnerability method is developed as an additional tool in risk assessment. The method uses ecological traits for individual species of wildlife to assess (1) their exposure to soil contaminants, (2) internal regulation and toxicological sensitivity to toxicants, and (3) potential for population recovery from harmful effects. Vulnerability of wildlife species was studied for different model compounds, including the persistent veterinary pharmaceutical ivermectin, with low to medium toxicity. The species did not include dung insects. The field distribution of ivermectin is more patchy than other persistent compounds, and can be very different between plots. Vulnerability of wildlife species for ivermectin was mostly determined by exposure through habitat: a preference for soil as the main habitat increases vulnerability. The life history strategy characteristics of species vulnerable to ivermectin are intermediate in the spectrum from r-strategy (opportunistic) to K-strategy (long-lived). In the category population recovery, most characteristic factors correlated with a low vulnerability. The most vulnerable species included Slow worm, Viviparous lizard, European mole, and Sand lizard. The method assesses direct effects on species. Indirect effects such as food depletion of higher animals caused by ivermectin effects on invertebrate food species cannot yet be properly predicted by our method for lack of generic data. This should be further studied.

## WEPC2 - New developments in aquatic macrophyte testing, higher tier risk assessment and ecotoxicology

**WEPC2-1**

**Rooting for Lemna: the toxicological and statistical sensitivity of an under-utilized endpoint**

ML Hanson[1], P Antunes[2]
[1]University of Manitoba, WINNIPEG, Canada

Duckweeds (*Lemna* spp.) are floating macrophytes used extensively in ecotoxicology for regulatory testing, although their utility as a standard test species has been scrutinized due to their lack of an extensive rooting system from which toxicity can be assessed. Despite criticism, root length is a valuable endpoint to use in the development of risk assessment models such as the Biotic Ligand Model (BLM) for plants, where metal accumulation on the root is empirically related to toxicity. The purpose of this study was to assess the toxicological and statistical sensitivity of root length as an endpoint compared to the standard endpoints of plant dry weight and frond number. To achieve this, the toxicity of copper, nickel and lead to *Lemna minor* was assessed using a standard bioassay. Testing was performed with surface waters (5 to 7 waters per metal collected from various American locations) that had a range of water quality characteristics (e.g., DOC, pH, and $CaCO_3$/L hardness). To assess the toxicological sensitivity of each endpoint, $IC_x$ values (10%, 20% and 50% plus CIs) were calculated by using non-linear regression analysis to describe the relationship between the measured concentration of total dissolved Cu, Ni or Pb in solution and new growth only in the endpoints. To assess statistical sensitivity of each endpoint, the coefficient of variation, the minimum detectable difference, and the replication required to detect a 20% changed were calculated. Root length was found to be intermediate of frond number and dry mass, in terms of statistical sensitivity, with dry mass being the most sensitive endpoint evaluated. In terms of toxicological sensitivity, all $IC_x$ assessed for comparable testing scenarios (i.e., same metal and surface water) were within 10-fold of each other, with Cu being the most toxic metal, followed by Ni, then Pb. Still, no one endpoint was consistently the most responsive under tested exposure conditions. Overall, root length was found to be as statistically sensitive as the standard endpoints and at times significantly more toxicologically responsive. In contrast to the critique of duckweed lacking of a testable rooting system, this study shows that root elongation can be a valuable complement to currently recommended endpoints. These results allow for enhanced ERAs for aquatic macrophytes, since the endpoint is well suited to *in-situ* field measurements and consistent with the development of the BLM for plants.

**WEPC2-2**

**Lemna minor vs. Myriophyllum aquaticum: sensitivity and recovery potential after short and long term exposure to atrazine**

VZ Knezevic, TO Tunic, MA Cucak, IS Teodorovic
University of Novi Sad, NOVI SAD, Serbia
Two concepts have been highlighted as tools for refining ecotoxicological risk assessment and adding more ecological realism: the trait-based approach that has been built upon the hypothesis that sensitivity is a function of biological characteristics, and vulnerability analysis that combines susceptibility to exposure, sensitivity to a stressor and recovery potential. In recent years the risk assessment for aquatic macrophytes has triggered increasingly scientific attention, because in the past they had been barely taken into account in ecotoxicological assessment even though they are a significant component of aquatic ecosystems. Despite the great variety of species and important differences in morphology, physiology and life form, aquatic plants are only represented by duckweed species in risk assessment. Water and water-sediment tests with *Myriophyllum acquaticum* were recently developed in order to demonstrate more realistic exposure scenarios in refined risk assessment.
The poster will show the results of non-simultaneously conducted single - species laboratory toxicity test with two macrophyte species *Lemna minor* and *Myriophyllum aquaticum* exposed (short and long term) to atrazine - systemic herbicide with well known mode of action (inhibition of photosynthesis) still widely used throughout the world in agricultural applications. The recovery potential of both species after short and long exposure was estimated using growth rate, biomass and concentration of chlorophyll a as endpoints. *M. aquaticum* proved to be more sensitive to atrazine than *L. minor* after short as well as long term exposure. Also, its recovery potential is by far lower: *L. minor* recovered completely after short (3 days) and long (7 days) exposure to all test concentrations (max being 1280 _g/l) after only 6 and 5 days respectively, while the recovery of *M. aquaticum* was significantly slower and less efficient even after short term exposure (3 days): after 12 days long recovery period, it turned out that the concentration of 320 _g atrazine/l had caused irreversible changes and the recovery was impossible. The comparison of the results gained in water and water-sediment toxicity tests of atrazine on *M. aquaticum* will also be presented in a poster. The different experimental setup, different endpoints, the relative species-sensitivity and the applicability of vulnerability analysis (focusing on recovery potential) in ecotoxicological risk assessment will be discussed.

**WEPC2-3**
**Myriophyllum spicatum as a test organism for eco toxicity testing and the impact of sucrose in the test medium on the photosynthesis activity and sensitivity of the test species**
D Maletzki, CK Kussatz
Umweltbundesamt, BERLIN, Germany
The use of plant protection products is a common practice in modern agriculture and forestry. Their use, however, may result in risks for the environment because even correct application can not always prevent a possible contamination of the off-field environment. A contamination of surface waters may occur through driftage, precipitation, run-off and drainage from treated surfaces.
Dicotyledonous macrophytes are not part of the initial risk assessment of plant protection products in the aquatic environment although they are an important part of the ecosystem. In this context alternative test methods with Myriophyllum sp. are under development.
The Ecotoxicological Laboratory of the German Federal Environment Agency has conducted a standardised single-phase test system with the dicotyledonous water milfoil Myriophyllum spicatum following the ASTM Designation E 1913-04 (in Andrew's medium with 3% sucrose). In order to obtain substance-specific ecotoxicity data, a single-phase test system without sediment was chosen, to get results that are independent of the distribution of the test substances between water and sediment. The exposure of the test-plants only in the water phase reduces time and effort for analytics and facilitates modelling of the results.
Also, a direct comparison with results from investigations with the monocotyledonous duckweed Lemna spec. (OECD Guideline 221) is possible.
The used Andrew's medium and the presence of sucrose in the test system could impair photosynthesis activity and thus the sensitivity of the test species. To check and to quantify these unknown effects further tests with photosynthesis inhibitors were conducted. The results of tests with Lemna minor in a sucrose-free medium and Myriophyllum spicatum in Andrew's medium with 3% sucrose will be compared directly.

**WEPC2-4**
**Effects of linuron on a sediment-rooted aquatic plant in sediment-dosed test system**
H Buresova[1], GHP Arts[2], JDM Belgers[2]
[1]Institute of Chemical Technology Prague, PRAGUE, Czech Republic
[2]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
The availability of standardized methodologies to assess the environmental risks of pesticides to non-target aquatic plants is currently limited. Aquatic plant test guidelines are only available for algae and Lemna as representatives of primary producers. These studies may not be sufficient especially in the case when contamination via sediment is an important exposure pathway. In that case information on toxicity to sediment-rooted aquatic macrophytes may be required. Therefore a standardized test method protocol for the rooted aquatic macrophyte, Myriophyllum sp. has currently been proposed. This test method enables the study of exposure to a substance either via the water phase or via the sediment. Spiked sediment of the chosen concentration has to be prepared by addition of a solution of the test substance directly to the sediment. Test vessels have to be filled with spiked sediment. Three plants with known weight and shoot length are assigned to each replicate.
A study was initiated to investigate the effects of exposure via the sediment on a sediment-rooted aquatic plant, i.e. Myriophyllum spicatum. The objectives of the experiment were to quantify the exposure in the aquatic plant test and to assess the development of linuron concentrations in the compartments of the test system. The sediment was spiked with a concentration range of the herbicide linuron. Plant pots with sediment and three unbranched top shoots of Myriophyllum spicatum were placed into test vessels with standardized artificial sediment and Barko and Smart medium, and cultivated for 21 d under optimized conditions in a climate room. During the test period herbicide concentrations in sediment, water medium and plants were monitored. Although the artificial sediment was covered with a thin layer of sand and 1cm layer of non-contaminated sediment in order to minimize the exchange between sediment and the overlying water, linuron was already measured in the water layer in toxic concentrations at day 7. It is evident that linuron has not only effects on the plant through sediment exposure but also through exposure in the water medium. Overall effects of linuron on Myriophyllum spicatum are presented and discussed.

**WEPC2-5**
**A single species test with the filamentous green algae Oedogonium sp. for higher tier risk assessment**
T Strauss[1], U Hommen[2], M Hammers-Wirtz[1]
[1]Research Institute gaiac, AACHEN, Germany
[2]Fraunhofer IME, SCHMALLENBERG, Germany
Metaphyton, which is defined as filamentous, free-floating and scum-forming algae, is often the largest contributor to total algal productivity, especially in nutrient-rich shallow ponds and ditches. Many epiphytic algae and invertebrates associated with scums of metaphyton differ from those present in the plankton and on the sediments. Hence, metaphyton scums are unique and important communities within pond ecosystems.
When assessing environmental risks of chemicals and pesticides, aquatic primary producers are often represented by phytoplankton, macrophytes, and periphyton. However, it has been recently shown that also the metaphyton might be important to consider in environmental risk assessment due to the partly high sensitivity of its species to pesticides: In aquatic mesocosm studies, herbicides and fungicides were often found to cause pronounced direct effects on the metaphyton biomass (e.g. *Oedogonium*) and, as a consequence, indirect effects on water chemistry, species composition of plankton and invertebrates, and development of macrophytes. Despite its high ecological relevance, guidance for biotests with metaphyton is lacking until now.
*Oedogonium* is one of the most common members of the metaphyton as well as the genus *Cladophora*, which may also frequently detach from substrates to form floating scums. We developed a method for ecotoxicological testing of these filamentous green algae in the laboratory in vessels with and without sediment. The poster will show the experimental setup and exemplary results for one pesticide.

**WEPC2-6**
**Bioaccumulation of pharmaceutical active compounds and their metabolites in Ceratophyllum demersum and their resulting effects on the chlorophyll content**
JD Wrede[1], W Kloas[1], S Pflugmacher[2]
[1]Institute of Freshwater Ecology and Inland Fisheries, BERLIN, Germany
[2]Berlin Institute of Technology, Institute of Ecology, BERLIN, Germany
The occurrence of pharmaceuticals in surface water is an emerging problem worldwide. They are present in surface water at concentrations in the µg L-1 range. If pharmaceutical active compounds (PhACs) are transferred to drinking water, the resulting involuntary low-dose medication of large population groups may compromise public health. In addition, aquatic life may be affected. The physiological effects of 5 PhACs such as Bezafibrate (BZF), Carbamazepine (CBZ), Ibuprofen (IBU), Levonorgestrel (LNG) and Metoprolol (MET) were tested on a submerged macrophyte *Ceratophyllum demersum* in the laboratory over 1, 4, and 7 days. Concentration of PhACs in exposure medium and tissue was determined with LC/MS-MS. Bioaccumulation is important in the interactions between living organisms and PhACs in aquatic systems. Hence, to create a broader basis for the evaluation of the ecotoxicological relevance of PhACs, bioaccumulation tests were performed with different concentration of the five selected PhACs. As an additional ecotoxicological endpoint chlorophyll content was assessed.
Uptake of the PhACs in *C. demersum* showed a two step-process. In the first 24 h the PhACs were taken up more rapidly than in the second phase, which lasted until the end of the experiment. Total Chlorophyll and chlorophyll b were significantly decreased in exposed plants. LC/MS-MS measurement revealed not only the bioaccumulation of the PhACs, but also the presence of metabolites, which yields to the conclusion that the PhACs are partly biotransformed in the macrophyte.
The data of this study clearly revealed that PhACs can be accumulated by the submerged plant *C. demersum*, having also an effect on the total chlorophyll and chlorophyll b content.

**WEPC2-7**
**Impact of the herbicide Indaziflam in macrophyte-dominated microcosms including macrophyte-bioassays**
TCM Brock[1], E Bruns[2], SJH Crum[1], H Glass[2]
[1]Alterra, Wageningen UR, WAGENINGEN, The Netherlands
[2]Bayer CropScience AG, MONHEIM, Germany
Aquatic toxicity tests with the herbicide Indaziflam indicate that primary producers, particularly Lemna gibba, comprise the most sensitive standard test species. As a higher-tier test, an outdoor microcosm experiment was conducted characterized by naturally established macrophyte-vegetation and in situ macrophyte-bioassays. The bioassays were introduced to achieve concentration - response relationships for a wider array of macrophyte species. Eighteen outdoor microcosms were used to study herbicide concentration - response relationships during a 70 day post-treatment period (4 controls and 2 test systems each once received 0.01 - 0.032 - 0.10 - 0.32 - 1.00 - 3.20 and 10.0 µg a.s./L). Effects on macrophytes (biomass, growth), phytoplankton and zooplankton (species composition, abundance) and water quality parameters (e.g. pH, Dissolved Oxygen) were evaluated using univariate and multivariate statistical techniques.
In the microcosm study, several macrophyte species were far more sensitive than phytoplankton and zooplankton taxa. The lemnids Lemna gibba (in situ bioassay) and Spirodela polyrhiza (volunteer species) were most sensitive (NOEC of 0.01 µg a.s./L). Several non-lemnid bioassay plants started to show effects at (Myriophyllum spicatum, Elodea canadensis) or above (Salvinia natans, Potamogeton natans, Sagittaria sagittifolia) a treatment level of 0.32 µg a.s./L. The sensitivity of "free-growing"Myriophyllum spicatum was similar to that in the in situ bioassay and recovery of both "free-living"and bioassay Myriophyllum plants was not observed at a treatment of 1.0 µg a.s./L and higher. For macrophytes that showed a relatively minor growth in controls (Ceratophyllum demersum, Ranunculus circinatus, Lemna trisulca) hardly no treatment-related effects could be demonstrated.

**WEPC2-8**
**Effects of aquatic macrophytes on concentrations of contaminants in mesocosms**
HP Arts, JE Groenenberg, WHJ Beltman, PFAM Römkens
Alterra WUR, WAGENINGEN, The Netherlands
Aquatic macrophytes play important structural and functional roles in aquatic ecosystems. For example, they change their chemical environment by increasing pH and the diurnal variation thereof, cause fluctuations in dissolved $O_2$ levels and produce organic matter, both solid as well as dissolved organic carbon (DOC). Such changes in the chemical environment affect both concentration and speciation of contaminants in aquatic ecosystems. To determine the magnitude of such changes, experiments were conducted to monitor the impact of macrophyte growth form and macrophyte biomass on concentration and speciation of contaminants in various ecosystem compartments, i.e. sediment, plants and surface water. Effects of growth form were studied in a potted-plants experiment performed in mesocosms. The effects of biomass were studied in four flow-through experimental ditches. Concentrations of pesticides (dimethoate, λ-cyhalothrin, metribuzin and imidacloprid), pharmaceuticals (ibuprofen) and heavy metals zinc (Zn) and copper (Cu) were monitored over time. Concentrations of Cu and Zn diminished rapidly, the decrease

in the controls including sediment and lacking macrophytes being rapid as well. This implies an important influence of sediment and a minor additional impact of macrophytes for these heavy metals. For strongly absorbing contaminants macrophytes and sediment both act as an important sink. Macrophytes have an enormous influence on pH values and diurnal pH fluctuations. Different growth forms seem to act differently in this respect. As a consequence submerged, floating end emergent plants show different effects on contaminants which are subject to hydrolysis, like dimethoate. Initial results show that aquatic macrophytes also change their chemical environment by producing DOC. As absorbing contaminants also bind to DOC, DOC thus acts as a carrier for these compounds. Because part of the DOC fractions can be highly mobile, the interaction between DOC and hydrophobic organic contaminants can result in potentially high concentrations in surface water. Further research is needed on the role of DOC in the absorption and dissipation of contaminants.

## WEPC3 - Tropical ecotoxicology

**WEPC3-1**

**Assesment of physico-chemical and ecotoxicological characteristics of Limeira stream, the Paraiba Valley, São Paulo - Brazil**

TCB Paiva, JS Penido, FT Silva
Universidade de São Paulo/Escola de Engenharia de Lorena, LORENA, Brazil

The Paraíba Valley is located in southeastern Brazil, an important center of economic and industrial development of Brazil and need special attention in relation to water resources. The Limeira stream, a tributary of the left bank of the river Paraíba do Sul, in this basin there are military and abrasives industries, eucalyptus plantations and pasture areas. To evaluate water quality in this environment were analyzed physico-chemical and ecotoxicological properties of the stream between September 2007 and July 2008. The limnological parameters analyzed in water were: turbidity, conductivity, DO, pH, COD, BOD, nitrate, nitrite, total phosphorus, total dissolved solids, hardness, metals and fecal coliform. The acute and chronic toxicity were evaluated using the cladocerans Daphnia similis and Ceriodaphnia silvestrii, the algae Pseudokirchneriella subcapitata. The indexes of Aquatic Life Protection and Trophic State were applied. Cluster analysis (CA) and Principal Component Analysis (PCA) were applied for the information obtained in this environment. The results showed that seasonality influenced the dynamics of the environment and the analyzed variables, particularly in rainy periods. The increasing of particulate materials into the environment aquatic reflected the values of conductivity, hardness and STD. Spatial variation was suggested due anthropogenic influences in river, especially at the point P1, area that received discharges of solid waste from a military industry. Acute effect was observed in Sept/07, in points P1, P2, P4 and P6 to D. similis. This results may be related to the presence of Fe and Pb in water with values above the allowed (0.3 mg.L-1 and 0.01 mg.L-1, respectively) according to CONAMA Resolution 357/05.Chronic effect was observed in the water to the microcrustacean C. silvestrii in Feb/08, Mar/08 (P2) and the alga P. subcapitata in Mar/08 (P1) and May/08 (P1, P2). The presence of Fe and Pb in Feb/08 and Mar/08, may have influenced the results of toxicity assays, causing chronic effects to organisms. The Limeira stream showed regular water quality according the index of Aquatic Protection Life and was regarded as mesotrophic in all sampling points, conform the Trophic State index. The analysis of CA and PCA indicated that this stream can be divided into three main groups according to degree of pollution: group 1 (P0, P3), group 2 (P1, P2) and group 3 (P4, P5, P6) had low pollution, high pollution and moderate pollution, respectively.

**WEPC3-2**

**Methodologies for aquatic model ecosystem studies in tropical climate zones: lessons learned from Thailand and way forward**

MA Daam[1], PJ van den Brink[2]
[1]ISA/UTL, LISBON, Portugal
[2]Alterra and Wageningen University, WAGENINGEN, The Netherlands

Little research has been done so far into the environmental fate and side effects of pesticides in the tropical freshwaters. In addition, those studies conducted in tropical regions have focussed almost exclusively on single species laboratory tests. Hence, fate and effects of pesticides on higher-tier levels have barely been studied under tropical conditions. To address this lack of knowledge, four outdoor aquatic model ecosystem experiments using two different test systems were conducted in Thailand evaluating the insecticide chlorpyrifos, the herbicide linuron and the fungicide carbendazim. Results of these experiments and comparisons of recorded fate and effects with temperate studies will be presented. In addition, the pros and cons of the methodologies applied will be discussed as well as indications for i) possible improvements; ii) important aspects that should be considered when performing model ecosystem experiments in the tropics; and iii) future research.

**WEPC3-3**

**The herbicide Atrazine impairs biotransformation, inhibits antioxidant defenses and increases DNA damage on a Neotropical fish species**

BR Martinez, G Santos
Universidade Estadual de Londrina, LONDRINA, Brazil

Atrazine, an herbicide widely used throughout the word, is considered a potential contaminant to the aquatic environments. The presence of atrazine in water has been detected above the limits determined by the official guidelines in many countries; even so, the effects of this herbicide on fish are not fully understood. At present, more studies are necessary to evaluate genetics and biochemical biomarkers in the freshwater fish *Prochilodus lineatus* exposed to atrazine to understand the mechanisms of toxicity of this herbicide. In this context, the goal of this work was to evaluate atrazine effects on biotransformation enzymes, antioxidant defenses and the occurrence of DNA damage on juveniles of *P. lineatus* after acute exposure to sublethal concentrations of the herbicide. This was done through the determination of the hepatic activity of CYP1A and glutathione-S-transferase (GST), antioxidant enzymes, such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx) and glutathione reductase (GR), the amount of reduced glutathione (GSH) in the liver and the occurrence of DNA lesion on blood, gills and liver cells by the comet assay. The results showed that exposure to 10 $\mu$ $L^{-1}$ of atrazine for 96 h reduced the liver activity of GST, which is the main route for the metabolization of the herbicide. Besides, fish exposed to both atrazine concentration, for 48 and 96 h, showed an inhibition of EROD activity, indicating that this herbicide might act as a potential endocrine disruptor. Both atrazine concentrations produced a general reduction on reduced antioxidant defenses, with the exception of GR activity, that was stimulated. The occurrence of DNA damage, in comparison to control groups, was significantly higher in blood cells of fish exposed to 10 $\mu$ $L^{-1}$ of atrazine for 48 and 96 h, in liver cells of fish after 48h exposure to 10 $\mu$ $L^{-1}$ of the herbicide and in the gills cells of fish exposed to 2 $\mu$ $L^{-1}$ of atrazine for 48 h. These results clearly show that atrazine interferes on biotransformation and antioxidants defenses and promotes DNA damage on different tissues of *P. lineatus*.The limit for atrazine in water (2 µg.$L^{-1}$ ) set by the Brazilian guidelines (CONAMA, 2005) is not safe to protect this freshwater fish species.

**WEPC3-4**

**Mercury contamination chronologic trends in a tropical ecosystem (Ceará, Brazil)**

SN Abreu[1], DMS Sampaio[1], ACM Rodrigues[1], RMAL Santos[1], LM Buruaem[2], JR Gadelha[1], F Morgado[1], LV Costa-Lotufo[2], AMVM Soares[1]
[1]Univ. Aveiro, AVEIRO, Portugal
[2]Labomar, Universidade Federal do Ceará, FORTALEZA, Brazil

Mercury (Hg) is a highly toxic persistent and global pollutant. Estuaries are transition ecosystems linking the terrestrial and ocean environments and are composed of an interdependent mosaic of subtidal, intertidal and surrounding terrestrial habitats. A mosaic of mangrove forests and associated plant communities defines the most tropical habitats. In this work, the study area is located in the State of Ceará, (Brazil) using a low contaminated area (Ceará river estuary) and a reference site (Pacoti river estuary). Hg was quantified by pyrolyse atomic absorption spectrometry in surface sediment cores and tree annular rings cores to obtain profiles of Hg contamination. Sediment cores in the reference site Pacoti estuary shows levels ranging from 0.01 to 0.02 µg g-1 whereas the Ceará estuary shows levels ten times higher in the top sediment layers but decreasing to in depth (around 30cm) to levels similar to the reference site. Similarity trends in both sediment and tree rings cores are presented and discussed. Data on historical trends of Hg contamination could provide a useful tool understanding past patterns, evaluating present levels and predicting future evolution.

**WEPC3-5**

**PBDEs, PCBs, and DDE in eggs of aplomado falcons (Falco femoralis) from Chihuahua and Veracruz, Mexico**

A Mora[1], C Baxter[1], J Sericano[1], AB Montoya[2], JC Gallardo[3]
[1]Texas A&M University, COLLEGE STATION, TEXAS, United States of America
[2]U.S. Fish and Wildlife Service, ALBUQUERQUE, United States of America
[3]Pronatura AC, XALAPA VERACRUZ, Mexico

The northern aplomado falcon (Falco femoralis septentrionalis) is a species threatened by habitat loss and agriculture in grasslands and tropical habitats in eastern Mexico. Currently there is little information about the potential impacts of environmental contaminants on raptor populations in eastern Mexico or in tropical regions. From 2004 to 2007 we collected 23 addled eggs from different nests of aplomado falcons in 4 regions of Chihuahua and Veracruz, Mexico. The eggs were analyzed for persistent organic pollutants including organochlorine pesticides, polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs). Of all the organochlorine pesticides, only DDE, a metabolite of DDT, was found in all egg samples at concentrations ranging from 129-7850 ng/g wet weight. Twenty PCB and six PBDE congeners were detected in over 50% of the eggs analyzed. Total PCB concentrations ranged from 44-2802 ng/g wet weight and total PBDEs from 62-798 ng/g lipid weight. There were no significant differences in DDE concentrations in eggs from the 4 regions in Chihuahua and Veracruz; however, total PCBs were significantly greater (P=0.015) in Coyame than in Ahumada in Chihuaha, but were similar with the other two regions in Veracruz. Total PBDEs were significantly higher in eggs from Veracruz than in those from Chihuahua. The most prominent congener was BDE-153, followed by BDE-99, -154, -100, and -47. This pattern of BDE-153 dominance is consistent with that reported for peregrine falcons in various parts of the world. Overall, concentrations of PCBs, PBDEs, and DDE were below those that could be associated with negative impacts on the aplomado falcon population in northern and eastern Mexico.

## WEPC4 - Experimental approaches for determining bioavailability, sorption and NER formation of chemicals in soils and sediments

**WEPC4-1**

**Toxicity and bioavailability of geogenic polycyclic aromatic compounds from coal**

W Meyer[1], TB Seiler[2], J Schwarzbauer[3], W Püttmann[4], H Hollert[2], C Achten[1]
[1]University of Münster, Geological-Palaeontological Institute, MÜNSTER, Germany
[2]RWTH Aachen University, Institute for Environmental Research, AACHEN, Germany
[3]RWTH Aachen University, Inst. of Geology and Geochemistry of Petroleum and Coal, AACHEN, Germany
[4]J.W. Goethe-Universität, Inst. for Atmospheric and Environmental Sciences, FRANKFURT/MAIN, Germany

Coals contain native polycyclic aromatic compounds (PAC) that are generated during the diagenetic process of coal formation from biological precursor materials [1, 2]. The amount of PAC depends on the various properties of coal, e.g. origin, coal rank or parent material. In abundant areas of the world soils and sediments are highly contaminated with unburned coal particles as a result of longtime mining activities, transport and usage of coal and overburden material [3]. A large part of PAC in coal-rich soils could be ascribed to coal particles [4]. It is assumed that the coal-derived PAC are of low environmental concern because coal acts as a very strong geosorbent for hydrophobic substances resulting in very low bioaccessibility indicating low environmental risk and reduced remediation costs.

In this investigation, eight coals of varying origin, coal rank and chemical properties were used in bioassays to study the toxicity and in particular bioavailability of coal-bound PAC. Apart from polycyclic aromatic hydrocarbons (PAH) heterocyclic aromatic compounds (NSO-PAH) which have not yet received much attention have been taken into account. NSO-PAH often show high toxicity and a higher mobility compared to PAH.

Sediment contact assays using ground coal as a substrate were performed (fish embryo assay with *Danio rerio*, nematode contact assay with *Caenorhabditis elegans* and a bioaccumulation test with *Lumbriculus variegatus*). The results are compared to the results of the same test systems performed with the solvent extracts in liquid media and additional tests (Neutral red retention assay, EROD assay, Ames fluctuation assay) to assess the toxic potential of the compounds present in the extracts. PAC were analyzed using one- and two-dimensional gas chromatography-mass spectrometry.

The results show that the coals used in the fish embryo contact assay did not cause any effects, while the extracts led to embryo mortality at very low concentrations and also caused strong effects in the other test systems. We conclude that the toxic compounds are not bioavailable to fish embryos when exposed in a contact assay whereas solvent extracts of the coals provide a very high toxic potential.

**WEPC4-2**

**Variability of Phenanthrene and Lindane extractability and bioavailability between ten artificial soils**

I Hovorkova[1], KS Semple[2], JH Hofman[1]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Lancaster university, The Lancaster Environment Centre, LANCASTER, United Kingdom

In standard soil bioassays, the artificial soil defined in OECD and ISO guidelines has been used routinely since 1980's. The use of standard soil helps to comparability and interpretation of measured data because natural soils are very variable. However, it is not clear how variable are artificial soils prepared in different laboratories. In our study, ten artificial soils were collected from different countries and differences in 14C-phenanthrene and 14C-lindane extractability and bioavailability were investigated in aging experiment. At each sampling point (1, 14, 28, 56 days after soil contamination), three extraction methods were employed:. extraction with DCM (dichloromethane) or MeOH (methanol) which represent exhaustive techniques and extraction with HPCD (hydroxypropyl-β-cyclodextrin) which is used as a mild extraction able to predict microbial degradation. The bioavailability of 14C-phenanthrene to microbes (Pseudomonas sp.) was measured by 15-day-respirometry assay. After 28 d contact time, comparable amounts of 14C-phenanthrene associated residues were extracted from all soils by DCM, not significantly different, the day 56 showed significant decrease in all artificial soils, except artificial soil 8 Significantly different amounts were extracted by HPCD (1d 49-83%, 14d 44-79%, 28d 20-72%, 56d 11-48%) and the aging effect was clearly apparent. Extraction of 14C-lindane by DCM and MeOH was not significantly different between soils at any sampling time. Significantly different amounts were extracted by HPCD (1d 68-92%, 14d 66-86%, 28d 61-79%, 56d 58-74%). The degradation of 14C-phenanthrene showed typical kinetics with rapid mineralization in the first 24h, slow-down in following 2-4 days and coming to plateau in next days. Total amount of phenanthrene mineralized was significantly different between soils (1 day 40-67%, 14 day 64-100%, 28 day 30-76%, 56 day 17-73%).
The observed variability was not correlated at any of soil properties, this means that there is no available predictor of these differences and it must be futher studied.
To summarize, variability of phenanthrene and lindane extractability and bioavailability was observed in artificial soils from different laboratories. The question remains if these differences might affect the results of ecotoxicity tests.

**WEPC4-3**

**Fate and bioavailability of pyrene and lindane in sterile artificial and real soils**

K Vlckova[1], J Hofman[1], KT Semple[2], AE Ite[2]
[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Centre for Chemicals Management , LEC, Lancaster University, LANCASTER, United Kingdom

Artificial soil is considerably different from real soil despite it was developed to serve as "model soil"in soil toxicity tests. From our earlier studies, it is apparent that organic carbon is not only determinant of pollutants fate, bioavailability and toxicity. Despite of this fact, some methodologies still use organic carbon for direct recalculation of toxicity or risk between different soils, i.e. also between artificial and real soils. This assumption might lead to the final risk under- or overestimation. Differences between artificial and natural soils are caused not only by components proportion (i.e. relatively high total organic carbon content) but also by their character - peat and kaolin clay are the most critical components affecting the fate of contaminants. This study is posing claim to investigate the differences in bioavailability of selected POPs between artificial and natural soils and its changes in time. Three natural soils were used with different total organic carbon content (TOC): arable soil (1.2%), grassland soil (3.5%) and forest soil (10.2%), and three artificial soils were prepared to have the same TOC as these real soils. Soils were sterilized to avoid the influence of microbes, and contaminated by radiolabelled 14C-pyrene and 14C-lindane. Total activity, DCM and HPCD extraction and bioaccumulation in earthworms *Eisenia fetida* was measured after 1, 14, 28 and 56 days. According to results it is clear that i) decline of bioavailability of selected compounds in time was less evident in sterile soils than in non-sterile soils studied in the past, ii) bioaccumulation and extractability showed different trends for pyrene and lindane, and iii) differences between artificial and natural soils were observed however they had the same TOC. These conclusions are in accordance with previous studies which also reported than not only organic carbon content (TOC) but also its character and other soils properties must be seriously considered in artificial to real soil extrapolation.

**Fate and behaviour of Azoxystrobin, Isoproturon, Cypermethin and Diazinon in four UK soils under laboratory conditions.**

Y Andreou[1], ND Jablonowski[2], PB Burauel[2]
[1]Cyprus University of Technology, LIMASSOL, Cyprus
[2]2Agrosphere Institute, ICG IV, Forschungszentrum Jülich, JÜLICH, Germany

Soil is a highly complex matrix in which pesticides are often applied on purpose directly or indirectly. This study aimed to investigate the fate and behaviour of azoxystrobin, isoproturon, diazinon and cypermethrin in four natural UK soils under laboratory aerobic conditions and for a period of 100 days. Fate and behaviour in this study were described in terms of losses due to biodegradation and extractability into three extractions solutions and the respective formation of non extractable residues. Losses of the pesticides related $^{14}C$-activity increased with time of incubation mainly due to biodegradation. Losses increased significantly ($p>0.05$) with incubation time in almost all the microcosms. Greater losses were observed in the case of diazinon and cypermethrin in Redesdale. Incubation time had also significant ($p>0.05$) negative effect on the extractability of all the pestcides in the three extraction schemes employed here ($CaCl_2$, HP-β-CD and acetonitrile). The effect of the incubation was shown to have a respective impact in the formation of nonextractable pesticide related $^{14}C$-residues. This study highlights how different extraction schemes, as these used in this study affect the availability of azoxystrobin, isoproturon, diazinon and cypermethrin in the four soils. It is also evident from this study that the HP-β-CD was able enhance the solubility of the pesticide molecule into the aqueous solution . Minerilisation extent for diazinon and cypermenthin was relatively high indicating increased availability of these pesticides to the soil microorganisms. This study highlights that degradation and sorption-desorption are processes unique to each soil and pesticide system and thus special consideration is required when interpreting data from laboratory based fate studies for purpose of prediction or the pesticide fate of pesticides in environmental media.

**WEPC4-5**

**Sorption-desorption behaviour of 14C-isoproturon and 14C-azoxystrobin in soil.**

Y Andreou[1], ND Jablonowski[2], PB Burauel[2], K Fenlon[3]
[1]Cyprus University of Technology, LIMASSOL, Cyprus
[2]2Agrosphere Institute, ICG IV, Forschungszentrum Jülich, JÜLICH, Germany
[3]Temple University, PHILADELPHIA, United States of America

Sorption-desorption isotherms are useful tools for the investigation of the fate and behaviour of pesticides in the soil. Isoproturon, a widely used herbicide, and azoxystrobin, a novel fungicide were investigated in this study in two organically managed soils. A standard batch equilibrium method was employed followed by serial desorption method. A linear partition isotherm model and Freundlich isotherm model were used for the data interpretation together with a simple desorption-release model. Pesticide polarity and soil organic carbon were shown to be the major factors determining pesticide's partitioning within the soils. Effects like sorption and desorption isotherm nonlinearity were shown to be more pronounced in the case of azoxystrobin; this was attributed to its stronger association to the soil. Observed hysteretic phenomena were attributed to specific interactions (H-bonding) among the pesticides and the soil. Azoxystrobin soption desorption data derived from this study are unique and offer an approximation of the fate and behaviour of azoxystrobin in agricultural soils. Previously published data were mainly gained through evaluation of the pesticide main characteristics (structure, charge, side chains). In the case of azoxystrobin, for the first time, in this study sorption-desorption profile of this pesticide in agricultural soils were reported.

**WEPC4-6**

**Long-term persistence of various 14C-labeled pesticides in soils**

ND Jablonowski, A Linden, S Köppchen, B Thiele, D Hofmann, W Mittelstaedt, T Pütz, P Burauel
Forschungszentrum Jülich GmbH, JÜLICH, Germany

The environmental fate of the ring-14C-labeled herbicides methabenthiazuron (MBT), ethidimuron (ETD), and the fungicide anilazine (ANI) in soils was evaluated after long-term aging in lysimeters under outdoor conditions. Pesticide applications were performed at customary rates in 1988/1992/1994 for MBT (totalling 8.79 kg hað'1) and 1997 for ETD (1.23 kg hað'1). ANI was applied on two different lysimeters in five consecutive years from 1985-1989, with a total of 9.68, and 19.78 kg hað'1, respectively. All pesticide treated soils were subject to environmental aging and crop-rotation until sampling in April 2006. Analyses of residual 14C-activity in the upper soil layer revealed 19% (ETD; 0-10 cm depth), 35% (MBT; 0-30 cm depth), 49% and 43% (ANI; 0-30 cm depth), respectively, of initially total applied 14C-activity. Soil sample extraction using accelerated solvent extraction with acetone-water mixture as a solvent yielded 90% (ETD-soil), 26% (MBT-soil), and 28% and 37% (ANI-soils), respectively, in total of the residual 14C-activity in the sample, after 8 consecutive extraction steps. Analyses of the extracts by means of LC-MS/MS and radio-HPLC revealed the parent compounds ETD and MBT in considerable amounts (24.5 µg ETD kg-1 and 45.9 µg MBT kg-1 soil, accounting for 3% and 2% of total active ingredient applied, respectively, calculated per layer 0-10 cm ETD-soil / 0-30 cm MBT-soil, and m-2), as well as dihydroxy-anilazine as the main ANI metabolite. Additionally, radio-HPLC analyses of the concentrated extracts revealed two metabolites for ETD. The results demonstrate the long-term persistence and extractability of various pesticides in soils even after prolonged environmental aging. Detailed knowledge about the mechanisms of molecule binding, entrapment, persistence and degradability in the soil matrix is therefore of continued importance. A reassessment of the long-term fate of chemicals in terms of environmental risk assessment and sustainable resource protection should be encouraged.

## THPC1 - Atmospheric chemistry, transport and deposition

**THPC1-1**

**Passive atmospheric sampling of Polychlorinated Biphenyl (PCBs) and Polycyclic Aromatic Hydrocarbons (PAHs) in urban and industrial sites in the coastal area of Milazzo, Sicily**

KAPG Pozo[1], VHE Estellano[1], GP Perra[1], SF Focardi[1], VE Esposito[2], TR Romeo[2]
[1]University of Siena, SIENA, Italy
[2]ISPRA, MILAZZO, Italy

Passive air samplers consisting of polyurethane foam disks were deployed concurrently at 18 locations and exposed for 60-90 days from February to September 2010 at Milazzo (coastal area) of Sicily to screen for levels of PCBs and PAHs in the atmosphere. The sampling sites were located on the vicinity of an industrial Settlements. Derived air concentrations (pg/m3) ranged as follows: the sum of 12 PCB congeners, BDL-182 for Period 1 (February-May), from 64-3721 for Period 2 (May-July), and from 94-4260 for Period 3 ( July-September). The PCBs with 6-cl were the most predominant congeners accounting for the 40, 52 and 39 % for the periods 1, 2 and 3, respectively. Following for the 5-cl (37%) during the first period, and for the 4-cl (24% and 31%) during the second and third periods respectively. For PAHs air concentrations ranged from 1114-4513 for Period 1, from 776-6131 for Period 2, and from 1475-20249 for Period 3. PAH with 3-6 benzene rings were analysed, the most abundant was 3 ring-congeners accounting for 63 ± 8 % (period 1), 77 ± 8 % (period 2) and 71 ± 8 % (period 3) of the total PAHs composition. Phenantrene alone accounted for the 48 ± 3 % of the total PAHs composition during the first period and for the 68 ± 8 % and 51 ± 5 % during the second and third period respectively. The percentage for 4 rings were 36 ± 8 % (period 1), 23 ± 8 % (period 2I) and 28 ± 7% (period 3). These results shows a clear seasonal variations for the targets compounds. Period 3 showed the highest concentrations for PCBs and PAHs. This information is useful to identify hot spots of PCBs and PAHs on local and regional scale.

**THPC1-2**

**Concentrations of organochlorine pesticides (OCPs) current use pesticides (OCPs) and polycyclic aromatic hydrocarbons (PAHs) using passive air sampling in Tuscany region, Italy**

VH Estellano Schulze, KP Pozo, VV Volpi, PG Perra, SC Corsolini, FS Focardi
University of Siena, SIENA, Italy

Passive air samplers consisting of polyurethane foam disk were deployed over a 3-month period from April to July 2008 at 15 locations throughout the Tuscany Region in central Italy. Sampling sites were selected based on different criteria including urban, rural and agricultural sites. The purpose of the study was to assess the gas-phase concentration of selected historic use organochlorine pesticides (OCPs) and current use pesticides (CUPs) on a local and regional scale. Five of the historic-use OCPs and seven CUPs were frequently detected. These include α- and γ-HCH, HCB, α-endosulfan, and DDT for OCPs. Trifluralin, diazinon, chlorpyripos methyl, chlorpyripos ethyl, malathion, chlortal-dimethil and pendimethalin for CUPs. Of the historic-use pesticides α-endosulfan and γ-HCH reported the higher concentration of the OCPs with ranges from below detection limit (BDL) to 2185 pg/m3 and from BDL to 1058 pg/m3 respectively. In general, OCPs do not presented a clear difference between the three categories of sites (agricultural, urban and rural). For CUPs, high concentrations (pg/m3) were detected for Malathion (BDL to 3554), Chlorpyrifos-ethly (BDL to 1312) and chlorpyrifos-methyl (BDL to 568). The concentration of CUPs showed a big variation between the different sites probably showing local dynamics. This study shows the feasibility of using PUF disks as time-integrated passive samplers, to asses curent use pesticides levels at local and regional scale.

### THPC1-3

**Latin American atmospheric passive sampling network (LAPAN) of POPs**

J Leonel
University of Rio Grande, RIO GRANDE, Brazil

A Latin American Atmospheric Passive Sampling Network (LAPAN) is been set up to: - monitor atmospheric levels of POPs; - identify areas of concern and local sources; - provide data for studies of global distribution and temporal trends; -and, evaluate the effectiveness of the control actions adopted by the countries members of the Stockholm Convention to eliminate the release of POPs to the environment. This network endeavor to install at least 80 XAD-2 based PAS in the Latin American countries, covering different environmental gradients, such as remote - urbanized areas, latitudinal, longitudinal and, possible, altitudinal. So far, approximately 46 PAS were already installed: 5 in Antarctica, 13 in Argentina, 16 in Brazil, 7 in Chile, 2 in Equator, and 3 in Peru.

### THPC1-4

**Biomarkers of oxidative stress in pine needles as a tool for the assessment of atmospheric pollution in Patagonia, Argentina**

M Mitton[1], ML Menone[1], G Lukaszewicz[1], JM Monserrat[2], G Fillmann[3], M Gonzalez[1], KSB Miglioranza[1]
[1]Universidad Nacional de Mar de Plata, MAR DEL PLATA, Argentina
[2]Univerisdade Federal do Rio Grande, FURG, Instituto de Ciencias Biológicas, RIO GRANDE, Brazil
[3]Laboratório de Microcontaminantes Orgânicos e Ecotoxicología Aquática, RIO GRANDE, Brazil

Persistent Organic Pollutants (POPs) are of environmental concern due to their recalcitrance, global distribution, and toxicity. Pollutants are known to generate Reactive Oxygen Species (ROS) formation, however, organisms have evolved multiple antioxidant defense wich include both enzymatic and non-enzymatic complex system. The aim of this work was to assess different oxidative stress biomarkers in pine needles in response to atmospheric pollution in the Patagonian region of Argentina. Levels of lipid peroxidation (MDA), glutathione-S-transferase (GST) activity and total antioxidant capacity (ACAP) were evaluated in pine needles (Pinus sp.) at longitudinal (Rio Negro watershed) and latitudinal (Patagonia) scale by performing a network of 20 sampling stations that were selected on the basis of previous work about atmospheric pollution monitoring. The Rio Negro watershed showed higher ACAP and GST activity than latitudinal sampling stations. Particularly, V. Regina station settled in the upper Rio Negro, showed the highest biomarker values. These results are in agreement to the fact that V. Regina constitutes an intensive fruit production area known to be a hot spot for POPs like DDTs, endosulfans and PBDEs. Moreover, a decrease gradient in the biomarkers levels from west to east was observed which was expected considering data about atmospheric POPs levels. In the latitudinal transect, the northest sampling station (Bahia Blanca), presented the highest ACAP, GST and MDA levels with decreasing values to the southest station. As was observed in V. Regina, results suggest a relationship between biomarkers and POPs levels. Although they could be mainly attributed to the insecticide endosulfan the influence of other pollutants such as polycyclic aromatic hydrocarbons should not be discarded. On the contrary, in the southest station (Rio Gallegos) a non direct relationship between biomarkers and POPs concentrations was observed. In conclusion, the results suggest that the studied biomarkers would be a useful tool in the assessment of atmospheric pollution associated with POPs occurrence. Considering the wide range of temperature variation among stations, future research focusing on the analyses of pine needle lipid classes, and temporal monitoring of POPs and biomarkers will be carried out.

### THPC1-5

**Indication of regional sources affecting polycyclic aromatic hydrocarbon levels in Antarctic snow**

A Dvorska[1], P Kukucka[1], G Lammel[1], J Klánová[1], A Moller[2], E Fries[3]
[1]Research Centre for Toxic Compounds in the Environment, BRNO, Czech Republic
[2]Aerotec Engineering GMBH, HAMBURG, Germany
[3]University of Osnabrueck, OSNABRUECK, Germany

Antarctica is an almost unpopulated continent, but anthropogenic pollution by sulfur, heavy metals (Boutron and Wolff, 1989; Graf et al., 2010) and persistent organic pollutants (POPs) (UNEP, 2002) has been verified. The main anthropogenic sources of sulfur in the region are suspected to be tourism and research stations (Graf et al., 2010). Intercontinental atmospheric transport to Antarctica has been proposed as a source of various POPs and polycyclic aromatic hydrocarbons (PAHs) (Klánová et al., 2008).

Firn samples attributed to the period between 2002 and 2005 were collected from a snow pit at Neumayer research station. Samples were analysed using SPME-GC/MS and dated according to the firn depth in the snow core and using records on snow precipitation.

PAH concentrations in snow were found within the range of 26-197 ng L-1. The most prevailing substances were determined to be naphthalene, 1- and 2-methylnaphthalene, acenaphthylene, acenaphthene and phenanthrene with naphthalene accounting for an overall mean of 82% of total PAHs. The PAH content was compared to levels of inorganic contaminants as well as methylsulphonic acid in order to distinguish between summer and winter samples. Five time intervals were selected for the investigation of long-range PAH transport and the determination of sources.

Potential emission sources of PAHs in snow were studied using air mass back-trajectory statistics and available emission data of combustion sources in and around Antarctica. The distance to the sources (ships and research stations) in this region was found to control the snow PAH concentrations. The results for the five studied periods did not indicate intercontinental transport or marine sources of PAHs.

**Persistent organic pollutant micrometeorological air-surface exchange flux measurement**

L Nizzetto[1], JA Perlinger[2]
[1]Norwegian Institute for Water Research, OSLO, Norway
[2]Michigan Technological University, HOUGHTON, United States of America

Together with mercury, persistent organic pollutants (POPs) require a unique regulatory framework as compared to other air pollutants not only because of their long presence in the environment, but also because they are capable of undergoing successive air-surface deposition-volatilization-transport cycles with condensed media. Therefore, to be appropriate, regulatory frameworks for POPs on local, regional, and global scales are highly dependent on knowledge of emission, advection, and deposition fluxes in air and water. Measurement of such fluxes is particularly demanding in air, where turbulent dispersion dominates over diffusion, and the timescales at which these transport processes occur (e.g., 10 Hz) cannot be measured by eddy covariance because sensors that measure POP concentration at high frequency are not available. Understanding of these transport processes has thus been limited by a lack of tools with which to observe them. Fluxes are commonly inferred using model parameterizations based on measured concentrations collected over long timescales, and these parameterizations are largely unvalidated. For example, the so-called "grasshopper effect"in which POPs undergo successive deposition-volatilization-transport cycles is purported to result in global transport of POPs. It has been inferred primarily from observations of POP concentrations in locations in which they were thought to be previously absent, e.g., in Arctic air, water, and wildlife, and observations of so-called "global distillation", the physico-chemical property dependent differentiation in POP concentration with latitude and/or altitude. Micrometeorological methods to measure air-surface exchange fluxes of POPs that do not require use of high-frequency sensors, including the modified Bowen ratio and relaxed eddy accumulation techniques, are available, and in this presentation we summarize these techniques. POP collection/extraction concentration measurement techniques have been developed that enable application of these flux measurement techniques in urban, rural, and remote environments. They will be useful in development of process-based understanding of POP transport.

### THPC1-7

**Characterization of Chinese coal fly ash and Beijing particulate matter for parent, methyl-, nitro-, oxy-, halogenated-, and high molecular weight polycyclic aromatic hydrocarbons**

JE Schrlau, Y Jia, N Jariyasopit, L Gonzales, SM Simonich
Oregon State University, CORVALLIS, United States of America

Reference materials are homogenous mixtures of an environmental matrix used to evaluate analytical methods for selected compounds. The purpose of this work was to 1) prepare and characterize an in-house Beijing particulate matter (PM) reference material (RM), and 2) apply newly-developed analytical methods for several classes of polycyclic aromatic hydrocarbons (PAHs) to the Chinese coal fly ash certified reference material (CRM) .

As part of an inter-disiplinary project on PAHs at Oregon State University, an in-house PM10 ambient air RM was needed for toxicology studies. The RM was prepared by extracting 229 twenty-four hour PM10 ambient air filters collected from Peking Univeristy in Beijing, China with hexane:acetone and ethyl actetate using pressurized liquid extraction (PLE). The extracts were combined and characterized for parent and methyl-, nitro- and oxy-, halogenated, and high molecular weight (HMW) (≥ MW 302) PAHs using gas chromatography mass spectrometry (GC/MS). The total PAH mass in both the hexane:acetone and ethyl acetate ranged from 4067 to 9.88 μg.

The Chinese CRM is composed of coal fly ash collected from a coal-fired boiler and was released in 1995. The certified values for five PAHs including phenanthrene, anthracene, fluoranthene, pyrene, and benzo[a]pyrene and reference values for benz[a]anthracene, chrysene, triphenylene, benzo[b]fluoranthene, benzo[k]fluoranthene, dibenzo[a,h]anthracene, and benzo[ghi]perylene were previously published. Anaysis of the CRM resulted in concentrations that were 11 to 86% lower than the certified values and 25 to 78% lower for the reference values. This difference may be explained by the particularly strong adsorption of PAHs to coal fly ash surfaces and the use of a different extraction solvent. The total concentrations for 17 parent, 12 methyl- and 22 HMW PAHs were 28, 10, and 3.1 μg/g, respectively.

The Society of Environmental Toxicology and Chemistry (SETAC) is a not-for-profit, global professional organization comprised of some 5500 individual members and institutions dedicated to the study, analysis and solution of environmental problems, the management and regulation of natural resources, research and development, and environmental education.

SETAC Europe is one of the four Geographic Units of the global Society, established to promote and undertake activities of SETAC in Europe, and to support activities of SETAC in the Middle East and Africa, currently organised as a Regional Branch of SETAC Europe. The Society is dedicated to the use of multidisciplinary approaches to examine the impacts of stressors, chemicals and technology on the environment. We also provide an open forum for scientists and institutions engaged in the study of environmental problems, management and regulation of natural resources, education, research and development, and manufacturing. SETAC Europe is incorporated in Belgium as a not-for-profit organisation. The Society is governed according to its articles of association and by-laws. SETAC Europe maintains its administrative office in Brussels, Belgium.
